

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

LONDON & BUNGAY.**

INSTRUCTIONS TO ABSTRACTORS,

GIVING THE

NOMENCLATURE AND SYSTEM OF NOTATION

ADOPTED IN THE ABSTRACTS.

The object of the abstracts of chemical papers published elsewhere than in the Transactions of the Society is to furnish the Fellows with a concise account of the progress of chemical science from month to month. It must be understood that as the abstracts are prepared for the information of the Fellows in general, they cannot possibly be made so full or so detailed as to obviate on the part of those who are engaged on special investigations the necessity of consulting the original memoirs.

1. Titles of papers must be given literally.
2. Before beginning to write the abstract, the whole of the original paper must be read, in order that a judgment may be formed of its importance and of the scale on which the abstract should be made.
3. In the case of papers dealing with subjects not strictly chemical, the abstract should refer only to matters of chemical interest in the original.
4. The abstract should consist mainly of the expression, in the abstractor's own words, of the substance of the paper.
5. The abstract should be made as short as is consistent with a clear and accurate statement of the author's results.
6. If an abstract of a paper on the same subject, either by the author of the paper abstracted, or by some other author, has already appeared, note should, as a rule, be made of this fact.
7. Matter which has appeared once in the *Abstracts* is not to be abstracted again, a reference being given to the volume in which the abstract may be found.
8. As a rule, details of methods of preparation or analysis, or generally speaking of work, are to be omitted, unless such details are essential to the understanding of the results, or have some independent value. Further, comparatively unimportant compounds, such as the inorganic salts of organic bases or acids, should be mentioned quite shortly. On the other hand, data such as melting and boiling points, sp. gr., specific rotation, &c., must be given in every case unless recorded in earlier papers.

Nomenclature.

9. Employ names such as *sodium chloride*, *potassium sulphate* for inorganic compounds, and use the terminals *ous* and *ic* only in distinguishing compounds of different orders derived from the same elementary radicle; such, for instance, as mercurous and mercuric chlorides, sulphurous and sulphuric acids.

10. Term compounds of metallic radicles with the OH-group *hydroxides* and not hydrates, the name hydrate being reserved for compounds supposed to contain water of combination or crystallisation.

11. Term salts containing an amount of metal equivalent to the displaceable hydrogen of the acid, *normal* and not neutral salts, and assign names such as sodium hydrogen sulphate, disodium hydrogen phosphate, &c., to the acid salts. Basic salts as a rule are best designated merely by their *formulae*.

12. Names in common use for oxides should be employed, for example: NO, nitric oxide; CO₂, carbon dioxide; P₄O₁₀, phosphoric oxide; As₂O₃, arsenious oxide; Fe₂O₃, ferric oxide.

13. In open chain compounds, Greek letters must be used to indicate the position of a substituent, the letter α being assigned to the first carbon atom in the formula, except in the case of CN and CO₂H, for example, CH₃·CH₂·CH₂·CH₂I α -iodobutane, CH₃·CH₂·CH₂·CN α -cyanopropane.

14. Isomeric open chain compounds are most conveniently represented as substitution derivatives of the longest carbon chain in the formula; for example,

should be termed $\beta\gamma$ -dimethylpentane, not methylethylisopropylmethane, and $\begin{array}{c} \text{CH}_3 \\ \diagup \\ \text{CH}_3 \end{array} > \text{CH} \cdot \text{CH} < \begin{array}{c} \text{CH}_3 \\ \diagdown \\ \text{CO}_2\text{H} \end{array}$ or CH₃·CHMe·CHMe·CO₂H should be termed $\alpha\beta$ -dimethylbutyric acid, not $\alpha\beta\beta$ -trimethylpropionic, or α -methylisovaleric, or methylisopropylacetic acid.

15. Use names such as methane, ethane, &c., for the normal paraffins or hydrocarbons of the C_nH_{2n+2} series of the form CH₃·[CH₂]_n·CH₃, &c. Term the hydrocarbons C₂H₄ and C₂H₂ ethylene and acetylene respectively (not ethene and ethine). Homologues of the ethylene series are to be indicated by the suffix *-ene*, and those of the acetylene series, wherever possible, by *-ine*. Adopt the name allene for the hydrocarbon CH₂:C:CH₂.

16. Distinguish all hydroxyl derivatives of hydrocarbons by names ending in *ol*. Alcohols should be spoken of as mono-, di-, tri-, or n-hydric, according to the number of OH-groups. Compounds which are not alcohols, but for which names ending in *ol* have been used, are to be represented by names ending in *ole*, if a systematic name cannot be given, thus anisole not anisoil, indole not indol. Compounds such as MeONa, EtONa, &c., should be termed sodium methoxide, sodium ethoxide, &c.

17. The radicles indicated in the name of a compound are to be

given in the order fluoro-, chloro-, bromo-, iodo-, nitro-, nitroso-, amino-, imino-, cyano-, thiocyno-, hydroxy-.

18. Compounds analogous to the acids of the lactic series containing the OH-group should be termed *hydroxy*-derivatives, and not *oxy*-derivatives; for example, hydroxyacetic and not oxyacetic acid. Compounds containing the analogous groups OEt, OPh, OAc, &c., should in like manner be termed ethoxyl, phenoxy, acetoxy derivatives. Thus α -ethoxypropionic acid, $\text{OEt}\cdot\text{CHMe}\cdot\text{CO}_2\text{H}$, instead of ethyl-lactic acid; 3:4-diethoxybenzoic acid, $(\text{OEt})_2\text{C}_6\text{H}_3\cdot\text{CO}_2\text{H}$, instead of diethylprotocatechuic acid; and α -acetoxypropionic acid, $\text{OAc}\cdot\text{CHMe}\cdot\text{CO}_2\text{H}$, instead of acetyl-lactic acid. Terms such as diethylprotocatechuic acid should be understood to mean a compound formed by the displacement of hydrogen atoms in the hydrocarbon radicle of protocatechuic acid by ethyl, viz., $\text{C}_6\text{H}_5\text{Et}_2(\text{OH})_2\cdot\text{CO}_2\text{H}$, and not $\text{C}_6\text{H}_5(\text{OEt})_2\cdot\text{CO}_2\text{H}$, just as dibromoprotocatechuic acid is understood to be the name of a compound of the formula $\text{C}_6\text{HBr}_2(\text{OH})_2\cdot\text{CO}_2\text{H}$.

19. The term *ether* should be restricted to the oxides of hydrocarbon radicles and their derivatives, and the esters (so-called compound ethers or ethereal salts) should be represented by names similar to those given to metallic salts.

20. When a substituent is one of the groups NH_2 , NHR , NR_2 , NH or NR , its name should end in *ino*; for example, β -aminopropionic acid, $\text{NH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$, β -anilino-acrylic acid, $\text{NHPh}\cdot\text{CH}\cdot\text{CH}\cdot\text{CO}_2\text{H}$, α -iminopropionic acid, $\text{NH}\cdot\text{CMe}\cdot\text{CO}_2\text{H}$.

21. Compounds of the radicle SO_3H should, whenever possible, be termed sulphonic acids, or failing this, sulpho-compounds; for example, benzenesulphonic acid, sulphobenzoic acid.

22. Basic substances should invariably be indicated by names ending in *ine*, as aniline instead of anilin, the termination *in* being restricted to certain neutral compounds, viz., glycerides, glucosides, bitter principles, and proteids, such as palmitin, amygdalin, albumin. The compounds of basic substances with hydrogen chloride, bromide or iodide should always receive names ending in *ide* and not *ate*, as morphine hydrochloride and not morphine hydrochlorate.

23. The Collective Index, 2nd decade (1883—1892) should be adopted as the standard of reference on questions of nomenclature not provided for in the preceding sections.

Notation.

24. In empirical formulæ the elements are to be given in the order C, H, O, N, Cl, Br, I, F, S, P, and the remainder alphabetically.

25. Equations should be omitted unless essential to the understanding of the results; as a rule, they should not be written on a separate line, but should "run on" with the text.

26. To economise space, it is desirable:

- (a) That *dots* should be used instead of *dashes* in connecting contiguous symbols or radicles, whenever this does not interfere with the clearness of the formula.

- (b) That formulæ should be shortened by the judicious employment of the symbols Me for CH_3 , Et for C_2H_5 , Pr^a for $\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_3$, Pr^s for $\text{CH}(\text{CH}_3)_2$, Ph for C_6H_5 , Py for $\text{C}_5\text{H}_4\text{N}$, Ac for $\text{CO}\cdot\text{CH}_3$, and Bz for $\text{CO}\cdot\text{C}_6\text{H}_5$.

- (c) That formulæ should be written in *one line* whenever this can be done without obscuring their meaning.

27. In representing the constitution of benzene derivatives, the relative positions of the radicles in the symbol of benzene should be indicated by numerals, instead of by means of the hexagon formula.

- (a) The abbreviations *o*-, *m*-, and *p*-, should be used in place of 1:2- or ortho-, 1:3- or meta-, and 1:4- or para.
- (b) In numbering positions in the case of substitution derivatives of phenol, aniline, benzonitrile, benzoic acid, benzenesulphonic acid, benzaldehyde, and toluene, the characteristic radicle of each of these parent substances is to be regarded as in position 1 (compare Collective Index).
- (c) Names of substitution derivatives should be given in such a way that the position of the substituent is indicated by a numeral prefixed; for example:—

28. In representing the constitution of derivatives of other "closed chain" hydrocarbons, graphic formulæ should not be employed, but the system of numbering positions indicated in Richter's *Lexikon der Kohlenstoff-Verbindungen* (2nd edition, 1899, pp. 16—26) should be used, of which the following schemes may be regarded as typical:—

Purine

Pyridine.

Indole.

Naphthalene.

Quinoline.

iso-Quinoline.

Anthracene.

Phenanthrene.

Diphenyl.

 $\beta\beta$ -Dinaphthyl.

Manuscript.

29. In view of the difficulty of dealing with MSS. of widely varying sizes, abstracts cannot be accepted unless written on quarto paper (10 x 8 in.).

30. Not more than one abstract must appear on a sheet.

31. When an abstract exceeds a sheet in length, the sheets must be fastened together by means of gum at the top left-hand corner.

32. The name of the abstractor must be written diagonally at the top left-hand corner of the first sheet of the abstract.

Proofs.

33. Abstractors are expected to read and correct proofs carefully, and to check all formulæ and figures against MSS.

34. All proofs, however small, must be returned to the Sub-Editor not later than 24 hours after receipt from the printers.

**** The Editor's decision, in all matters connected with the Abstracts, must be considered final.**

JOURNAL

OF

THE CHEMICAL SOCIETY.

ABSTRACTS OF CHEMICAL PAPERS PUBLISHED IN
BRITISH AND FOREIGN JOURNALS.

PART II.

General and Physical Chemistry.

Influence of Slight Impurity on the Spectrum of a Gas. By PERCIVAL LEWIS (*Ann. Phys. Chem.*, 1899, [ii], 69, 398—425).—The spectrum of pure hydrogen was compared with that obtained when the gas contained small quantities of (a) mercury vapour, (b) oxygen, (c) water vapour, external electrodes being employed. With the apparatus used, the intensity of the hydrogen spectrum was a maximum at a pressure of 3 mm. When a small trace of mercury vapour was present, the green mercury line appeared in the spectrum at all temperatures above -20° , its intensity being for a given hydrogen pressure proportional to the density of the mercury vapour. The appearance of the mercury line was accompanied by a diminished intensity of both the simple and compound hydrogen spectra. For pressures less than 6 mm., the relative intensities of the hydrogen and mercury spectra appear to be proportional to their densities; the addition of 4 per cent. of mercury vapour to pure hydrogen diminishes by half the intensity of the latter spectrum.

When hydrogen contains a small quantity of oxygen, the intensity of the hydrogen spectrum is increased if the pressure is less than 1.5 mm., and diminished if the pressure is greater. The similarity of the effect produced by water vapour is probably to be explained by the formation of the latter, when a discharge passes through hydrogen containing a trace of oxygen.

The observations made lead to the conclusion that the compound spectrum is really characteristic of hydrogen, and not due to any impurities.

The spectrum of oxygen containing a trace of mercury vapour gave no evidence of the presence of the latter; the addition, however, of a trace of hydrogen was followed immediately by the appearance of the green mercury line, a phenomenon which it is difficult to explain satisfactorily. J. C. P.

Phototropy. By WILHELM MARCKWALD (*Zeit. physikal. Chem.*, 1899, 30, 140—145).—The anhydrous chloride of quinoquinoline (Abstr., 1894, i, 474), on exposure to light, changes in colour from yellow to an intense green, and returns to its original state immediately at 90°, or in the dark at ordinary temperatures in a few days. The change is brought about in a few seconds by bright sunlight, and in a few minutes by diffused daylight, and is chiefly due to the more refrangible rays: Röntgen rays have no effect. Similar changes are obtained with β -tetrachloro- α -ketonaphthalene (Abstr., 1888, 710), which, by crystallisation from solvents, forms colourless, transparent crystals; these, when powdered and exposed to light, change to an amethyst colour, whilst large crystals become pleochroic, exhibiting a reddish-violet colour in one direction. The change does not appear to be connected with any chemical or crystallographic alteration, and by fusion a non-sensitive modification can be obtained which slowly returns to the sensitive form. To these phenomena, the author applies the term phototropy. L. M. J.

Concentration-cells with Unalterable Electrodes. By KARL SCHAUM (*Zeit. Elektrochem.*, 1899, 5, 316—319).—If two electrodes of a material which is not acted on by the electrolytes to be employed are immersed in solutions of an oxidising agent and of the substance formed by its reduction, a galvanic cell is formed, the E.M.F. of which is proportional to the absolute temperature, and depends on the relative concentrations of the ions present, but not on their chemical nature.

The E.M.F. is given by the formula $E = RT/n\epsilon \log.(c_1c'_2)/(c_2c'_1)$, where n is the difference between the number of electrical charges carried by the ion in question in its higher and lower stages of oxidation, $\epsilon = 96540$ coulombs, c_1 and c_2 are the concentrations of the ions of the higher and lower stage of oxidation respectively in one solution, and c'_1 and c'_2 the same quantities in the other solution.

Some experiments with solutions containing potassium ferro- and ferri-cyanides and platinum electrodes gave numbers which were in satisfactory agreement with the requirements of the formula. T. E.

Theory of Lead Accumulators. By F. DOLEZALEK (*Zeit. Elektrochem.*, 1899, 5, 533—539).—In a previous paper (Abstr., 1898, ii, 551), the author obtained, by thermodynamics, a formula showing the relation between the E.M.F. of a lead accumulator and the concentration of the sulphuric acid used in it. For concentrations not exceeding 1 gram-molecule per litre, this may be simplified to the form,

$$E_2 - E_1 = 0.000198 \nu T [\log_{10} c_2/c_1 + 0.009 (c_2 - c_1)]$$

where E_1 and E_2 are the E.M.F. s of accumulators containing acid of

the concentrations c_1 and c_2 respectively, and ν is the average number of ions formed from 1 molecule of sulphuric acid. The same formula is obtained by means of Nernst's osmotic theory, whether the theory of the chemical action of the accumulator due to Liebenow or that due to Le Blanc is assumed to be true. The formula is shown to be in good agreement with experimental results.

The E.M.F. of an accumulator filled with a saturated solution of lead sulphate is 1.25 volts at 0° . Combining this with the E.M.F. found for an acid of known concentration, it is easy to calculate, from the formula, the concentration of the sulphuric acid formed by hydrolytic dissociation in the lead sulphate solution. The calculation shows that 15 per cent. of the lead sulphate has suffered hydrolytic dissociation.

The E.M.F. of an accumulator containing a saturated solution of lead oxide in $N/10$ sodium hydroxide solution is 0.8 volt, and this is shown to be practically identical with the E.M.F. which an accumulator filled with pure water would possess. From this, the concentration of the hydrogen ions in pure water is readily calculated to be 0.33×10^{-7} gram-mol. per litre, in excellent agreement with the determination of Kohlrausch and Heydweiller.

Measurements are made of the difference of potential between a hydrogen electrode and the positive or negative plate of an accumulator in sulphuric acid of various concentrations, which are also shown to be in agreement with the author's theory. Similar measurements and calculations are made with a mercury-mercurous sulphate electrode.

The results obtained with the hydrogen electrode are of interest in connection with the gradual discharge of accumulators when not in use. This is due to the presence of particles of impurities in the plates which give rise to local electrolytic action; on the lead plate, hydrogen must be evolved on the surface of the impurity giving rise to a hydrogen-lead couple, on the peroxide plate, oxygen is evolved on the surface of the impurity, producing a lead peroxide-oxygen couple. The E.M.F.'s of these couples in acids of different concentration are as follows:—

	4.86	9.33	19.76	26.36	52.93 per cent. H_2SO_4
$PbO_2 : O_2$	0.55	0.56	0.59	0.62	0.72 volt.
$Pb : H_2$	0.27	0.28	0.32	0.34	0.43 volt.

Since the E.M.F. of the couples and the conductivity of the acid both increase as the concentration of the acid increases, the rate of discharge of the plates increases rapidly with increasing concentration of the acid, which is quite in accordance with practical experience. T. E.

Dielectrical Researches and Electrical Waves. By W. D. COOLIDGE (*Ann. Phys. Chem.*, 1899, [ii], 69, 125—166).—An electrical resonance method of determining the dielectric constant is described, which differs from that of Drude (compare Abstr., 1897, ii, 438) in that the condenser with the substance to be examined is in the oscillating system instead of in the receiving system. Comparison of the results obtained with a number of esters shows the method to be trustworthy and accurate; the author estimates that, by a few measurements,

the dielectric constant can be determined with a probable error of only 0.1 per cent.

At 14°, the dielectric constants of several liquefied gases have the following values: sulphur dioxide, 13.75; ammonia, 16.2; chlorine, 1.88. Linde found 14.8 for the sulphur dioxide constant at 23°, and 1.93 for the chlorine constant at 14°.

The temperature coefficient of the dielectric constant of water is found to be -0.432 per cent. at 17°, a value agreeing with the results of Drude and Heerwagen.

The anomalous absorption of water, previously observed up to $\lambda = 10$ cm., can, by the author's method, be determined up to $\lambda = 147$ cm., for which wave-length the absorption index = 0.0082. The absorption indices of a few esters have also been determined.

The value 4.35 is found for the dielectric constant of ether at 17.8°, in close agreement with Drude's determination. Experiments with mixtures of ether and chloroform confirm the existence of a maximum dielectric constant, found by Philip (compare Abstr., 1898, ii, 9) by a slow vibration method.

From the formula,

$$(\sqrt{\epsilon} - 1).100/d = (\sqrt{\epsilon_1} - 1).p_1/d_1 + (\sqrt{\epsilon_2} - 1)(100 - p_1)/d_2,$$

where ϵ , ϵ_1 , ϵ_2 are the dielectric constants of a mixture and its two components, d , d_1 , d_2 the corresponding densities, and p_1 the percentage of one component; the author has calculated the dielectric constants of a number of alcohols in dilute benzene and toluene solution. These calculated dielectric constants diminish with falling concentration, and approach limiting values agreeing closely with those determined by Philip (*loc. cit.*) with Nernst's apparatus. Thus for the alcohols slow and rapid vibration methods lead to the same limiting values, which may be considered free from electrical dispersion.

The paper contains also a theoretical discussion of the method employed and the phenomena described.

J. C. P.

Electrical Charges of freshly prepared Gases from Electrolytic Sources. By WILHELM KÖSTERS (*Ann. Phys. Chem.*, 1899, [ii], 69, 12—33).—The author confirms Townsend's results (*Phil. Mag.*, 1898, [vi], 45, 125), who showed that gases obtained by electrolysis have a positive or negative charge, according to the nature of the gas and the electrolyte employed, but rejects the theory that the phenomenon is to be explained by the escape of undischarged ions from the electrolyte. A connection is rather suggested with the observation of Lenard (*Ann. Phys. Chem.*, 1892, [ii], 46, 584), that air is negatively electrified when falling drops of water encounter an obstacle, and with the closely allied phenomenon of a gas being electrified by its passage through water.

Gases rendered non-electric and freed from dust particles by filtration through a tube connected to earth and filled with moist cotton wool were bubbled through various electrolytes. A comparison of the electrification produced with that obtained in electrolytic gases showed that the charges in the two cases generally agreed in sign, but were not at all proportional in quantity. Further, the ratio of the

charge to the volume of gas was much greater in the case of the electrolytic gases, but experiment showed that this might be due to the presence of fine particles of the electrolyte.

When hydrogen is bubbled through pure water, the former acquires a considerable negative charge; this action, however, is prevented by very small quantities of any dissolved substance. For a number of inorganic acids and salts, the electrifying action is found to vary with the concentration in a similar manner. In concentrated solutions, the action either is *nil* or approaches that value. The electrification of hydrogen bubbled through sulphuric acid of sp. gr. 1.3 is independent of the temperature. Absorption of the gas by the liquid slightly diminishes the electrification produced.

J. C. P.

Change of Resistance of Lead Dioxide. By TH. SUNDORPH (*Ann. Phys. Chem.*, 1899, [ii], 69, 319—323).—When two brass rods, separated by a layer of lead dioxide, have a potential difference of 33 volts (the exact value depending on the state of compression of the dioxide), the current produced first increases, and then decreases, reaching finally a constant value. This behaviour is probably due to the heat developed, which is greatest at the positive electrode, and to the formation of badly conducting monoxide. When the heat is supplied externally, and the current strength is determined at intervals, the latter is found to change in the same way as before. The period during which the current strength increases is lengthened when the potential is less than 33 volts, and shortened when the potential is greater than 33 volts, ultimately vanishing altogether. In the latter case, the rise of temperature is slight, and the amount of dioxide decomposed small compared with the great and sudden increase of resistance; the decomposition is probably due to sparks, chiefly in the neighbourhood of the electrodes.

J. C. P.

Electrolytic Conductivity of Pure Substances. By RICHARD ABEGG (*Zeit. Elektrochem.*, 1899, 5, 353—355).—In order that a pure substance shall possess electrolytic conductivity, its chemical constitution must be such that ions may be formed from it, its dielectric constant should be high, and it should not contain a large proportion of polymerised molecules, since these cannot dissociate directly into ions. Many substances with large dielectric constants (water, methyl and ethyl alcohols, formic acid) consist mainly of polymerised molecules and are therefore bad conductors. Others, with large dielectric constants and small polymerisation, are unsuitably constituted; nitrobenzene, ethyl nitrate, and benzonitrile, for example, contain the groups NO_2 , NO_3 , and CN , which readily form ions, but on the other hand, they contain the groups C_6H_5 and C_2H_5 , which have never been observed in the form of ions.

Fused salts, in all probability, possess high dielectric constants, their chemical constitution is very favourable to the formation of ions, nothing is known of their association factor. They form the only group of pure substances with any considerable electrolytic conductivity.

In the case of solutions, it is extremely probable that the capacity of the ions to unite with molecules of the solvent has an important

influence on the degree of dissociation. Solutions in water and liquid anhydrous ammonia are mentioned as illustrations of this.

T. E.

Influence of Substituents on the Electrical Conductivity of Benzoic Acid. By ALFRED TINGLE (*J. Amer. Chem. Soc.*, 1899, 21, 792—803).—The conductivities of the alkali salts of benzoic acid and several halogen derivatives have been determined in aqueous solution for $v = 64$ and $v = 128$. The numbers obtained do not agree with the rule that the difference between the conductivities of two metals is constant, and independent of the acid with which they are combined; the deviation from this rule is most marked in the case of sodium and potassium iodobenzoates.

J. C. P.

Electrical Conductivity of Non-aqueous Solutions. By AZARIAH T. LINCOLN (*J. Physical Chem.*, 1899, 3, 457—494).—The paper contains an account of an extensive investigation of the electrical conductivity of solutions of inorganic salts in solvents other than water. The compounds employed were the chlorides of aluminium, chromium, manganese, zinc, cobalt, nickel, copper, cadmium, arsenic, tin, potassium and lithium, nitrates of lead and silver, cyanides of mercury and silver, and copper sulphate, while as solvents the following liquids were used:—Ethyl, propyl, allyl, benzyl alcohols; benzaldehyde, salicylaldehyde, furfuraldehyde, acetone, methyl propyl ketone, acetophenone, ethyl acetate, ethyl monochloroacetate, ethyl cyanoacetate, ethyl acetoacetate, ethyl benzoate, ethyl oxalate, ethyl nitrate, amyl nitrite; nitrobenzene *o*-nitrotoluene, aniline, xylidine, benzonitrile, pyridine, piperidine, quinoline, phosphorus trichloride, and tin tetrachloride. Although with methyl and ethyl alcohols, limiting values for the molecular conductivity were reached, yet as a general rule this is not the case, and the values for the dissociation in propyl alcohol given by Schlamp (*Abstr.*, 1894, ii, 376) are, on this account, not justified. Solutions in ketones conduct, the highest values being obtained with acetone; in some cases, the molecular conductivity was found to decrease after certain dilutions. Pyridine yields conducting solutions, as does nitrobenzene, but here also limiting values are seldom indicated. It hence follows that as a general rule dissociation values cannot be calculated except in a few cases with alcoholic solutions, and in these the agreement of the values with those obtained by other methods is not satisfactory. Many conducting solutions have been found to give normal molecular weights by the boiling point methods, as, for example, solutions in acetone (Dutoit, *Abstr.*, 1899, ii, 350), and in benzonitrile and pyridine (Werner, *Abstr.*, 1897, ii, 214), so that in non-aqueous solutions there is no agreement between the evidence concerning dissociation afforded by the different methods. In alcoholic solutions also, in which considerable dissociation occurs, the results are not in accord with the dilution law of either Ostwald or Rudolphi. Examination of the degrees of association of the various solvents used indicates that the theories of Dutoit and of Crompton (*Trans.*, 1897, 71, 925), that only associated solvents yield conducting solutions, are untenable, inasmuch as many solutions of high conductivity were

obtained with non-associated solvents. Comparisons of dielectric constants show that while, as a general rule, solvents with high constants yield solutions that conduct well, yet there is no proportionality between the two values (see Brühl, *Abstr.*, 1899, ii, 735; this vol., ii, 11). The author hence considers that the dissociation theory, in its present form, cannot be applied to explain the conductivity of non-aqueous solutions, and urges the desirability of obtaining further data (compare *Abstr.*, 1899, ii, 397; also Kahlenberg, *Abstr.*, 1899, ii, 624).

L. M. J.

Electrolytic Gas Development. By WILLIAM A. CASPARI (*Zeit. physikal. Chem.*, 1899, 30, 89—97).—At ordinary temperatures, hydrogen is liberated at 1.55 to 1.56 volts, and with higher E.M.F.'s a mixture of oxygen with excess of hydrogen is obtained, whilst at a temperature of 98° to 100°, hydrogen production occurs at 1.33 volts (see Le Blanc, *Abstr.*, 1894, ii, 4; Nernst, *Abstr.*, 1897, ii, 394). After long electrolysis, hydrogen peroxide or persulphuric acid is present in the liquid. With electrodes of spongy platinum, the cathodic electrolysis is completely reversible; with bright platinum, a slight excess of tension was necessary for the liberation of hydrogen, whilst with other metals this excess of tension is considerable, and the electrolysis is hence non-reversible; it is least for those metals which possess the greatest occlusion capability. Experiments on the electrolysis of solutions of potassium bromide or potassium iodide in *N* sulphuric acid proved that the precipitation of the bromine or iodine on platinum electrodes is reversible; this is also found to be the case for the precipitation of silver on silver electrodes in solution of silver nitrate, or of double cyanides.

L. M. J.

Magnetic Susceptibility of Inorganic Compounds. By STEFAN MEYER (*Ann. Phys. Chem.*, 1899, [ii], 69, 236—263).—The magnetic susceptibility of a number of inorganic compounds in the form of powder has been determined by the balance method previously employed in the case of elements (compare *Abstr.*, 1899, ii, 587). The molecular magnetism is the coefficient of susceptibility divided by the number of gram-molecules per litre of space. Experiments in which the field strength varied from 6000 to 10000 (C.G.S. units) showed that the coefficient of susceptibility, except for ferric oxide, is independent of the field strength.

A compound of two diamagnetic elements is always diamagnetic, and a compound of two paramagnetic elements is generally paramagnetic, but may be diamagnetic, as in the case of beryllium, magnesium and aluminium oxides, and silica. Oxygen always lowers the susceptibility of an element, and thus the oxides of paramagnetic elements may be diamagnetic; the lowering effect is greater the greater the proportion of oxygen atoms in the oxide. Besides chromium, manganese, iron, cobalt, and nickel, there is another series of strongly magnetic elements—lanthanum, cerium, praseodymium, neodymium, ytterbium, samarium, gadolinum, and erbium, arranged in order of increasing magnetic susceptibility. The susceptibility of erbium oxide is about four times that of ferric oxide. The molecular magnetism of paramagnetic com-

pounds is less than the sum of the atomic magnetisms of the components, as shown by the oxides of chromium, manganese, iron, cobalt, and nickel. For diamagnetic substances, the molecular magnetism is approximately additive. That the molecular magnetism is not purely additive is shown by the fact that the value for a hydrated salt differs from the value for the anhydrous salt by less than the amount calculated for the water of crystallisation.

The molecular magnetism of the halogen compounds of a metal increases with the atomic weight of the halogen, and a similar law holds for compounds of different alkali metals with the same halogen.

The connection between the atomic volume and the magnetic susceptibility of the elements is shown by an atomic volume curve. Strongly magnetic elements are found at the minima and the parts of the curve immediately preceding, the chief exception being oxygen which, however, behaves in compounds as if it were diamagnetic. Polonium and radium in their compounds are found to be paramagnetic, and thus these elements will probably find a place at minima of the atomic volume curve. The connection between atomic volume and magnetic susceptibility is confirmed by the fact that when the atomic volume decreases with fall of temperature, the susceptibility increases: further, in compounds where there is an increase of volume, the susceptibility decreases.

J. C. P.

A Simple Protection for Fused-in Platinum Wires. By WILHELM PALMAER (*Ber.*, 1899, 32, 2570—2571).—Where a platinum wire has to be fused into the wall of a glass vessel, as is frequently the case in electrochemical apparatus, it is recommended to have only a very short piece of wire projecting outside the vessel; surrounding this wire is a small piece of narrow glass tubing fused on to the glass vessel. By pouring mercury into this glass tube, contact is made, and the danger of breaking the platinum wire or of splintering the glass around its point of entry is avoided.

T. H. P.

Heat of Oxidation of Tungsten. By MARCEL DELÉPINE and L. A. HALLOPEAU (*Compt. rend.*, 1899, 129, 600—603).—When finely divided tungsten is burnt in oxygen in the calorimetric bomb, the heat liberated per gram is 1062 cal., whilst the dioxide WO_2 , under similar conditions, gives 299.2 cal. It follows that

The heat developed by combination with the successive atoms of oxygen is approximately the same, and is practically identical with the heat of oxidation of iron, which explains the interactions of water, tungsten, hydrogen, and tungstic anhydride at different temperatures. The results also explain the reactions of tungsten with various metallic oxides, the reduction of tungstic anhydride by certain metals only, and the reduction of mercuric, cupric, platonic, silver and gold salts by the red and blue tungsten oxides.

C. H. B.

A Simplification of Beckmann's Boiling Point Apparatus. By SAMUEL L. BIGELOW (*Amer. Chem. J.*, 1899, 22, 280—287).—To obviate the danger of superheating, and to secure a constant heating effect independent of changes of gas pressure, the author adopts as the source of heat a spiral of thin platinum wire immersed in the solvent and heated by means of an electric current of constant strength; the boiling vessel adopted is the same as in Beckmann's method, but is surrounded by a layer of felt to avoid cooling by radiation and convection. The electric connection to the heating wire is furnished by two glass tubes filled with mercury, passing through the cork and reaching nearly to the bottom of the vessel; through the lower ends of these are fused platinum hooks on which the heating spiral is suspended. The beads which are necessary in Beckmann's method to ensure uniformity of temperature and avoid superheating are not required with the new apparatus. Although, in general with electric heating, the results are normal, remarkably low values are obtained with very dilute solutions which point to dissociation occurring, "under the conditions of the experiment, of non-electrolytes in solvents to which it is not usual to ascribe dissociating power"; the author intends investigating this question.

W. A. D.

Relation between Pressure and Evaporation. By EDWIN H. HALL (*J. Physical Chem.*, 1899, 3, 452—456).—Nernst derives the equation of reaction isotherms from the consideration of a system in which a reaction proceeds in a given direction, and in which the concentration is maintained constant by the introduction and removal of the compounds reacting and produced in the states of solids or non-miscible liquids, and he assumes that the work required for this is zero. This necessitates equality of volumes, and the author hence introduces an additional term $P(\bar{V} - \bar{V}')$ and applies the altered equation to the case of a single liquid or solid in the presence of its gaseous phase. Expressions are thus obtained for the vapour density, as a function of external pressure, for water over ice at -10° and over liquid water at 0° .

L. M. J.

Density of Liquids and Saturated Vapours. By RUDOLF VON HIRSCH (*Ann. Phys. Chem.*, 1899, [ii], 69, 456—478).—The densities of toluene, *o*-xylene, *m*-xylene, *p*-xylene, propionic acid, normal and iso-butyric acids, both as liquids and saturated vapours, have been determined at 190° , 212° , 237° , and 276° , the boiling points of dimethylaniline, diethylaniline, isobutyl benzoate and bromonaphthalene respectively. The method adopted was essentially that of Young (*Trans.* 1891, 59, 37 and 911).

When D and d are the densities at a given temperature of liquid and saturated vapour respectively, the mean values $(D + d)/2$ for different temperatures lie on a straight line in all cases examined, in conformity with Matthias' law. The curve connecting density and temperature would thus naturally be a parabola, but the actual curve

is found to differ from the parabolic form in being flattened at the vertex.

The constants a and b of van der Waal's equation, calculated from the determined densities, are found to alter with the temperature, b slowly increasing and a generally diminishing with rising temperature; a increases with the temperature only in the case of p -xylene.

The author criticises the commonly accepted theory of the critical point, and considers illogical the view that the densities of liquid and vapour are equal at the critical temperature. The existence of a critical point is denied, for both liquid and vapour are regarded as having a critical density. From this point of view, van der Waal's assumptions that at the critical point $dp/dv = 0$ and $d^2p/dv^2 = 0$ are not justified.

J. C. P.

Phenomena of Effusion of Permanent Gases. By ROBERT EMDEN (*Ann. Phys. Chem.*, 1899, [ii], 69, 264—289 and 426—453).—When a gas issues under pressure from a narrow opening, stationary sound waves are formed in the jet. Photographs of the jet afford a means of measuring the wave-length and determining its variation with the size of aperture, with the pressure of the gas flow, and with the chemical nature of the gas. Experiments with air, carbon dioxide, and hydrogen show that, for a given size of aperture and a given gas pressure, the wave-length is independent of the molecular weight of the gas.

J. C. P.

Van't Hoff's Equation and the Molecular Weights of Liquids. By CLARENCE L. SPEYERS (*J. Amer. Chem. Soc.*, 1899, 21, 725—732. Compare Abstr., ii, 1898, 213).—The equations $n/(N+n) = (p-p')/p$ and $n/N = (p-p')/p'$, where n and N are the number of gram-molecules of solute and solvent, p and p' the vapour pressures of solvent and solution respectively, give numbers agreeing well with observation, whilst the equation $n/N = U(p/p')$ is not at all in harmony with experiment, especially at higher concentrations. The molecular weight of acetic acid calculated by this formula from Linebarger's experiments on a mixture of benzene and acetic acid has quite absurd values. The author deduces the latter equation by a process similar to that employed by van't Hoff, but is unable to suggest any correction which would bring the formula into harmony with experiment.

J. C. P.

A New Inorganic Dissociative Solvent. By PAUL WALDEN (*Ber.*, 1899, 32, 2862—2871).—Liquid sulphur dioxide has a remarkable power of dissolving the most varied substances, both inorganic and organic, the solutions often showing a characteristic colour: thus potassium, sodium, and ammonium iodides all dissolve readily, forming yellow solutions. Among soluble organic substances are benzene, naphthalene, ethyl alcohol, benzoic acid, phenol, ethyl acetate, aniline, diphenylamine, α - and β -naphthylamine. The solutions of diphenylamine and α -naphthylamine are blood-red in colour, that of β -naphthylamine is orange.

The fact that the dissolved substances react readily with each other

points to their being electrolytically dissociated: thus by double decomposition $\text{KI} + \text{NH}(\text{CH}_3)_3\text{Cl} = \text{KCl} + \text{NH}(\text{CH}_3)_3\text{I}$; all these substances are soluble in liquid sulphur dioxide except potassium chloride, which is accordingly precipitated. Ammonium thiocyanate and sublimed ferric chloride give a blood-red colour, exactly as in aqueous solution.

The conductivity of sulphur dioxide solutions is considerable, and in some cases greater than that of equally concentrated aqueous solutions. The increase of the molecular conductivity with dilution is irregular, and for the iodides much more marked than in their aqueous solutions. Ammonium salts in sulphur dioxide solution have a smaller conductivity than potassium or rubidium salt solutions of equal concentration: the conductivity of ammonium, tetramethylammonium, and tetraethylammonium iodides increases with the complexity of the positive ion. The difference between μ_{512} and μ_{16} for potassium iodide is greater in sulphur dioxide solution than in aqueous solution; hence both the degree of dissociation and the ionic velocities differ in the two solvents.

As a further test of the degree of dissociation, determinations of the molecular weight were carried out, the boiling point method being employed. The molecular rise of the boiling point of sulphur dioxide was calculated to be 15° , and with this constant the method gave normal and steady values for the molecular weights of naphthalene, toluene, and acetanilide. The iodides of potassium, sodium, rubidium, and ammonium give a value for the molecular weight which is nearly twice the normal value, whilst certain other salts, such as potassium thiocyanate and tetramethylammonium iodide, have approximately the theoretical molecular weight, thus behaving like non-electrolytes.

An explanation of this abnormal behaviour, which is to a certain extent analogous to that of liquid ammonia solutions (compare *Abstr.*, 1899, ii, 202), is reserved until further investigations have been made.

J. C. P.

Nature of Colloidal Solutions. By K. STOECKL and LUDWIG VANINO (*Zeit. physikal. Chem.*, 1899, 30, 98—112).—The authors consider that colloidal metallic solutions consist of suspensions of extremely finely divided solid particles, and give the following reasons for their view. By boiling there is no continuous change in the boiling point, and the suspended material is almost completely precipitated after short boiling. Colloidal solutions bring about elliptic polarisation of light, which could be caused by solid particles, the diameters of which are smaller than the wave-length of the light, whilst, further, the colour of colloidal gold solutions is also explicable on the assumption that they contain small suspended particles. The electrical properties of these solutions and their behaviour to dialysers are also in accord with this view of their nature. The same reasoning may also be applied in the case of colloidal solutions of metallic sulphides.

L. M. J.

Function of the Medium in Chemical Change. By JULIUS WILHELM BRÜHL (*Zeit. physikal. Chem.*, 1899, 30, 1—63).—The velocity of the tautomeric change of ethyl mesityloxidoxalate from the enolic

to the ketonic form has been investigated in various solvents, and found to vary greatly with the nature of the latter (Abstr., 1899, ii, 735). The dissociative powers of solvents are closely associated with their dielectric constants (Abstr., 1894, ii, 266), and the same is found to obtain for their powers of inducing the above tautomeric change. No absolute proportionality exists, or can be expected, inasmuch as the dielectric constant varies greatly with temperature and also with the frequency of the electrical waves. This dissociative power is regarded as due to a form of energy which the author terms the "medial energy"; this, although not identical, is closely connected with the heat energy of the compound. The internal energy of a compound cannot be actually determined, since physical and chemical changes are only connected with changes of energy, but it is probable that it is greatest in compounds with the highest specific heat, and latent heat of fusion or evaporation. The examination of these constants for a large number of compounds indicates that high values are also generally associated with high dielectric constants and dissociative power. For the recognition and estimation of the tautomeric forms (chemical methods are not available, and cryoscopic methods are untrustworthy), the author considers the best methods to be the determination of the optical properties or the electrical conductivity.

L. M. J.

Gaseous Reactions in Chemical Kinetics. VI. and VII. By MAX BODENSTEIN (*Zeit. physikal. Chem.*, 1899, 30, 113—139).—The author gives a detailed account of the various thermostats used in his researches on gaseous reactions (Abstr., 1899, ii, 548, 637, 638, 639, 733). For vapour baths, sulphur, phosphorus pentasulphide, mercury, and diphenylamine were employed; for liquid baths, oil, lead, and an alloy of tin and lead. Temperatures were measured by mercury thermometers containing carbon dioxide under pressure, and by an air thermometer, and he considers the temperatures accurate to one degree. In summarising the results of the whole work, the author considers he has proved that gaseous reactions proceed continuously, and only at the absolute zero would an absolute inertness be reached, and hence that the assumption of a state of "false equilibrium" is erroneous. In the oxidation of phosphorus or phosphorus trihydride, the reaction apparently ceases at certain pressures of oxygen; in these cases, however, the reaction is very complicated, and the author does not consider that the supposition of a state of false equilibrium is necessitated (see also Duhem, Abstr., 1899, ii, 739).

L. M. J.

Application of the Equilibrium Law to the Formation of Oceanic Salt Deposits with Especial Reference to the Stassfurt Beds. II. Equilibrium Relations of Carnallite. By JACOBUS H. VAN'T HOFF and WILHELM MEYERHOFFER (*Zeit. physikal. Chem.*, 1899, 30, 64—88. Compare Abstr., 1898, ii, 564).—The authors have previously investigated the solubility curves for magnesium chloride, and the present paper contains an extension of this work to carnallite, but the diagrams and curves are necessary for the complete explanation of the results. Below zero, the following equilibrium points are obtained: — 11.1° ice, potassium chloride, solution: — 33.6° ice, magnesium

chloride dodecahydrate, solution: -34.3° , ice, potassium chloride, magnesium chloride dodecahydrate, solution. At -21° , carnallite is formed, being unstable in solution below this temperature, and from this point two curves branch, those for the solid phases (1) carnallite and potassium chloride, (2) carnallite and magnesium chloride. The latter curve has various transition points for the various hydrates of magnesium chloride in the presence of carnallite, these temperatures being different from those for the pure compound. At 152.5° , an upper limiting temperature for carnallite is reached, at which it decomposes into potassium chloride and magnesium chloride tetrahydrate. From the -21° transition point also proceeds the curve for the solid phase carnallite and potassium chloride to the temperature 167.5° , where the carnallite decomposes and melts. From this point to the previous decomposition point at 152.5° is another curve for the equilibrium of carnallite with potassium chloride, and the curve then proceeds as the solubility curve of magnesium chloride tetrahydrate in the presence of potassium chloride to the temperature of 176° , when a transition point to the dehydrated salt is reached. The solubility experiments were carried to 186° , and complete melting in sealed tubes was found to occur at 265° ; no evidence of any compound of the two chlorides other than carnallite was obtained. L. M. J.

Inorganic Chemistry.

Production of Ozone by the Decomposition of Water by Fluorine. By HENRI MOISSAN (*Compt. rend.*, 1899, 129, 570—573).—When fluorine is passed into water cooled at 0° , the liberated oxygen contains from 10 to 12 per cent., or, under the most favourable conditions, as much as 14.39 per cent., of ozone, and is decidedly blue. The proportion of ozone is higher the more rapid the current of fluorine, provided that the water is kept at 0° , and subject to the maximum limit of 14.39 per cent.; it is markedly less if the temperature of the water is allowed to rise. C. H. B.

Hyposulphurous Acid. By ARNOLD NABL (*Monatsh.*, 1899, 20, 679—684).—If dry sulphur dioxide is passed into absolute alcohol in which metallic zinc is suspended, and contained in a flask from which air is excluded, a white precipitate is formed. This is left for a day, filtered, and the operation then repeated. The solution deposits small, microscopical, rhombic needles which, after drying in vacuum to eliminate the alcohol of crystallisation, give figures on analysis agreeing with the formula ZnS_2O_4 . The other product, insoluble in alcohol, appears to be a mixture. R. H. P.

Isomerism of Salts of Ammonium, Hydroxylamine, and Hydrazine. By ALEXANDER P. SABANÉEFF [with A. DSHEWACHOFF, M. EFROSS, Z. GINSBURG, J. LEMKE, M. PROSIN, and A. WLIASSOFF] (*Chem. Centr.*, 1899, ii, 32—33; from *J. Russ. Chem. Soc.*, 1899, 31, 375—383. Compare Abstr., 1898, ii, 577).—The following pairs of

isomeric compounds have been prepared and their molecular weights determined by Raoult's method: (1a) ammonium hydroxylamine hydrogen phosphite, (1b) diammonium hydrogen phosphate; (2a) hydroxylamine dihydrogen phosphite, (2b) ammonium dihydrogen phosphate; (3a) hydroxylamine formate, (3b) ammonium hydrogen carbonate; (4a) hydroxylamine acetate, (4b) ammonium glycolate; (5a) hydrazine oxalate, (5b) hydroxylamine oxamate; (6a) hydrazine succinate, (6b) hydroxylamine succinamate; (7a) hydroxylamine benzoate, (7b) ammonium salicylate; (8a) hydroxylamine *m*-aminobenzoate, (8b) hydrazine salicylate, $\text{C}_6\text{H}_4\text{O} \text{---} \text{CO}_2 \text{---} \text{N}_2\text{H}_6$.

(2a) is a syrup which, with absolute alcohol, yields hydroxylamine phosphate. (3a) crystallises in needles, and is easily soluble in water, forming an acid solution which decomposes on boiling, and does not then give the hydroxylamine reaction. (4b) is prepared by mixing glycollic acid with the calculated quantity of ammonia and evaporating in a vacuum; if an excess of ammonia is used, diammonium glycolate is formed; it separates in needles, is easily soluble in water, giving an acid solution from which the acid salt is obtained on evaporating. (5a) crystallises in needles, and is very slightly soluble in water. (5b) forms crystals, and is easily soluble in water. (6a) separates in very perfect crystals, and is soluble in water. (6b) gradually changes into hydroxamic acid; the same change is brought about by boiling the solution. (7a) is very slightly soluble in water. (7b) separates as the anhydrous salt when aqueous solutions of ammonia and salicylic acid are mixed and heated. (8a) is very slightly soluble in water, but more so in alcohol. (8b) is prepared from salicylic acid and hydrazine hydroxide. (2a), (3a), (4a), (5b), (6b), (7a), and (8a) are prepared from the barium salts of the corresponding acids and the sulphates of the nitrogen bases. Whilst measuring the electrical conductivity of hydrazine sulphate, its oxidation by platinum black was observed, and when oxygen is passed into an aqueous solution in which platinum black is suspended, the sulphate is completely oxidised, nitrogen, ammonium sulphate, sulphuric acid, and water being formed. E. W. W.

Action of Potassammonium on Arsenic. By C. HUGOT (*Compt. rend.*, 1899, 129, 603—605).—The action of excess of potassammonium on arsenic yields a brick-red compound, AsK_3NH_3 , analogous to that previously obtained from sodammonium (*Abstr.*, 1899, ii, 151), and when this is heated at 300° in a vacuum, it yields a black compound, AsK_3 . When the arsenic is in excess, the product is an orange solid, $\text{K}_2\text{As}_4\text{NH}_3$, which, when heated a little below 300° , yields a cinnabar-red compound, K_2As_4 . C. H. B.

The Atomic Weight of Boron. By HENRI GAUTIER (*Compt. rend.*, 1899, 129, 595—598).—Boron sulphide, B_2S_3 , prepared by the action of dry hydrogen sulphide on dry amorphous boron at a red heat, was decomposed by sodium hydroxide solution, oxidised with bromine water, and precipitated with barium chloride. Four experiments give $B = 11.041$ with a probable error ± 0.017 .

Boron carbide prepared in the electric furnace by the action of

sugar-charcoal on amorphous boron in presence of copper, was decomposed by chlorine, and the residual carbon weighed as such, and also in the form of carbon dioxide. Two experiments give $B = 10.997$.

C. H. B.

Atomic Weight of Boron. By HENRI GAUTIER (*Compt. rend.*, 1899, 129, 678—681. Compare Abrahall, *Trans.*, 1892, 61, 650; Ramsay and Aston, *Trans.*, 1893, 63, 207; Rimbach, *Abstr.*, 1893, ii, 207).—Boron tribromide, obtained by passing pure bromine over pure boron heated to a dull red heat, was fractionally distilled alone, and then finally over reduced silver, when it distilled quite constantly at 90.5° . Pure boron trichloride was obtained in a similar manner. A weighed quantity of the boron haloid was decomposed by water, and the halogen determined as silver haloid. The mean value obtained for the atomic weight of boron by nine experiments on the decomposition of the bromide was 11.021, with a probable error of ± 0.006 , and from five experiments on the chloride, 11.011, with a probable error of ± 0.008 . The mean of these values is 11.016, a number which the author adopts for the atomic weight of boron in preference to the values obtained by analysis of boron sulphide and boron carbide (compare preceding abstract).

H. R. LE S.

Graphite. By LUDWIG STAUDENMAIER (*Ber.*, 1899, 32, 2824—2834. Compare *Abstr.*, 1898, ii, 96; 1899, ii, 481).—When graphitic acid is heated with sulphuric acid and water at 180° , it gives an insoluble *pyrographitic acid*, which retains the form and appearance of the original graphite. When oxidised with nitric acid, this gives a soluble product containing mellitic acid, a red substance soluble in ether, a dark brownish-red substance soluble in alcohol, and a black residue insoluble in alcohol or ether. When treated with a mixture of fuming nitric acid and potassium chlorate, unlike ordinary pyrographitic acid, it gives a transparent, yellowish-green *pseudo-graphitic acid*; this resembles graphitic acid but is more soluble, less stable, and more readily oxidised; it gives a black reduction product with stannous chloride.

T. M. L.

Treatment of Lepidolite. By JULIUS FORMÁNEK (*Chem. Centr.*, 1899, ii, 11—12; from *Oesterr. Chem. Zeit.*, 2, 309—312).—In order to obtain caesium and rubidium compounds from lepidolite, the finely powdered mineral is decomposed with concentrated sulphuric acid in an iron pan, and the solution evaporated in a lead vessel. The residue is taken up with water, and the potassium, caesium, and rubidium alums which separate are crystallised from water several times, and then treated with barium hydroxide. The excess of the baryta and most of the alumina are removed by means of carbon dioxide, and the solution, after neutralising with oxalic acid, is evaporated until crystals begin to form. Most of the potassium salt separates on cooling, and the rest is removed from the residue by fractional crystallisation, the caesium and rubidium salts being afterwards separated by the same means.

E. W. W.

Commercial Calcium Carbide. By HENRI MOISSAN (*Bull. Soc. Chim.*, 1899, [iii], 21, 865—871).—Theoretically, 1 gram

of calcium carbide should yield 349 c.c. of acetylene, the amounts obtained from seven commercial samples varied from 292.8—318.7 c.c.; three inferior specimens, which were grey and porous, instead of having a fused, crystalline structure, gave only 228.6, 250.4, and 260.3 c.c. respectively. The gas sometimes contains notable quantities of ammonia, and several specimens of carbide yielded a little hydrogen phosphide. To facilitate the study of the insoluble residue, the carbide was decomposed with an aqueous solution of sugar, whereby the lime produced is kept in solution. The residue consists principally of the silicides of carbon, calcium, and iron, sometimes mixed with a little graphite and calcium sulphide; dilute (10 per cent.) hydrochloric acid extracts iron, lime, and small quantities of aluminium and phosphorus; the concentrated acid dissolves further quantities of lime and silica, whilst carbon silicide and graphite remain unattacked. The various forms in which these impurities exist were recognised by microscopical examination. The *silicon* occurs chiefly as carbon silicide, but small quantities of calcium silicide, silica, and a compound containing iron, carbon, and silicon are also formed. Silicon hydride, from the decomposition of calcium silicide, is often evolved in the treatment with concentrated hydrochloric acid. The total *sulphur* in three samples of carbide was found to be 0.37, 0.43, and 0.74 per cent.; it exists as calcium sulphide and aluminium sulphide. Hydrogen sulphide is not liberated when impure calcium carbide is decomposed by water, since it is retained by the calcium hydroxide formed in the reaction; traces of a volatile organic compound containing sulphur seem, however, to be formed in some cases, since the gas, after being washed with potash and lead acetate solution, yields a small quantity of sulphuric acid when burnt. Iron is found as silicide and carbo-silicide. Phosphorus occurs chiefly as calcium phosphide, but is also found combined with iron and silicon. Carbon is sometimes found as graphite retaining calcium and silicon; none was detected in the form of diamond.

N. L.

Action of Magnesium on Saline Solutions. By DONATO TOMMASI (*Bull. Soc. Chim.*, 1899, [iii], 21, 885—887).—When magnesium wire is placed in a solution of potassium chloride, the metal is converted into hydroxide, with liberation of hydrogen; the potassium chloride simply favours the oxidation of the magnesium, and is not itself decomposed. With ammonium chloride solution, a vigorous reaction occurs, hydrogen is evolved, and ammonium magnesium chloride formed. A 30 per cent. solution of calcium chloride attacks magnesium, slightly in the cold and more readily on heating, with the formation of magnesium hydroxide and hydrogen, but a saturated solution is without action unless the metal is finely divided and the liquid heated. A 30 per cent. solution of magnesium chloride has very little action on magnesium, but the boiling solution is easily decomposed by a magnesium-platinum couple, with the formation of magnesium hydroxide and oxychloride. The action on magnesium of solutions of various other salts was examined, and the products of the reactions, in addition to hydrogen, were found to be as follows. Sodium and lithium chlorides: magnesium hydroxide. Barium and strontium

chlorides: scarcely any action on magnesium. Cupric chloride: cuprous chloride, copper oxychloride, and magnesium chloride. Cadmium chloride: cadmium oxychloride, metallic cadmium, and magnesium chloride. Cobalt chloride: cobalt hydroxide and magnesium chloride. Lead chloride: lead oxychloride, metallic lead, and magnesium chloride. Mercuric chloride: mercurous chloride, mercury oxide, and magnesium chloride. Ferric chloride: ferric hydroxide, ferric oxychloride, and magnesium chloride; ferric chloride is not reduced by magnesium. Chromic chloride: chromium hydroxide and magnesium chloride. Platinic chloride: metallic platinum and magnesium hydroxide. Gold chloride: metallic gold, magnesium hydroxide, and magnesium chloride. Copper sulphate: metallic copper, cuprous hydroxide, basic copper sulphate, and magnesium sulphate; at 0° , cuprous hydroxide only is obtained. Zinc sulphate: metallic zinc, zinc hydroxide, basic zinc sulphate, and magnesium sulphate. Ferrous sulphate: ferrous hydroxide, and magnesium sulphate. Manganese sulphate: manganese hydroxide and magnesium sulphate. N. L.

Anhydrous Magnesium Carbonate. By RODOLPHE ENGEL (*Compt. rend.*, 1899, 129, 598—600).—When magnesium ammonium carbonate is gradually heated in a current of dry air at a temperature not exceeding 130° — 140° , it yields anhydrous magnesium carbonate which differs from the natural mineral, and from the carbonate prepared by Senarmont, but resembles that obtained by the action of heat on magnesium potassium sesquicarbonate (*Abstr.*, 1886, 821). It retains the crystalline form of the double carbonate, is very hygroscopic, sets like plaster when mixed with water, and absorbs almost instantly about 100 times its own volume of ammonia gas.

Attempts to prepare an ammonium magnesium sesquicarbonate gave negative results, and the compound, $\text{MgCO}_3 \cdot \text{NH}_4\text{HCO}_3 + 4\text{H}_2\text{O}$, ascribed to Favre, was never described by him. C. H. B.

Dicarbonyl Cuprous Chloride. By WILLIAM APP JONES (*Amer. Chem. J.*, 1899, 22, 287—311).—Carbonic oxide is not absorbed by dry cuprous chloride, but in presence of sufficient hydrochloric acid to form a thin paste, an amount of gas is absorbed at 0° which corresponds with the formation of *dicarbonyl cuprous chloride*, $\text{Cu}_2\text{Cl}_2 \cdot 2\text{CO} + 4\text{H}_2\text{O}$; on adding ice-water, white plates having this composition separate which rapidly decompose in the air. The compound prepared by passing carbonic oxide into cuprous chloride in presence of water or dilute hydrochloric acid ($1\text{HCl} : 2\text{H}_2\text{O}$) is not decomposed by diminishing the pressure until the latter is reduced to 135—125 mm., when complete decomposition occurs; in presence of concentrated hydrochloric acid, decomposition begins at 410 mm. pressure and gradually increases as the pressure is reduced to 160 mm., when it takes place more rapidly and is complete at 130 mm. pressure. Curves are given showing these results.

On passing carbonic oxide into a solution of cuprous chloride in pyridine at 0° , the compound $2\text{Cu}_2\text{Cl}_2 \cdot 3\text{CO}$ appears to be formed, but could not be isolated; on raising the temperature, decomposition occurs

regularly, until at 100° it is nearly complete. The results are plotted in the form of a curve.

When oxygen is passed into dicarbonyl cuprous chloride at 0° , the latter is decomposed, giving rise to a small quantity of carbon dioxide; the formation of this cannot be due to increased activity of the oxygen brought about by the cuprous chloride undergoing oxidation, and thus splitting the molecular into atomic oxygen, for when a mixture of oxygen and carbonic oxide is passed through ferrous sulphate or chloride these compounds are oxidised, but no carbon dioxide is formed.

In discussing the decomposition of dicarbonyl cuprous chloride by reducing the pressure or raising the temperature, it is pointed out that this takes place similarly to that of compounds the "atomic" nature of which cannot be doubted; its properties are compared with those of other inorganic compounds containing carbonic oxide, and the conclusion is reached that it must be regarded as a true chemical compound.

The behaviour of dicarbonyl cuprous chloride with oxygen, chlorine, hydrogen, and nitrogen shows that, at the moment of its liberation from the compound, carbonic oxide possesses no increased chemical activity.

W. A. D.

Spectroscopic Analysis of Neodymium and of Praseodymium. By WILHELM MUTHMANN and L. STÜTZEL (*Ber.*, 1899, 32, 2653—2677. Compare Abstr., 1898, ii, 518; von Scheele, Abstr., 1898, ii, 519; 1899, ii, 291; Bettendorf, Abstr., 1890, 851).—According to Crookes' "one band one element" theory, praseodymium must contain 37 different elements, whereas according to von Scheele the substance is homogeneous. The authors themselves consider that the composite nature of praseodymium is probable, although not established, and that even if true the separation of the constituents, on account of the similarity in their chemical behaviour, presents an almost impossible task. Specimens of praseodymium from Bastnäs cerite and from Australian and Brazilian monazite have been compared with Shapleigh's preparations and no differences have been detected. The composite nature of neodymium is even still more in doubt, as, so far, pure neodymium has not been obtained; the product obtained by the sulphate method of separation contains 2 per cent. of praseodymium. A new separation by the aid of the chromates is quicker, and it is hoped will give better results.

Neodymium has the most complex absorption spectrum of all the earths, the number of bands in neutral chloride solution being 24. All these are not necessarily visible at the same time; in certain concentrated solutions, the six yellow bands become one, similarly for the green; on dilution, several groups disappear completely, particularly the narrow bands at the red end of the spectrum.

Numerous instances of change in the configuration of bands of the rare earths are known, but the causes have not been determined. A notable instance is found in the case of praseodymium; ordinary didymium gives the blue line λ 469 of praseodymium as a well-defined, not over broad, absorption band; when the earth is fractionated by Welsbach's

method, the line loses in intensity, broadens and moves towards the violet end of the spectrum; on further fractionation, the band becomes smaller and more intense, but even in the purest specimens is never so sharp as in the crude didymium.

Bunsen (*Annalen*, 1866, 123, 190) pointed out that the bands in the spectra of didymium salts vary considerably, according to the nature of the acid constituent. Further variations have been found in the case of both praseodymium and neodymium. Neodymium nitrate and chloride give different absorption spectra, especially in the green part of the spectrum; the nitrate in dilute nitric acid gives a single pale band about $\lambda = 522$, whereas in the chloride there are two bands, 525.5 and 521.5, and a pale band 520.5; the yellow bands in the chloride are sharper than in the nitrate.

Still greater differences are observed when the spectra of salts derived from carboxylic acids are examined. A solution of carbonate, probably containing the metal as the hydrogen carbonate, has not the characteristic dark red colour of the nitrate, but a fairly intense blue, due to the fact that the yellow absorption band has increased considerably in intensity, whilst the violet band λ 432—424 has completely disappeared; the green bands are more pronounced than in the nitrate, and all bands are some 7.5 λ nearer the red end of the spectrum, and, in addition, a new orange band, $\lambda = 600.5$, has made its appearance.

Somewhat similar differences have been observed in the case of praseodymium, not merely does the relative luminosity of the bands vary with different salts, but also the order in which the lines disappear on diluting the solutions.

It is obvious that the absorption spectrum is not simply dependent on the molecular weight of the anhydrous salt, as Bunsen suggested.

The authors have employed a spectroscopic method for the estimation of praseodymium and neodymium, although, according to Schottländer (*Ber.*, 1892, 25, 569), this method is inapplicable. The observations were made with a special Krüss apparatus, and in calculating the results, Vierordt's equation, $A = c / -\log J$, was employed, where A = constant, c = concentration, and J = intensity of light after passing through a 10 mm. layer of the solution when the original intensity of the light = 1.

In the following minerals—orthite from Miask, cerite from Riddarhyttan, and orthite (allanite) from Llano Co., Texas, it was found that the percentage of neodymium was practically twice that of praseodymium. J. J. S.

Radio-active Barium Salts and Polonium. By FRITZ GIESEL (*Ann. Phys. Chem.*, 1899, [ii], 69, 91—94).—The author has independently obtained from uranium ores other than pitchblende a substance, consisting chiefly of barium sulphate, which emits Becquerel rays. The substance is similar to that obtained by P. and S. Curie, according to whom it contains an active element radium.

Freshly crystallised barium salts containing radium are only slightly active, but in the course of a few days or weeks the activity increases to a maximum; the portions which crystallise first are more active than

those subsequently obtained from the mother liquor. The chloride, bromide, and iodide phosphoresce without any previous illumination, especially when anhydrous; in moist air, they gradually lose this property, but renewed heating restores it to them. The stronger the phosphorescence of any particular specimen, the feebler is the emission of Becquerel rays. Barium platino-cyanide, prepared from active barium chloride and potassium platino-cyanide, shows strong, spontaneous phosphorescence, which grows less intense as time goes on, the green colour of the double salt changing to yellow and finally to brown. By dissolving and crystallising the brown product, the green salt can again be obtained. The active constituent of the barium salts has not been isolated, and it seems impossible to effect a separation by fractional crystallisation alone.

Strongly active products containing polonium are also being investigated. Hydrogen sulphide produces in them a precipitate which surpasses in activity the best barium salt preparation. The chloride prepared from this sulphur compound is equally effective, as is also the metal deposited from the chloride solution by metallic zinc or an electric current.

The penetrating power of polonium rays is much less than that of radium rays, and consequently the shadow produced by a hard or metallic object is much sharper and deeper with the former than with the latter.

J. C. P.

A New Radio-active Substance. By A. DEBIERNE (*Compt. rend.*, 1899, 129, 593—595).—The constituents of pitchblende which are not precipitated by hydrogen sulphide from an acid solution, but are precipitated by ammonia or ammonium sulphide, include a small quantity of a substance which emits radiations capable of acting on a photographic plate, making barium platino-cyanide phosphorescent and accelerating the discharge of electrified bodies. Apart from its radio-activity, which seems to be about 100,000 times as great as that of uranium, it resembles titanium in general properties. It differs from radium in not being luminescent.

L. J. S.

Identity of Binnite with Tennantite : Composition of Fahlerz. By GEORGE T. PRIOR and LEONARD J. SPENCER (*Min. Mag.*, 1899, 12, 184—213).—The small, brilliant crystals of "binnite" are of rare occurrence in the white, saccharoidal dolomite of the Binnenthal in Switzerland. They are cubic and hexakistetrahedral, and the formula usually assigned to them is $3\text{Cu}_2\text{S}, 2\text{As}_2\text{S}_3$. It is now shown that they are crystallographically, physically and chemically identical with the less perfectly developed crystals of Cornish tennantite. Analysis I was made on eleven crystals (weighing 0.3101 gram), of which the streak is chestnut-brown; thin splinters are translucent and crimson by transmitted light. This analysis gives the formula $3\text{Cu}_2\text{S}, \text{As}_2\text{S}_3 = \text{Cu}_3\text{AsS}_3$. Analysis II is of crystals, of which the streak is black, and which, in thin splinters, are opaque; formula $[3(\text{Cu}, \text{Ag})_2\text{S}, \text{As}_2\text{S}_3] + \frac{1}{15}[6\text{FeS}, \text{As}_2\text{S}_3]$. The variation in the colour of the streak of the mineral depends on the amount of iron present.

Analyses I—V by G. T. Prior. In each case, detailed descriptions are given of the crystallographic and physical characters and of the associations of the material analysed.

	Cu.	Ag.	As.	Sb.	Bi.	Fe.	Zn.	Pb.	S.	Total.	Sp. gr.
I. 49.83	1.87	19.04	—	—	—	1.11	—	0.17	27.60	99.62	4.62
II. 44.12	4.77	[20.49]	—	—	—	3.68	—	—	26.94	100.00	4.598
III. 45.39	—	trace	28.85	—	—	1.32	—	0.11	24.48	100.15	4.921
IV. 41.55	—	trace	28.32	0.83	—	1.02	2.63	0.62	24.33	99.30	4.969
V. 30.56	15.26	trace	27.73	—	—	3.51	trace	0.05	23.15	100.26	5.047

The results of these analyses of "binnite," as well as the published analyses of Cornish tennantite, differ considerably from the figures required by the accepted formula for fahlerz (tetrahedrite and tennantite), namely, $4\text{R}''\text{S}, \text{R}'''\text{S}_3$, where $\text{R}'' = \text{Cu}, \text{Ag}, \text{Fe}, \text{Zn}$, and $\text{R}''' = \text{As}, \text{Sb}, \text{Bi}$. Very few of the published analyses of fahlerz agree with this formula, and minerals which have given the formula $3\text{R}''\text{S}, \text{R}'''\text{S}_3$, have often received new names. Three new analyses were therefore made of specially pure tetrahedrite crystals free from copper pyrites, blende and pyrites which are usually so intimately associated with fahlerz; the fracture of these crystals was smooth and conchoidal and with a brilliant lustre.

Analysis III is of material from a large crystal of octahedral habit from "Fresney d'Oisans, Dauphiné"; the streak is dark brown; after deducting the iron as pyrites, the formula is $3\text{Cu}_2\text{S}, \text{Sb}_2\text{S}_3 = \text{Cu}_3\text{SbS}_3$. Analysis IV is of the well-known brilliant crystals from Horhausen, in Rhenish Prussia; very thin flakes are crimson by transmitted light, and the streak is dark brown. Analysis V is of tetrahedral crystals, probably from Wolfach, Baden; the streak is black. IV and V give the formula $[3(\text{Cu}, \text{Ag})_2\text{S}, \text{Sb}_2\text{S}_3] + \frac{1}{10}[6(\text{Fe}, \text{Zn})\text{S}, \text{Sb}_2\text{S}_3]$.

These analyses suggest the new formula $3\text{R}'_2\text{S}, \text{R}'''\text{S}_2 + x[6\text{R}''\text{S}, \text{R}'''\text{S}_2]$, where $\text{R}' = \text{Cu}, \text{Ag}$; $\text{R}'' = \text{Fe}, \text{Zn}$; $\text{R}''' = \text{As}, \text{Sb}, \text{Bi}$; and x is a small fraction, often $= \frac{1}{10}$ and $\frac{1}{2}$, but rising to $\frac{1}{3}$ in the case of the highly ferriferous tetrahedrite "coppite." In this formula, the group $(\text{Fe}, \text{Zn})_6\text{S}_6$, and not $(\text{Fe}, \text{Zn})_3\text{S}_3$, is isomorphous with Cu_6S_6 . Only in those cases where iron and zinc are absent does the simple formula $3\text{R}'\text{S}, \text{R}'''\text{S}_2$ hold good.

Numerous previous analyses are discussed and found to agree with the new formula.

Melonite (?), Coloradoite (?), Petzite and Hessite. By WILLIAM F. HILLEBRAND (*Amer. J. Sci.*, 1899, [iv], 8, 295—298).—*Melonite*?—Impure material from the Melones mine, in the Mother Lode region, California, gave the results under I; after deducting a little hessite and tellurium, this gives the formula NiTe_2 . In colour and cleavage, the material agrees with Genth's melonite from the same locality; Genth, however, gave the formula Ni_3Te_3 .

Coloradoite?—One small specimen from the Norwegian mine in the same district showed dolomite, petzite, hessite, and a mercury telluride, which is probably coloradoite.

Petzite.—Analysis of pure material from the Norwegian mine gave II, agreeing with the formula $\text{Au}_2\text{Te}, 3\text{Ag}_2\text{Te}$.

Hessite.—Material from San Sebastian, Jalisco, Mexico, gave analysis III; sulphur, iron and zinc are also present.

	Te.	Ni.	Ag.	Au.	Se.	Mo.	Pb.	Total.	Sp. gr.

L. J. S.

Langbeinite from the Punjab Salt Range. By FREDERICK R. MALLEY (*Min. Mag.*, 1899, 12, 159—166).—A potassium magnesium sulphate occurring as a lenticular stratum in the 'kallar' (impure rock salt) of the Mayo mines, Punjab, India, was discovered and analysed in 1873. The material has now been more completely examined, and found to be the same as the cubic mineral langbeinite, $2\text{MgSO}_4, \text{K}_2\text{SO}_4$, recently described from the Prussian salt deposits (*Abstr.*, 1898, ii, 168).

The Indian mineral is associated with salt, sylvite and kieserite, and sometimes encloses these. It is colourless and transparent, and optically isotropic. Sp gr. 2.84; $H = 4$. The powder is slowly but completely soluble in water. Analysis gave:

K ₂ O.	MgO.	SO ₃ .	NaCl.	H ₂ O.	Total.
22.23	19.08	57.27	0.41	0.84	99.83

On exposure to the air, the powder absorbs water, and there is an increase in weight of nearly 57 per cent. ; the decomposition therefore takes place in accordance with the equation : $2\text{MgSO}_4, \text{K}_2\text{SO}_4$ (langbeinite) + $13\text{H}_2\text{O} = \text{K}_2\text{SO}_4, \text{MgSO}_4, 6\text{H}_2\text{O}$ (picromerite) + $\text{MgSO}_4, 7\text{H}_2\text{O}$ (epsomite).

Langbeinite, as isotropic octahedra, may be artificially produced by fusing together magnesium and potassium sulphates in the proper proportions.

L. J. S.

Formation of Oceanic Salt Deposits, particularly of the Stassfurt Beds. XIII. Evaporation of Sea Water at 25°. By JACOBUS H. VAN'T HOFF and W. MEYERHOFFER (*Chem. Centr.*, 1899, ii, 76 ; from *Sitzungsber. Akad. Wiss. Berlin*, 20, 372—383).—The most recent and trustworthy analyses of sea water show that on an average 1000 parts contain NaCl, 47 ; KCl, 1.03 ; MgCl_2 , 7.36 ; and MgSO_4 , 3.57. When sea water is evaporated at 25°, the salts separate out in the following order :—(1) NaCl ; (2) NaCl + $\text{MgSO}_4, 7\text{H}_2\text{O}$ and NaCl + $\text{MgSO}_4, 6\text{H}_2\text{O}$; (3a) NaCl + $\text{MgSO}_4, 6\text{H}_2\text{O}$ + KCl and NaCl + $\text{MgSO}_4, 5\text{H}_2\text{O}$ + KCl ; (3b) NaCl + $\text{MgSO}_4, 4\text{H}_2\text{O}$ + $\text{MgCl}_2, \text{KCl}, 6\text{H}_2\text{O}$; (4) NaCl + $\text{MgSO}_4, 4\text{H}_2\text{O}$ + $\text{MgCl}_2, \text{KCl}, 6\text{H}_2\text{O}$ + $\text{MgCl}_2, 6\text{H}_2\text{O}$, and in the following relative quantities :

	NaCl.	MgSO_4 .	KCl.	MgCl_2 .	$\text{KCl}, 6\text{H}_2\text{O}$.	MgCl_2 .
1.	94.5					
2.	2.39	1.63				
3a.	0.59	1.42	0.72			
3b.	0.50	0.22		1.27		
4.	0.02	0.30		0.07	6.02	

These quantities, however, are only obtained when the separate crystallisations are removed from the mother liquor.

E. W. W.

Pharmacosiderite. By ERNALD G. J. HARTLEY (*Min. Mag.*, 1899, 12, 152—158).—The formula of pharmacosiderite is uncertain ; it is based on an analysis by Berzelius (1824), and no analysis has since been made. The present analyses were made on selected green crystals from Cornwall ; sp. gr. 2.798. A green crystal placed in ammonia solution very soon becomes red throughout without alteration of the optical characters ; on placing such a red crystal in dilute hydrochloric acid, the green colour is restored to the whole crystal. Two preliminary analyses (I and II) show a deficit, which was afterwards found to be due to the presence of potassium. This element is present in all the Cornish specimens examined, but in variable amount (2.68 and 4.12 per cent. K_2O), and in two specimens from Hungary only traces were found. About 10 per cent. of water is lost at 100° ; at 130°, the crystals begin to turn brown and opaque, and about 14.18 per cent. is lost ($=5\text{H}_2\text{O}$ in the formula given below). A complete analysis made on another specimen is given under III.

	As_2O_5 .	P_2O_5 .	Fe_2O_3 .	K_2O .	H_2O .	Total.
I.	37.53	2.04	39.29	—	19.63	98.49
II.	36.85	2.06	38.61	—	[19.63]	97.35
III.	37.16	1.20	37.58	4.54	18.85	99.33

The ratios between the iron, arsenic acid and water are fairly constant, and give the formula

The potassium is assumed to replace hydrogen in the hydroxyl, and the formula is finally written as $2\text{FeAsO}_4, \text{Fe}[\text{O}(\text{H}, \text{K})]_3, 5\text{H}_2\text{O}$. L. J. S.

[Chabazite] from North Carolina. By JULIUS H. PRATT (*Jahrb. f. Min.*, 1899, i, Ref. 229—231; from *Jour. Elisha Mitchell Sci. Soc.*, 1897, 14, 61—83).—Analyses by C. Baskerville are given of the small crystals of chabazite associated with wellsite (Abstr., 1897, ii, 565) in the Buck Creek corundum mine, Clay Co., North Carolina. The simple and twinned rhombohedra occur on felspar, hornblende and corundum. The material for analysis was separated into two portions by means of a heavy liquid; anal. I on material of sp. gr. 2.147—2.203; II of sp. gr. 2.203—2.244.

	SiO ₂ .	Al ₂ O ₃ .	FeO.	CaO.	BaO.	MgO.	K ₂ O.	Na ₂ O.	H ₂ O.	Total.
I.	45.08	19.68	2.00	7.22	0.18	0.23	4.34	3.35	18.00	100.08
II.	46.15	20.74	2.00	6.92	0.24	0.22	4.10	3.35	16.30	100.02

This variation in composition and specific gravity supports Streng's hypothesis as to the composition of chabazite.

Other minerals from North Carolina, described in this paper, have already been noticed (Abstr., 1898, ii, 342, 606). L. J. S.

Constitution of Pectolite, Pyrophyllite, Hemimorphite and Analcite. By FRANK W. CLARKE and GEORGE STEIGER (*Amer. J. Sci.*, 1899, [iv], 8, 245—257).—In continuing the investigation of the constitution of natural silicates, special importance is attached to the two following reactions: (1), when talc is ignited there is a liberation of one-fourth of the silica (Abstr., 1890, 948); this suggests that other acid metasilicates may behave in a similar way; (2), dry ammonium chloride, at its temperature of dissociation, acts differently on different minerals (Abstr., 1892, 772).

Pectolite.—The material used in the experiments was from Bergen Hill, New Jersey; analysis gave the results under I, agreeing with the accepted formula $\text{HNaCa}_2\text{Si}_2\text{O}_6$. Only a small portion of the water is given off below a dull red heat. After igniting the mineral, sodium carbonate solution takes up 8.68 per cent. of silica, or one-sixth of the total amount. This, it is considered, indicates that the mineral is an acid metasilicate as expressed by the above formula. Before ignition, sodium carbonate solution, or even distilled water, has a slow, decomposing action on the mineral, both silica and bases being withdrawn; the action is, however, not one of simple solution.

Pyrophyllite.—The material used was from Deep River, North Carolina, and gave the results under II. The empirical formula, AlHSi_2O_6 , is apparently that of an acid metasilicate, but after ignition, only about 2 per cent. of silica is liberated. The formula is therefore written as $\text{OH} \cdot \text{Al} : \text{Si}_2\text{O}_5$, that is, as a basic salt of the acid $\text{H}_2\text{Si}_2\text{O}_5$. The mineral is very slightly attacked when heated with dry ammonium chloride.

Hemimorphite.—White material from Franklin, New Jersey, gave the results under III. The formula generally accepted represents the

mineral as a basic metasilicate, $\text{SiO}_3(\text{Zn}\cdot\text{OH})_2$. Here the hydrogen is all combined in one way, and so, too, is the zinc. In all other possible formulæ, the hydrogen, as well as the zinc, must be represented as present in at least two modes of combination. Several experiments were made with the idea of extracting a definite fraction of the zinc or water, but the results were negative and only tend to support the usual formula. Water and sodium carbonate solution have very little action either before or after ignition of the mineral. By heating with dry ammonium chloride, all the zinc is converted into zinc chloride.

Analcite.—Crystals from Wasson's Bluff in Nova Scotia gave analysis IV. The water is lost as follows :

Temperature.	100°.	180°.	260°.	300°.	Low redness.	Full redness.	Blast.	Total.
H ₂ O per cent.	0·58	1·16	3·64	1·57	1·90	0·11	nil	8·96

Before or after ignition very little silica is extracted by sodium carbonate solution. Heated at 350° with dry ammonium chloride, about half of the sodium is converted into chloride, and ammonia is retained ; this ammonia is not given off when the residue is warmed with caustic sodium solution. The composition of the residue, after extracting sodium chloride, is given under V, which agrees approximately with $\text{H}_2\text{Na}_2\text{Al}_4\text{Si}_8\text{O}_{24}\cdot\text{NH}_3$. This ammonia derivative suggests that the analcite formula should be quadrupled, namely, $\text{Na}_4\text{Al}_4\text{Si}_8\text{O}_{24}\cdot 4\text{H}_2\text{O}$. G. Friedel has previously shown that the water of analcite may be replaced by ammonia (Abstr., 1896, ii, 481).

An excess of silica over that required by the accepted analcite formula, $\text{NaAlSi}_2\text{O}_6\cdot\text{H}_2\text{O}$, is shown by analysis IV and by some previous analyses. This is explained by analcite being, not a metasilicate, but a mixture of ortho- and tri-silicate, the general formula being $\text{NaAlX}\cdot\text{H}_2\text{O}$, where $\text{X} = n\text{SiO}_4 + m\text{Si}_2\text{O}_8$. This explains the alteration of albite, $\text{NaAlSi}_3\text{O}_8$, and nephelite, NaAlSiO_4 , to analcite. For normal analcite, the formula is finally written as $\text{Al}_4\text{Na}_4(\text{SiO}_4)_2(\text{Si}_2\text{O}_8)_2\cdot 4\text{H}_2\text{O}$. This is written structurally to show the relation between analcite, leucite and the garnet-sodalite group.

L. J. S.

Analysis of Rocks. By ERNST A. WÜLFING (*Ber.*, 1899, 32, 2214—2224).—Analyses are given of four samples of Keuper marl from the neighbourhood of Tübingen ; some were made by the author, the others by Dittrich. The agreement is fairly close, except in the case of alumina and ferric and sodium oxides. The author separated the iron and aluminium by running the nearly neutral solution of the chlorides into excess of a boiling solution of caustic soda (made from the metal), and found more alumina and less ferric oxide than Dittrich, who fused the mixed oxides with pure caustic soda in a silver crucible ; the discrepancy in the sodium is unexplained.

Stress is laid upon the necessity that the reagents used in a rock-analysis, including the distilled water, should be pure. C. F. B.

Experimental Petrology. By K. BAUER (*Jahrb. f. Min.*, 1899, Beil. Bd. 12, 535—580).—In continuing the experiments of Doelter and Schmutz (*Abstr.*, 1897, ii, 54, 329) on the artificial production of rocks, the main object has been to test whether different rocks can be formed from the same magma. Powdered rocks—mica-schist, granite, diorite, phonolite, leucite-lava, nepheline-basalt and andesite, or mixtures having the same composition as these—were fused in a platinum crucible with various fluxes. The following will serve as an example of the several experiments made. A mixture consisting of mica schist, potassium fluoride, sodium fluoride, calcium fluoride, sodium tungstate and potassium tungstate was maintained in a fused condition at 1400° for two hours, in a plastic condition for seven hours, and allowed to cool slowly for five hours. Under the microscope, the product resembled a mica-andesite, and was seen to contain plagioclase, biotite, augite, magnetite, scapolite, nepheline and glass. The same mica-schist with other fluxes gave a product resembling a melilite-basalt. Using diorite with various fluxes, the products were quartz-basalt, andesite, melilite-basalt, mica-andesite and phonolite-pitchstone. Phonolite-pitchstone was also produced from mixtures having the compositions of granite and of phonolite. This is taken to indicate that different rocks may be formed from the same magma, and *vice versa*. [The chemical composition of the magmas have, however, been considerably modified by the large amount of fluxes used.]

Hornblende was formed in three of the fusions, whilst quartz was formed only once. L. J. S.

[**Mineral Analyses**]. By W. TARASSENKO (*Jahrb. f. Min.*, 1899, i, Ref., 458—475; from *Mem. Kieff Naturalists' Soc.* (Russian), 1896, 15, 1—347).—The following mineral analyses are given in a petrological paper on the gabbro and allied rocks in the districts of Radomysl, gov. Volhynia, and Shitomir, gov. Kieff, Russia.

Orthoclase (micropertthite) in a labradorite-rock from Poromowka, Shitomir district, gave anal. I; the material analysed contained spindle-shaped enclosures of plagioclase.

Labradorite from the same rock gave II and III; the former of sp. gr. 2.692—2.686; the latter of sp. gr. 2.686—2.677; this material also contained spindle-shaped enclosures, possibly of orthoclase.

Diallage in a labradorite-rock from Kamenny Brod, Radomysl district, gave IV (also MnO, trace; X, 0.15).

L. J. S.

Trap-rock of Rocky Hill, New Jersey. By ALEXANDER HAMILTON PHILLIPS (*Amer. J. Sci.*, 1899, [iv], 8, 267—285).—A dyke of dolerite in the Triassic strata at Rocky Hill, New Jersey, shows, in its width of half a mile, variations in chemical composition and in structure. Analysis I is of the microcrystalline rock at the margins; III is of the most coarsely crystalline material towards the centre of the dyke, and II is of an intermediate rock. Analyses are also given of material separated from the rocks by means of heavy solutions. IV and V are of the diallage from the rocks II and III respectively. VI and VII are of felspar (plagioclase) from the rock II, the former of sp. gr. >2.69, and the latter of sp. gr. <2.69. VIII and IX are of felspar, sp. gr. >2.69 and <2.69, from rock III; and X is of felspar (anorthoclase), of sp. gr. <2.60 from the same rock.

	SiO ₂	TiO ₂	Al ₂ O ₃	Fe ₂ O ₃	FeO	MnO	CaO	MgO	Na ₂ O	K ₂ O	P ₂ O ₅	H ₂ O	Total

L. J. S.

Analyses of Italian Volcanic Rocks. By HENRY S. WASHINGTON (*Amer. J. Sci.*, 1899, [iv], 8, 286—294).—Five analyses are given of trachytes from the Phlegrean Fields and from Ischia. L. J. S.

Meteoric Iron from Caperr, Patagonia. By LAZARUS FLETCHER (*Min. Mag.*, 1899, 12, 167—170).—This iron was known before 1869 in the neighbourhood of Caperr, Rio Senguerr, Patagonia. It weighs 114 kilograms, and measures 48 × 31 × 27 cm. The structure is octahedral, and the etched surface shows distinct Widmanstätten figures with kamacite, tænite and plessite. Schreibersite is embedded in the kamacite. No troilite or silicate was seen. Sp. gr. 7.837. Analysis gave:

Fe.	Ni.	Co.	P.	Cr.	Cu.	S.	Total.
89.87	9.33	0.53	0.24	trace	trace	nil.	99.97

In composition and structure, this iron resembles the Joel iron from Atacama. L. J. S.

Cliftonite and Tænite in the Youndegin Meteoric Iron. By LAZARUS FLETCHER (*Min. Mag.*, 1899, 12, 171—174).—Cliftonite is the name given by the author to cubic crystals of graphitic carbon obtained from the meteoric iron found in 1884 in the sub-district of Youndegin, Western Australia. From a fragment weighing 8.32 grams, three milligrams of cliftonite were isolated (Abstr., 1888, 30). More recently, a larger mass (97.25 grams) of the same iron was dissolved in dilute hydrochloric acid, but no cliftonite was seen. The cliftonite is there-

fore localised in one or more parts of the mass, and not uniformly distributed through it.

During the solution of the iron, thin, lustrous, black plates (total weight, 0.0870 gram) were set free; they appeared to be an alloy of nickel and iron belonging to the ténite group. After being kept for eleven years in a weighing tube, the material had increased in weight and altered in character owing to the formation of a layer of magnetic iron oxide on the surface. Sp. gr. 6.75. An analysis shows the material to be ténite, with the composition: Fe, 61.87; Ni(Co), 38.13. Phosphorus, copper and magnesium were also present in small amount.

L. J. S.

Fluorine in the Mineral Waters of Portugal and Spain. By ANTONIO J. FERREIRA DA SILVA and ALBERTO D'AGUIAR (*Bull. Soc. Chim.*, 1899, [iii], 21, 887—890. Compare Abstr., 1899, ii, 501, 602, 675).—The general question of the presence and detection of fluorine in mineral waters is discussed. The Campilho spring at Vidago has been found by one of the authors to contain fluorine equivalent to 0.000942 gram of sodium fluoride per litre, a result which may be compared with the corresponding figures for the Gerez spring (0.02288) and for the Spanish mineral waters of Lugo (0.0242) and Guitiriz (0.0234). According to Gil, the presence of fluorine in many alkaline and sulphurous waters has hitherto been overlooked, owing to the fact that the tests usually applied for this element depend on the formation of hydrogen fluoride, whereas, since silica or silicates are also commonly present, it is rather silicon fluoride which is produced and should be sought for.

N. L.

Physiological Chemistry.

Autodigestion of the Pancreas. By S. PFÖRRINGER (*Virchow's Archiv*, 1899, 158, 126—147).—Previous authors have called attention to the possibility of self-digestion being a cause of pancreatic cysts and necroses. Chiari (*Zeit. Heilk.*, 1896, 17), in particular, has directed attention to the fact that the pancreas is often found partially digested after death, and he considers that this may begin in the last hours of life. The present investigation confirms Chiari's views; it contains records of a hundred autopsies; the pancreas was examined microscopically, and evidence of digestive necrosis was found in forty-five, and this was very marked in eleven cases. The conditions of the patients (age, disease, &c.) appear to be as varied where such necrosis is found as in those cases where it is not found.

W. D. H.

Action of Arginine on the Tryptic Digestion of Proteid. By D. LAWROFF (*Zeit. physiol. Chem.*, 1899, 28, 303—306).—The presence of arginine is helpful to the tryptic digestion of proteid. This appears to be connected with its alkalinity; an equivalent amount of sodium carbonate acts similarly. Arginine, like sodium carbonate, aids the

emulsification of fats; excess of arginine, as of sodium carbonate, is harmful.
W. D. H.

The Fluorine in Tooth- and Bone-ash. By HEINRICH HARMS (*Zeit. Biol.*, 1899, 38, 487—498).—Fresenius' method with certain small modifications is well adapted for the detection of quite minimal quantities of fluorine. The amount of fluorine in bones and teeth as given by Carnot, T. Wilson, and Gabriel is much too great. The amount varies from 0.022 to 0.005 per cent. The variations in the amount of fluorine, as compared with the other constituents of the ash, which are fairly constant, show that the fluorine is not chemically combined with these, but is rather an accessory constituent; this view is confirmed by the presence in the bone of microscopic crystals of calcium fluoride.
W. D. H.

Composition of the Cartilage of the Shark. By GUSTAV VON BUNGE (*Zeit. physiol. Chem.*, 1899, 28, 300—302).—The cartilage removed from the fish *Scymnus borealis*, which had been packed in ice, gave the following analytical results: water, 92.8 per cent.; organic material, 5.9; inorganic material, 1.3.

Of the inorganic material, sodium and chlorine were the most abundant constituents; details are also given of the other inorganic constituents.

Petersen and Soxhlet (*J. pr. Chem.*, 1873, [ii], 7, 181) state that the fresh cartilage contains 16.7 per cent. of sodium chloride; their specimen, however, had been packed in salt.
W. D. H.

Substances present in the Liver which are converted into Sugar by Acids. By JOSEF SEEGEN (*Chem. Centr.*, 1899, ii, 58; from *Centr. Physiol.*, 13, 115—120. Compare *Abstr.*, 1898, i, 619).—After liver-extract has been heated with hydrochloric acid, more sugar is found than corresponds with the sugar and glycogen contained in the extract. The substance prepared from liver-extract by means of 90 per cent. alcohol contains nitrogen, reduces alkaline copper solutions, and, when heated with acids, yields a sugar with reducing properties, but the quantity so obtained is far too little to account for the excess of sugar formed from the extract by acid, hence the liver must contain yet another compound which is easily converted into sugar. The carbohydrate groups of the albumin are supposed to be affected by the action of the liver in such a way that they easily form sugar by the action of hydrochloric acid.

E. W. W.

Amount of Urea in the Liver. By RUDOLF GOTTLIEB (*Chem. Centr.*, 1899, i, 1298; from *Arch. exp. Path. Pharm.*, 42, 238—249).—See this vol., ii, 57.

Human Bile. By RICHARD VON ZEYNEK (*Chem. Centr.*, 1899, ii, 213—214; from *Wien. klin. Woch.*, 12, 568—569).—The quantity of bile secreted in a day amounts to 300—400 grams, containing 7—12 grams of solid matter; it is strongly alkaline, and has a sp. gr. 1.011—1.012. The bile pigments are completely precipitated by basic

lead acetate, but only partially by the normal salt; the bile acids, mucin, and the colouring matter are thrown down by saturating with ammonium sulphate. Only a slight precipitate is formed by supersaturating with magnesium sulphate. Hydrochloric or sulphuric acid gives an amorphous precipitate and the liquid becomes deep green and gradually deposits the bile acids. Bile gives a yellow coloration with alkalis; this is shown best by samples which have become of a greenish tinge by exposure to the air. The precipitate obtained by means of alcohol, when rubbed with glycerol, is capable of converting starch into sugar, but does not digest albumin. The bile secreted by the patient during each hour of a day was examined and found to be of a sp. gr. 1.011 and to contain in 1000 parts, 21.88 of solids, 2.39 of mucin, 13.8 of alkali salts of the bile acids, 8.96 of soluble salts, and 0.23 of insoluble salts. Another sample had a sp. gr. 1.012 and yielded 30.76 of solids, 2.087 of mucin, 18.31 of alkali salts of the bile acids, 0.78 of lecithin, 2.307 of cholesterol and fat, 9.10 of soluble salts, 0.31 of insoluble salts, 0.054 of ammonia and trimethylamine, and 2.087 of acid ethereal extract. On one day when 336.73 grams of bile were secreted, the solid residue amounted to 10.69 grams; the amounts of the former per hour varied from 2.01 to 30.25 grams, and of the latter from 0.054 to 0.99 gram. The ash is principally made up of sodium chloride, the insoluble portion containing traces of iron and copper.

By adding zinc chloride and excess of ammonia to a very dilute aqueous solution of bile, a green coloration is formed in $\frac{1}{2}$ —1 hour, and the liquid shows a characteristic band in the red part of the spectrum about 650 μ wave-length. Human urine containing bile pigments and bilirubin also give this reaction.

E. W. W.

Degradation of Caffeine in the Organism of the Dog. By MARTIN KRÜGER (*Ber.*, 1899, 32, 2818—2824).—On administering 50.5 grams of caffeine during a period of 20 days to a dog which was fed exclusively on flesh, there was found in the urine excreted during this period 7.4 grams of 4:6-dimethylxanthine (theophylline), 6.6 grams of unchanged caffeine, 4.61 grams of 4-methylxanthine, 1.9 grams of 1:4-dimethylxanthine (theobromine), and about the same quantity of 1:6-dimethylxanthine (paraxanthine)—per 100 grams of caffeine originally administered. For the method of separation adopted, the original paper should be consulted. The results obtained show that all three methyl groups of caffeine are attacked simultaneously, and that the group in position 1 offers least resistance to elimination; so that theophylline is the principal initial degradation product of caffeine, just as 4-methylxanthine is the principal product in the case of theobromine (Krüger and Schmidt, following abstract). The small quantity of theobromine obtained, taken in conjunction with Krüger and Schmidt's results, explains why heteroxanthine (1-methylxanthine) is not formed by the degradation of caffeine, and suggests that the 4-methylxanthine isolated owes its origin to theophylline rather than to theobromine. It is pointed out that theophylline and theobromine have hitherto never been isolated in the animal organism, but only from plant extracts.

W. A. D.

Decomposition of Theobromine, Paraxanthine, and 4-Methylxanthine in the Animal Organism. By MARTIN KRÜGER and PAUL SCHMIDT (*Ber.*, 1899, 32, 2677—2682. Compare Albanese, *Abstr.*, 1899, ii, 777).—Bondzynski and Gottlieb's experiments (*Abstr.*, 1895, i, 434) have been repeated. Theobromine, when introduced into the bodies of dogs or rabbits, is excreted in the urine partly in an unaltered condition, but mainly as 1- and 4-methylxanthine. Paraxanthine is converted in the body of rabbits into 6-methylxanthine, identical with that found in human urine. Neither 1-methylxanthine nor xanthine could be isolated.

Although theobromine is converted into 1-methylxanthine in the animal system, attempts to obtain xanthine from 4-methylxanthine were abortive.

The separation of the purine derivatives from urea was accomplished by precipitating them with sodium hydrogen sulphite and copper sulphate; the purine derivatives obtained from the copper precipitate were treated with manganese peroxide in dilute acetic acid solution in order to destroy uric acid (compare *Abstr.*, 1898, i, 699).

J. J. S.

Intestinal Absorption and Saline Cathartics. By GEORGE B. WALLACE and ARTHUR R. CUSHNY (*Pflüger's Archiv*, 1899, 77, 202—209. Compare *Abstr.*, 1898, ii, 442).—Höber (*ibid.*, 74, 346) describes the absorption of saline solutions in the small intestine as depending on purely physical factors. This theory is opposed to the results previously published by the authors; the present paper restates their views, and adds some further confirmatory experiments.

W. D. H.

Passage into the Urine of Chloroform administered by Inhalation. By DIOSCORIDE VITALI (*L'Orosi*, 1899, 22, 145—148).—From the results of tests made on the urine of four patients before and after the administration of chloroform, the conclusion is drawn that chloroform does not pass into the urine. The presence in the urine of organic chlorine compounds produced from the chloroform could not be detected.

T. H. P.

Excretion in Blood-free and in Fasting Frogs. By WACŁAW VON MORACZEWSKI (*Pflüger's Archiv*, 1899, 77, 290—310).—The excreta from a number of normal fasting frogs kept in a clean vessel were collected, and in them the nitrogen, phosphorus, chlorine, ammonia, potassium, sodium, calcium, and magnesium were estimated. The results are given in full and compared with what occurs in frogs whose blood had been replaced by an iso-osmotic solution of sodium chloride; in these animals, which often live a considerable time, the metabolic changes are slow as evidenced by the reduction in the various substances excreted and mentioned above. When sodium nitrate is used instead, the amount of nitrogen is high from the excretion of nitrates, but the amount of potassium and sodium is high also. Sodium acetate is more fatal. Sodium sulphate raises the excretion of nitrogen, but the other substances are diminished, as when sodium chloride is used.

If a urea solution is substituted for the blood, there is an increase in the excretion of nitrogen, and of some of the other substances also. If sugar solution is used, the frogs stand it exceedingly well; all excretion diminishes except that of calcium; this probably depends on the ready solubility of calcium phosphate in solutions of sugar.

Frogs can stand considerable dilution of their blood without interference with nitrogenous metabolism. W. D. H.

Fat of Normal and of Degenerated Heart Muscle. By W. LINDEMANN (*Zeit. Biol.*, 1899, 38, 405—418).—The question always arises in connection with fatty degeneration, whether the fat is produced from proteid in the cells, or whether it has been merely transported from other parts and stored there. The comparison of the heart-fat in cases of fatty degeneration, mostly from cases of anæmia, with that in normal hearts, and with that in other parts of the body, appears to support the former view. The following table summarises the results obtained: column 1 gives the acid number, column 2 the saponification number; column 3 the iodine number, and column 4 the Reichert-Meissl number.

	1.	2.	3.	4.
Degeneration fat	18.35	257.4	108.5	23.9
Normal heart fat	7.3	202.3	61.1	2.0
Kidney and subcutaneous fat ...	3.76	201.8	70.8	0.9

The degeneration fat, in its high saponification number and large percentage of volatile fatty acids, resembles butter fat and the fat in the so-called tears of marine mammalia. W. D. H.

[Physiological Action of] Acetonedicarboxylic Acid and Citric Acid. By LUIGI SABBATANI (*Chem. Centr.*, 1899, ii, 22—23; from *Atti Real. Accad. Torino*, 34).—Experiments on dogs and rabbits show that the stupefying effect of acetone is not shared by citric, acetonedicarboxylic, or acetoacetic acids, which are only injurious in large doses. When acetonedicarboxylic acid is administered to healthy animals, it is partly decomposed in the stomach with liberation of carbon dioxide, but only very small quantities of acetone or of unchanged acid are found in the urine. Citric acid, under similar conditions, does not yield ketonic acids, or at most traces which escape detection in the urine.

Acetone may be separated from acetoacetic acid, ethyl acetoacetate and acetonedicarboxylic acid by the following method. Insoluble bromine compounds, such as ethyl *αα*-dibromoacetate, pentabromoacetone, &c., are precipitated from the urine acidified with sulphuric acid by adding a slight excess of bromine water and allowing the mixture to remain 12 hours. The acetone itself is not attacked, and is distilled from the filtrate after removing the excess of bromine by means of powdered iron. Its amount is then determined by means of Lieben's method of conversion into iodoform. The amount of acetone, together with that derived from the ketonic acids, is similarly estimated in the liquid obtained by directly distilling a second portion of the acidified urine. Acetoacetic acid cannot be separated from ethyl acetoacetate, or acetonedicarboxylic acid by this method. E. W. W.

Chemistry of Vegetable Physiology and Agriculture.

[Effect of Mineral and Nitrogenous Nutritive Matters on the Fermenting Capacity of Yeasts.] By R. KUSSEKOW (*Bied. Centr.*, 1899, 28, 630—632; from *Brenneri-Zeit.*, 1897, 14, Nos. 318—320; and *Centr. Bakt. Parasit.*, 1898, 4, ii, 154).—Addition of superphosphate, potassium phosphate, and magnesium sulphate increases the productive power of yeast in bad mash-material. Yeast distilleries should employ lower mash temperatures, to avoid separation of proteids with phosphates; in thick mash distilleries, the temperatures should be higher in order to separate froth-producing proteids, and to convert peptones and albumoses, as far as possible, into amides.

N. H. J. M.

Yeast. By CARL BÖTTINGER (*Chem. Zeit.*, 1899, 23, 313 and 645).—Solutions of grape sugar (5—6 per cent.) to which yeast was added were treated with lime (0.25 to 2 per cent.), with copper sulphate (0.17—1 per cent.), and with both substances together. In every case, there was a partial or complete destruction of the sugar in a few days, either with or without evolution of gas. With glycollic acid (0.33 per cent.) all the sugar fermented with abundant liberation of carbon dioxide. With glyoxylic acid, the production of carbon dioxide was only slight and soon ceased; further addition of yeast induced renewed liberation of gas, and in 30 days nearly half of the sugar was recovered; oxalic acid was found to be present. Pyruvic acid acts similarly to, but less energetically than, glyoxylic acid, and gives rise to an intense odour of *Lotus*. Further experiments were made with paraldehyde, acetone, acetic acid, benzaldehyde, tartaric, citric, and oxalic acids.

As regards the effect of sugar on the fermentation of grape juice, it was found that addition of 10 per cent. of grape sugar delayed the production of mould. In both cases, evolution of gas was very limited, and on distilling on the 20th day, there was only enough alcohol produced, both with and without sugar, to allow of detection by the iodoform test. The effect of sugar was rather physical than chemical.

N. H. J. M.

A Sugar Bacterium. By H. MARSHALL WARD and JOSEPH REYNOLDS GREEN (*Proc. Roy. Soc.*, 1899, 65, 65—84).—The bacterium occurs along with at least one yeast in a mixture of organisms said to have come from Madagascar, where it occurs as an "excrecence on the sugar cane." The clumps induce vigorous fermentation in sugar solutions (15—20 per cent.), liberating relatively enormous amounts of carbon dioxide and some acid; oxygen is not necessary in any quantity.

The bacterium will practically only grow in presence of sugar, and only certain sugars are suitable: sucrose (after undergoing inversion) is far the best, levulose is utilised to a slight extent, and dextrose is not a favourable medium. Dextrin, maltodextrin, maltose, lactose,

and soluble starch are all unsuitable or useless. Negative results were also obtained with glycerol and yeast extract, starch treated with diastase, potato, carrot, and milk.

In order to throw some light on the rôle of the bacterium and the yeasts respectively in the fermentation produced by the mixed organisms, a number of experiments were made in which different solutions (such as sucrose, a mixture of sucrose and lævulose, dextrose, &c.) were sown with pure cultures of (1) the yeast, (2) the bacterium, (3) the yeast and bacterium separately, and (4) the yeast and bacterium as ordinarily associated. It was found that production of alcohol was due to the yeast alone, the bacterium being without influence. The acid (acetic and succinic) was produced mainly by the bacterium; of the two acids relatively more acetic acid was produced by the bacterium than succinic acid. In sucrose, and in dark brown sugar containing lævulose, the conjoint organism produced less acids than the bacterium alone, whilst in dextrose the contrary was the case.

The presence of the bacterium is of no advantage, but rather disadvantageous to the yeast, whilst the yeast is of use to the bacterium in excreting nitrogenous food. The bacterium does not affect alcohol like ordinary acetifying organisms, and seems to act directly on the sugar with production of acid, the immediate antecedent of which is probably lævulose.

In sucrose, the bacterium produces a viscous material containing two carbohydrates in many respects similar to, but not quite identical with, Scheibler's dextran.

Permanent Forms of Nitric and Nitrous Organisms. By ALFRED BEDDIES (*Chem. Zeit.*, 1899, 23, 645—647).—Sterilised solutions containing the nutritive substances present in manure heaps, the percentage of nitrogen being raised to 3 per cent. by the addition of ammonium sulphate, in which the alkalinity was made suitable by the addition of sodium carbonate or of phosphoric acid, were inoculated with soil. After being kept for several weeks in diffused light at 20—25°, the cultures in which nitrification was complete were employed for inoculating a fresh nutritive substance containing 1 per cent. of a strong solution of humus and 0.25 per cent. of sodium silicate.

Cultivations of nitrifying organisms prepared in this manner proved to be much less sensitive than those obtained by Winogradsky in absence of organic matter. Four stable varieties of nitric and three varieties of nitrous bacteria were isolated. The strongest form of the nitric bacterium resisted the action of steam at 100° for 2 minutes; and one form of nitrous bacterium lived for 1 minute in steam at 100°. Nitric and nitrous bacteria can be cultivated together and do not interfere with each other, and an inoculating material was prepared by drying previously sterilised calcareous soil to which both forms had been added.

Pot experiments are described in which grasses and cereals were grown in sterilised sand to which sterilised humus, ammonium sulphate, and minerals were added, with and without the addition of the inoculating material. With inoculation, the growth was stronger and more luxuriant.

Evidence was obtained that, in presence of an abundance of nitrifying organisms, denitrification is hindered and there is no loss of free nitrogen. When, however, denitrifying organisms predominate, the nitrifying bacteria are injured, especially if aëration is limited.

Germination of the Carob Bean (*Ceratonia Siliqua*): Production of Mannose by a Soluble Ferment. By ÉMILE BOURQUELOT and HENRI HÉRISSEY (*Compt. rend.*, 1899, 129, 614—616).—In the germination of the carob bean, a soluble ferment is produced which acts on the albumin in the seed and produces from it mannose and galactose. Since saliva does not act on this albumin, it follows that the ferment in question is distinct from diastase. This is the first instance of the production of mannose by a soluble ferment (compare *Abstr.*, 1899, i, 839, 968).

C. H. B.

Action of Anæsthetic Vapours on the Vitality of Dry and Moist Seeds. By HENRI COUPIN (*Compt. rend.*, 1899, 129, 561—562).—The germinating power of the seeds of wheat and clover is not in the least affected by exposure, in the dry state, to the saturated vapour of ether or chloroform for 680 hours. These liquids may therefore be safely used for the destruction of insects in grain, and are to be preferred to carbon disulphide, which has an injurious action on some seeds, such as wheat. Experiments with white lupin, purple clover, hairy spring vetch, buckwheat, wheat, barley, maize, and hemp show that moist seeds are much more susceptible to the action of anæsthetics. In an atmosphere containing 1 c.c. of ether per 10 litres, germination takes place as usual; with a larger quantity of ether, growth is more or less retarded, purple clover being the most resistant of the seeds examined, and with 3.7 c.c. of ether per 10 litres all the seeds are killed, and will not germinate even when removed from the action of the ether and washed well with water.

N. L.

Absorption of Water and Dissolved Substances by the Stems of Plants. By ÉMILE BRÉAL (*Ann. Agron.*, 1899, 25, 449—458).—The absorption of different substances by plants was effected by inserting in the stems glass tubes drawn out to a suitable size, containing the solutions.

Whilst nitrates can accumulate in plants, it was found that ammonium salts, although absorbed, are soon converted into other substances. Nitrates accumulated abundantly in the stems, but could not be detected in the roots. Potassium humate was absorbed by lupins, and was afterwards visible when the stems were cut open. In the case of maize, it was observed that absorption of potassium humate resulted in the destruction of the nitrates present. Potassium humate, in conjunction with ammonium phosphate, diminished the amount of nitrate in amaranth without causing its entire disappearance; in the case of lupins, all the pre-existing nitrate disappeared.

N. H. J. M.

Food-stuffs of the Leaves of the Plane-tree and their Migration during the Growth and Decay of the Leaves. By G. M. TUCKER and BERNHARD TOLLENS (*Ber.*, 1899, 32, 2575—2583).—The leaves examined were picked at intervals during the summer; 500

being taken on each occasion; to obtain comparable results, only the two oldest leaves on any one twig were selected. After weighing and measuring the surface of an average sample, the leaves were dried, burnt, and the ash analysed, the constituents determined being SiO_2 , $\text{Fe}_2\text{O}_3 + \text{Al}_2\text{O}_3$, CaO , MgO , P_2O_5 , SO_3 , K_2O , Na_2O , Cl , and N .

The results show that the weight and also the amount of ash of the leaves increased until the leaves died, and then slightly decreased. The amounts of silica and lime show a similar behaviour, but the chlorine and sulphuric acid show a continuous increase, leaves plucked in November containing three times as much sulphuric acid as those plucked in June. Those constituents regarded as the more important food-stuffs show a quite different behaviour; the phosphoric acid and the potash increase very slightly until the leaves die, after which they diminish to less than half their original amounts. The amount of nitrogen steadily falls, having at the end a value less than one-fourth of the initial value.

Young leaves gathered in November show the presence of large quantities of potash, phosphoric acid, and nitrogen, the amounts of which are sufficient to account for the loss in these constituents suffered by the older leaves after death; any backward motion of these food-stuffs from the leaves to the stem or wood of the twigs the authors regard as of small amount.

Comparative experiments with leaves protected from rain and others non-protected show that rain has little, if any, washing-out action on the food stuffs of the leaves.

T. H. P.

The Replacement of Potassium Salts by Rubidium Salts in Lower Fungi. By OSCAR LOEW (*Bied Centr.*, 1899, 28, 646—647; from *Bot. Centr.*, 1898, 74, 202—205).—Whilst the author has shown that rubidium can take the place of potassium in putrefaction bacteria, yeast, and *Penicillium*, the results of Günther's experiments indicate that such substitution can take place to some extent in *Botrytis cinerea*, but not in *Rhizopus nigricans*. The experiments now described confirm Günther's observation that differences exist in the case of various fungi as regards the power of utilising rubidium.

Bacillus coli develops equally well in the presence of rubidium and of potassium; *B. pyocyaneus* grows twice as quickly in the presence of potassium as with rubidium. *Cladothrix* failed to develop in the presence of rubidium, whilst a moderate growth was obtained with potassium (the organic food was 1 per cent. dextrose and 0.5 per cent. sodium acetate).

N. H. J. M.

Yellow Colouring Matters accompanying Chlorophyll and their Spectroscopic Relations. By C. A. SCHUNCK (*Proc. Roy. Soc.*, 1899, 65, 177—186. Compare Abstr., 1899, ii, 540).—Alcoholic extracts of healthy green leaves contain two yellow colouring matters: (1) chrysophyll which separates in lustrous, red crystals, usually in minute quantities, and (2) an amorphous substance to which the author would restrict the name xanthophyll. This is obtained by spontaneous evaporation of the solution, after removing the chlorophyll by means of animal charcoal, and is impregnated with much

fatty matter. Another yellow colouring matter sometimes occurs with the xanthophyll; this gives no absorption bands, but only an obscuration in the violet and ultra-violet portion of the spectrum. Other yellow colouring matters may exist, but xanthophyll seems to predominate, and is also the principal yellow colouring matter of autumn leaves.

The absorption spectrum of chrysophyll consists of three bands, that of xanthophyll of four bands, in the violet and ultra-violet portions. The author concludes that the spectrum of crude chlorophyll (four bands in the less refrangible region and three in the violet) are due to chlorophyll alone, and not, as usually supposed, in part to the accompanying yellow colouring matters. Phyllocyanin and phylloxanthin have bands in positions identical with the three chlorophyll bands in the violet part of the spectrum. N. H. J. M.

Wheat. By GEORGE B. FRANKFORDER and E. P. HARDING (*J. Amer. Chem. Soc.*, 1899, 21, 758—769).—The germ of wheat was found to contain on the average 11.6 per cent. of oil. The sp. gr. of the oil is 0.9292 at 15° and 0.9374 at 0°. At 0°, the oil is a cloudy semi-solid, at 15° it is milky, and at 100° it becomes reddish-brown. When dried at the ordinary temperature, it increases slightly in weight during the first 45 days, and loses rather more during the next 30 days. The index of refraction of the oil when purified is 1.48325, 1.47936, and 1.47447 at 20°, 30°, and 40° respectively. As regards solubility, 1 gram of the oil dissolves in 1 c.c. of ether, 1 c.c. of chloroform, 30 c.c. of absolute alcohol, or 250 c.c. of 90 per cent. alcohol. The saponification value, according to Köttstorfer's method, is 188.83 mg. of KOH to 1 gram of oil. Iodine number (Hübl) 115.64. Acid value, 40.7. Five determinations of glycerol gave an average percentage of 7.35. The oil contains 2.0 per cent. of lecithin and 2.47 (mean of 5 analyses) of paracholesterol. The elaidin method gave 1.8 and 2.2 per cent. of paracholesterol. N. H. J. M.

Constituents of Chicory. By JULES WOLFF (*Chem. Centr.*, 1899, ii, 211—212; from *Ann. chim. anal. appl.*, 4, 157—162, 187—193).—The root of *Cichorium Intybus* contains inulin, $6C_6H_{10}O_5 + H_2O$, but no starch. The inulin obtained from the aqueous extract of the root by precipitating with 90 per cent. alcohol has a specific rotatory power $[\alpha]_D - 36.57^\circ$ (Lescœur and Morelle) and does not reduce Fehling's solution. It is completely inverted by boiling for 20 minutes with 5 c.c. of hydrochloric acid, and the levulose formed may be estimated by reduction or polarimetrically. An optically inactive sugar, *levulin* or *synanthrose*, which does not reduce Fehling's solution, is also present, and is decomposed by hydrochloric acid into dextrose and levulose. Chicory only contains a very small quantity of a sugar which reduces Fehling's solution directly, and this is probably levulose derived from the inulin. The sugars are practically unchanged by drying the root, but by roasting, the quantity of reducing sugars which consist mainly of levulose with some dextrose is increased, a large portion of the inulin is changed, and caramel and dextrin are formed.

The inulin contained in chicory may possibly be of use as a food in

cases of diabetes. The fresh root contains about 13—15 per cent. and commercial chicory from about 11—16 per cent. of inulin. Analyses of the fresh root, the dried material, and samples of commercial chicory are quoted.

E. W. W.

Constituents of Flores Kosso. By IWAN L. KONDAKOFF (*Arch. Pharm.*, 1899, 237, 481—493).—An historical account of previous investigations, serving as an introduction to the following abstract (compare especially, Flückiger and Buri, *Abstr.*, 1875, 468; Levin, *Diss.*, St. Petersburg, 1892; Leichsenring, *Abstr.*, 1894, i, 424; Dacomo and Malagnini, *Abstr.*, 1899, i, 158).

C. F. B.

Kossin or Taeniin of Pavesi and Vée. By IWAN L. KONDAKOFF and N. SCHATZ (*Arch. Pharm.*, 1899, 237, 493—507).—*Flores Kosso*, the female flowers of *Hagenia abyssinica*, are used as a vermifuge; the sample examined contained moisture 10.5 and ash 10.3 per cent. The flowers were treated with lime, 90 per cent. alcohol, and water, after the method of Pavesi (*Journ. Pharm. d'Amers*, 1858, 472) and Vée (*Neuss Rep. Pharm.*, 8, 325); the alcohol was distilled off from the extract, and the residue decomposed with acetic acid, when kossin separated. When a solution of kossin in cold acetic acid or in alcohol is allowed to remain, crystals of kossin separate. If a solution of kossin in caustic alkalis is acidified with phosphoric acid, or a solution in baryta water decomposed with carbon dioxide, an amorphous variety of kossin, melting at 142°, separates; probably kossin contains a good deal of this.

The ethereal extract of another sample of the flowers contained (a) an amorphous substance mixed with (b) another substance, which was insoluble in cold alcohol, and formed crystals melting at 63°, (c) an amorphous substance, characterised by acid and reducing properties, and melting at 155—157°; (d) a wax-like substance, melting at 55°; (e) a resinous substance, and (f) kosotoxin. The latter amounted to 6 per cent. of the dry extract (which itself formed 4.7 per cent. of the drug). As regards kosotoxin, Leichsenring's results were not entirely confirmed; the melting point is 76°; the molecular formula, as determined by analysis and cryoscopically, is $C_{25}H_{32}O_9$, and the acid formed, in addition to kossin, when kosotoxin is boiled with 5 per cent. aqueous barium hydroxide, is not wholly a butyric acid, but contains another acid (valeric?) admixed.

The residue left after extraction of the flowers with ether yielded to alcohol an amorphous tannin, the amorphous substance (a), kosotoxin, and other substances which were not separated.

C. F. B.

Detection of Sulphur Dioxide in the Atmosphere of the Tharandt Forest. By HANS WISLIGENUS (*Bied. Centr.*, 1899, 29, 643—644; from *Tharandt forst. Jahrb.*, 1898, 173—184).—Experiments made by the Ost process from May to October in different parts of the forest, at a distance of 10 kilometres from any source of smoke, showed the presence of sulphur dioxide inside the forest, although in less quantity than at the edges. The results of previous experiments indicate, however, that in consequence of the limited amount of light in the forest the sulphurous acid is comparatively harmless.

N. H. J. M.

Maize as Food in Servia. By ALEXANDER ZEGA and R. MAJSTOROVIĆ (*Chem. Zeit.*, 1899, 23, 544—545).—Maize is the most important food in Servia, and in some districts nothing else is used. Besides boiled and roasted maize, different kinds of bread (including "famine bread," an inferior kind in which carrots, nettles, &c., are employed as well as maize), cakes, and other kinds of food, and a beverage, prepared from maize meal and wheat bran, are described. Maize meal (1) yellow, and (2) white, has the following composition :

	Water.	Nitrog. subst.	Fat.	Carbo- hydrates.	Sugar.	Crude fibre.	Ash.	P ₂ O ₅ .
1.	12.69	10.11	4.23	67.44	2.70	1.43	1.40	0.74
2.	13.36	9.56	4.84	66.36	2.68	1.72	1.48	0.68

The composition of the various foods is given.

N. H. J. M.

Determination of the Action of some new Foods on the Secretion of Milk, with Special Reference to the Amount of Fat in the Rations formed with these Foods. By EBERHARD RAMM and W. MINTROP (*Bied. Centr.*, 1899, 28, 614—616; from *Milchzeit.*, 1898, No. 33).—The following conclusions are drawn from the results of the feeding experiments. A high percentage of fat in food does not result in higher percentage of fat in milk, but the different concentrated foods, in rations differing very little in composition, produced considerable variations in the percentage of fat in the milk (2.327—3.437).

As regards the various foods, it was found that cocoa-molasses (cocoa-husk meal mixed with molasses) was consumed in large amounts and, in conjunction with oil-cake rich in proteids, increased the yield of butter-fat above the average. Maize bran had no injurious effect on the health of the cows, even when consumed in large quantities. Blood molasses (blood, molasses, and offal of cereals) in quantities of 6—8 kilos. was not injurious, was in every respect favourable to milk secretion, and is a very valuable food for cows.

N. H. J. M.

Value of various Concentrated Foods. By WALDEMAR VON KNIERIM (*Bied. Centr.*, 1899, 28, 616—618; from *Landw. Jahrb.*, 1898, Heft. 3 and 4).—The constituents of cocoa-nut cake show, according to results obtained with rabbits, the following percentage digestibility: crude protein, 95.7; crude fat, 99.1; crude fibre, 89.1; non-nitrogenous substance, 95.2. With a ram, the results were very similar (except in the case of crude fibre) to those obtained by Kühn with bullocks. The cake is one of the best concentrated foods. Hemp cake causes indigestion with rabbits as well as with sheep and horses; it can, however, be given to cows in conjunction with considerable amounts of roots, potatoes, malt-germs, or brewers' grains, and is of importance in the feeding of young cattle. Sunflower cake gave lower results with rabbits than those given by Wolff, which were obtained with sheep. Rape cake in small quantities favours the digestion of non-nitrogenous constituents; in the case of cows, it must be employed with care to avoid indigestion, especially when the cake develops mustard oil. Palm cake resembles cocoa-nut cake and is chiefly useful in promoting milk production.

N. H. J. M.

In Feeding with Sesamé Cake, do Substances which give the Baudouin Reaction appear in the Butter? By H. WEIGMANN (*Bied. Centr.*, 1899, 28, 629—630; from *Milchzeit.*, 1898, 529).—Experiments with cows in which sesamé cake was given in increasing quantity (up to 3 kilos. per day) showed that the butter was quite free from sesamé oil.

In examining butter for sesamé oil, it is important to employ only 0·1 c.c. of 1 per cent. furfuraldehyde solution; with 1 per cent. sesamé oil or 10 per cent. margarine, the coloration appears at once, whilst any other coloration can only appear in the course of about half an hour. The results obtained by Scheibe (*Milchzeit.*, 1897, 745) and Siegfeld (*Bied. Centr.*, 1899, 28, 415), which are opposed to those just described, are attributed to the employment of unsuitable amounts of furfuraldehyde, and to the correct conditions as to time and temperature not having been observed. N. H. J. M.

Alkali Soil in Montana. By FRANK W. TRAPHAGEN and W. M. COBLEIGH (*J. Amer. Chem. Soc.*, 1899, 21, 753—757).—The bare patches of soil incrustated with white, red, or yellow salt which occur in Montana, and are known as "alkali" soils, are of two kinds, the "white," consisting mainly of sodium sulphate, and the "black," of sodium carbonate. The appearance of the latter is due to the solvent action of the carbonate on humus which, on evaporation, is left as a shiny black coating on the surface. As little as 0·1 per cent. of sodium carbonate at the surface is deleterious, whilst crops will thrive in the presence of as much as 0·6 per cent. of "white alkali." Larger quantities of white alkali are injurious rather by interference with the process of osmosis than through any chemical action.

Analyses of different soils and crusts are given, showing that the amounts of soluble salts differ widely; there is, however, a very constant relation of the amounts of different salts in the extracts. In virgin soils, the alkali occurs at considerable depths, and is mostly concentrated in a particular zone. Under the influence of irrigation, the salts rise to the surface. The best remedy would seem to be under-drainage, but, in the case of land of insufficient value, much can be done by careful surface flooding and suitable cropping.

N. H. J. M.

Distribution and Biological Importance of Furfuroids in Soil. By JULIUS STOKLASA (*Bied. Centr.*, 1899, 28, 588—589; from *Zeit. landw. Versuchswesen Oesterr.*, 1898, 1, 251—266. Compare Abstr., 1898, ii, 132).—The furfuroids in soil are produced by algæ and bacteria. The dry substance of *Pleurococcus vulgaris*, which grows on rocks, contains 3·43, that of *Nostoc*, 5·06 per cent. of pentosans. Cultures of *Bacillus mesentericus*, which is very common in soils, contained 2·31 per cent. of pentosans in the dry substance. *Parmelia*, *Lecanora*, *Hypnum Schreberi* and *H. dicranum*, and *Sphagnum cymbifolium* contain respectively 3·46, 3·43, 6·19, 10·78, and 15·44 per cent. of pentosans. Other plants of importance in peat production were found to contain the following amounts of pentosans: *Pteris aquilina*, 18·8; *Aspidium*, 19·1; *Equisetum arvense*, 33·5 and 21·1; *Lycopodium*, 24·6; *Carex acuta*, 19·6 in above-ground growth

and 26.5 in roots; *Calluna vulgaris*, 17.3 and 23.2 per cent. in above-ground growth and roots respectively.

Peat was found to contain 17.4 per cent. of pentosans in the first 10 cm., 10.38 per cent. at a depth of 50 cm., 5.34 per cent. at 100 cm., and 1.60 per cent. at a depth of 2 metres. The surface soil of forest land yielded 3.27, the soil at a depth of 50 cm. 0.83 per cent. of furfuraldehyde.

N. H. J. M.

Observations on the Growth of Maize continuously for Nine Years. By EDWARD H. JENKINS (*Ann. Rep. Conn. Agric. Exper. Stat.* for 1896, No. 20, 335—341).—The four plots received: (1) cow manure, (2) hog manure, (3) chemical manures, and (4) no manure. The average relative yield of dry produce from 1890—1896 was as follows: plot 1, 100; plot 2, 100.4; plot 3, 81.8; and plot 4, 51.0. Taking the produce of each plot as 100 in 1890, the following amounts were obtained in 1896. (1), 116; (2), 101; (3), 79; (4), 31.

The average composition (6 years) of the kernels and stalks was practically the same in the case of plots 1 and 2. In plot 3 (1,500 lbs. of chemical manure), the kernels contain rather less ash and fat, and 0.5 per cent. less proteids than those of plots 1 and 2, but more nitrogen-free extract. The stalks show similar differences. The kernels of the unmanured plot contain 2 per cent. less proteids, rather less ash and fat, but more fibre and nitrogen-free extract than those of plots 1 and 2.

The calculated gain or loss of manure constituents in the soil after 9 years cropping with maize was as follows in lbs. per acre:

Plot 1.			Plot 2.			Plot 3.			Plot 4.		
N	P ₂ O ₅	K ₂ O	N	P ₂ O ₅	K ₂ O	N	P ₂ O ₅	K ₂ O	N	P ₂ O ₅	K ₂ O
+1283	+898	+156	+2174	+3987	-7	+611	+1111	+171	-388	+46	-78

N. H. J. M.

Manurial Experiments with Barley. By JOSEPH HANAMANN (*Bisd. Centr.*, 1899, 28, 638; from *Zeit. landw. Versuchswesen Oesterr.*, 1898, 1, 277—285).—The experiments were conducted in zinc vessels containing 12.5 kilograms of sandy soil, loamy sand, loam, and clay soil respectively (five pots in each case). One pot of each soil was without manure, whilst pots 2—4 received sodium nitrate and potassium chloride. The third pots had in addition superphosphate, the fourth pots basic slag (containing the same amount of phosphate as was given to No. 3), the fifth pots basic slag in double quantity.

The results indicate that spring manuring with basic slag is only advisable in the case of sandy soil, loamy sand, and peaty soil, but not in the case of loamy and clay soils, and the amount applied should be twice as great as that of superphosphate.

N. H. J. M.

Manurial Experiments with Lucerne. By MAX MAERCKER (*Bisd. Centr.*, 1899, 28, 635; from *Landw. Jahrb.*, 1898, 27, 155).—It is thought that liberal application of phosphates will not only increase the yield of lucerne, but will be of use in preventing the injurious effects of lucerne on a succeeding cereal crop (liability to be laid, fungus attack, &c.).

N. H. J. M.

Experiments on the Availability of Fertiliser-Nitrogen. By SAMUEL W. JOHNSON, EDWARD H. JENKINS, and W. E. BRITTON (*Ann. Rep. Conn. Agric. Exper. Stat.* for 1896, No. 20, 178—204. Compare *ibid.*, No. 19, and Abstr., 1896, ii, 620).—The nitrogen availability of the different manures for maize grown in coal-ashes and peat, compared with that of sodium nitrate as 100, was found to be as follows (average of three years, 1894—6): collier castor pomace, 77; cotton seed meal, 74; red seal castor pomace, 70; linseed meal, 70; dried blood, 68; dry fish, 69; dissolved leather, 65; horn and hoof, 67; tankage, 61; steamed leather, 13; roasted leather, 9; raw leather, 2.

On comparing the nitrogen availability of some nitrogenous superphosphates, determined by vegetation experiments, with the solubility in chemical agents, the following results were obtained:

	Available for maize.	Soluble in pepsin.	Soluble in permanganate. Acid.	Alkaline.
Blood	47	47	47	47
Tankage	45	39	45	43
Horn and hoof ...	43	28	42	52
Leather	3	8	14	25

The chemical methods would therefore seem to be of value as indicating the probable relative effect of inferior nitrogenous manures. The agricultural value cannot, however, at present be fixed without vegetation experiments.
N. H. J. M.

Manurial Experiment on Meadow Land. By MAX MAERCKER (*Bied. Centr.*, 1899, 28, 637; from *Landw. Jahrb.*, 1898, 27, 151).—The effect of potassium phosphate and of kainite was to increase the percentage of proteids in the hay owing, as a botanical separation of the herbage showed, to increased growth of more nitrogenous plants, especially *Leguminosæ*.
N. H. J. M.

Field Experiments on Peat Land, 1892—1897. By BRUNO TACKE (*Bied. Centr.*, 1899, 28, 589—611; from *Landw. Jahrb.*, 1898, 27, iv, 1—258. Compare Abstr., 1897, ii, 515).—Manure salts containing 38 per cent. of potash as potassium chloride gave very good results with potatoes, and had practically no injurious effect when applied in the spring in amounts of as much as 200 kilos. of potash per hectare. Carnallite and kainite (225 kilos.) applied in the spring considerably diminished both the yield of tubers and the amount of starch; in some cases there is a decrease of starch in the dry matter, in others the lower percentage of starch in the tubers is due to an increase in the amount of water. Application of lime seems to lessen the injurious effect of spring manuring with potash on potatoes.

Application of lime or marl to the soil for all kinds of crops is very beneficial for a time, and is even necessary when artificial manures are employed, but is subsequently injurious owing to the shrinking of the comparatively shallow layer of the surface soil. The injury can be overcome by subsoil liming.

Phosphoric acid in the form of phosphorite should only be applied to peat land which retains a certain degree of acidity.

N. H. J. M.

Manurial Experiments with Phosphorite and Basic Slag. By A. SEMPOŁOWSKI (*Bied. Centr.*, 1899, 28, 637—638; from *Zeit. landw. Versuchswesen Oesterr.*, 1898, 1, 267—276).—Whilst hard crystalline phosphorite has to be converted into superphosphate, the so-called soft, non-crystalline mineral, if finely ground, can be employed, without further treatment, as manure. Experiments in which barley was grown in sandy loam and in peaty soil (contained in bottomless wooden boxes) manured with phosphorite meal and basic slag respectively, in addition to other manures, showed that the phosphorite was decidedly effective, the increased production of barley, over the unmanured plots being not much less than that obtained under the influence of basic slag.

N. H. J. M.

Comparison between Bone- and Mineral-Superphosphate. By ANGELO MENOZZI (*Bied. Centr.*, 1899, 28, 635; from *Agricolt. moderna*, 1897, 50).—Maize grown in large zinc vessels was manured with equal amounts of phosphoric acid in the form of superphosphate from degelatinised bones and Florida phosphate respectively, in addition to other manures. The results indicated only slight superiority of the bone as compared with the mineral superphosphate.

N. H. J. M.

Phosphate Deposits in Japan. By K. TSUNETO (*Chem. Zeit.*, 1899, 23, 800 and 825—827).—In 1894, large deposits of phosphates were discovered in the miocene formation, extending over 720 square kilometres, in the south-west of the island Kiushu. The phosphates occur in nodules and aggregates in the lime-sandstone, in marl veins, and in dark brown veins of sandstone situated between the calcareous fine-grained sandstone. The nodules are generally rich in phosphates in the inner portion, whilst the outer layer is rich in iron; they contain organic remains. The following is the percentage composition of (1) grey nodules, (2) light brown nodules, (3 and 4) aggregates, (5) balls, and (6) breccia:

	Water and organic.	K ₂ O.	Na ₂ O.	CaO.	MgO.	FeO.	Fe ₂ O ₃ .	Al ₂ O ₃ .	Mn ₂ O ₃ .	P ₂ O ₅ .	SO ₃ .	CO ₂ .	Insol.
1.	1.26	—	—	9.62	2.28	8.77	2.98	2.14	0.35	8.35	0.29	8.26	55.65
2.	1.48	—	—	12.71	2.28	8.95	2.99	2.88	0.39	4.76	0.53	7.08	55.25
3.	0.65	—	—	11.73	2.36	7.37	2.46	1.65	0.23	5.85	0.63	7.92	54.22
4.	0.89	—	—	10.56	1.14	7.88	1.64	2.00	—	7.14	0.51	6.81	57.43
5.	2.21	2.25	0.42	30.28	1.30	—	3.76	3.72	—	20.29	1.23	1.82	28.38
6.	2.15	1.04	0.42	16.76	1.20	—	3.89	1.98	—	9.47	trace	2.28	47.15

In (5), a trace of chlorine and 2.09 per cent. of fluorine were found, and in (6) Cl=0.06 and F=2.13 per cent.

Although the percentage of phosphoric acid is generally low, the deposits are of importance in Japan where manures with very low percentages of phosphates are utilised. The best method for utilising the minerals containing 5—10 per cent. of phosphates seems to be extraction of the ground substance with 12.45 per cent. sulphuric acid (avoiding too great a rise of temperature) in amounts sufficient to decompose the phosphates and carbonates present.

N. H. J. M.

The Reversion of Soluble Phosphoric Acid in Superphosphates. By LUDWIG SCHUCHT (*Chem. Centr.*, 1899, i, 1165—1166; from *Chem. Ind.*, 22, 152—155).—Reversion does not take place unless the superphosphate is closely packed and consequently submitted to pressure. Ferric and aluminium compounds are harmful as their phosphates act on the undecomposed calcium triphosphate and so yield insoluble phosphates. Silicates are also a source of loss in phosphoric acid; their amount may be lessened by adding a regulated quantity of fluor-spar during the preparation of the superphosphate.

L. DE K.

Analytical Chemistry.

Standardising Acids. By ANTON SEYDA (*Chem. Centr.*, 1899, i, 1164; from *Zeit. öffentl. Chem.*, 5, 141—151).—Sodium carbonate, used for standardising acids, is likely to retain excess of carbon dioxide, or if overheated it may contain sodium hydroxide. A suitable article is, however, obtained by heating sodium hydrogen carbonate for an hour at 220° in an air-bath.

The results then perfectly agree with those obtained by standardising the acid with the aid of potassium hydrogen tartrate or ammonium chloride.

L. DE K.

Estimation of Sulphur in Bitumens. By STEPHEN F. PECKHAM and H. E. PECKHAM (*J. Amer. Chem. Soc.*, 1899, 21, 772—776).—In reply to Hodgson, the authors state that in order to get accurate estimations of sulphuric acid, any iron or aluminium oxides should be first removed.

The following method has been finally adopted for the estimation of sulphur in bitumen. A quantity of the substance representing about 0.5 gram of real bitumen is mixed with 15 grams of pure dry sodium carbonate and 15 grams of potassium nitrate and the mixture then fused by degrees in a platinum crucible. The product is dissolved in dilute hydrochloric acid, evaporated to dryness, and gently ignited to render any silica insoluble; the residue is then treated with dilute hydrochloric acid and the solution precipitated, while boiling, with a slight excess of ammonia to remove iron and aluminium. If desired, any calcium may be precipitated as oxalate. The filtrate is now acidified with hydrochloric acid and the boiling liquid precipitated with barium chloride solution added carefully from a pipette.

L. DE K.

Estimation of Hyposulphurous Acid. By N. FRADISS (*Chem. Centr.*, 1899, i, 1223; from *Bull. Assoc. Chimistes*, 16, 453).—The solution is neutralised and added from a burette to an ammoniacal standard solution of copper sulphate until this is quite decolorised. The presence of sulphites does not interfere. 1 mol. of hyposulphurous acid reduces 2 mols. of copper oxide to the cuprous state.

L. DE K.

Volumetric Estimation of Sulphuric Acid. By FRANZ LITTELSCHIED and KARL FEIST (*Arch. Pharm.*, 1899, 237, 521—525).—The authors have developed independently the method described by Grützner (this vol., ii, 530). The solution of the sulphate is acidified with hydrochloric acid, heated to boiling, treated with a measured excess of $N/4$ barium chloride solution, stirred well, and allowed to remain in a warm place for half-an-hour; the liquid is then made strongly alkaline with ammonia, excess of ammonium carbonate solution added, and the whole stirred and allowed to remain at 50—60° for ten minutes. The precipitate is then collected on a small filter, washed three or four times with hot water, and transferred to a conical flask, when the barium carbonate is titrated with $N/10$ hydrochloric acid. It may be titrated directly when methyl-orange is employed as an indicator; if phenolphthalein be used, excess of $N/10$ acid must be added, the carbon dioxide driven off by boiling, and the excess of acid titrated with $N/10$ caustic potash. On multiplying by 0.4 the number of c.c. of $N/10$ acid neutralised and subtracting the product from the number of c.c. of $N/4$ barium solution taken, the remainder multiplied by 0.01 gives the weight of SO_3 present, or multiplied by 0.004 the weight of S.

The solution of the sulphate must not contain any acid of which the barium salt is insoluble, such as phosphoric and oxalic acids; neither must it contain substances which are precipitated by ammonium carbonate, or, like tartaric and citric acids, hinder the precipitation of the barium. Alkaloids, if insoluble in ammoniacal ammonium carbonate solution, must be removed by extraction with a suitable solvent. The sulphates of potassium, sodium, ammonium, rubidium, cesium, copper, zinc, cadmium, nickel, and cobalt, may be estimated directly; so also that of lithium, provided the solution be dilute enough to retain the lithium carbonate in solution (solubility: 1 in 75 parts of water at 50°). Iron sulphate, and the solution obtained by oxidising copper pyrites with nitric acid and potassium chlorate, may also be estimated, if the iron is first removed as hydroxide. With magnesium sulphate, good results have not yet been obtained.

C. F. B.

Titration of Persulphates. By MAX LE BLANC and M. ECKARDT (*Zeit. Elektrochem.*, 1899, 5, 355—357).—The reaction between a persulphate and a ferrous salt in solution is comparatively slow at the ordinary temperature; erroneous results may therefore be obtained in the analysis of persulphates by treating the solution with ferrous sulphate and titrating the excess with permanganate. These errors are very easily avoided by warming the acidified mixture of persulphate and ferrous ammonium sulphate to 60—80° before titrating with permanganate.

T. E.

Estimation of Tellurous Acid in Presence of Haloid Salts. By FRANK A. GOOCH and C. A. PETERS (*Amer. J. Sci.*, 1899, 8, 122—126).—Tellurous acid is generally estimated by adding to its alkaline solution a slight excess of standard potassium permanganate. A definite volume of standardised ammonium oxalate is added, and then a sufficiency of dilute sulphuric acid (1 : 1) so as to have about 5 c.c. of the acid in excess. After heating at 60—80°, the excess of oxalic acid is estimated by standard permanganate.

The authors find that the presence of chlorides does not interfere if before the final titration about 1 gram of crystallised manganous chloride is added. Bromides are also harmless if the same precaution is taken and the temperature not allowed to rise above 25°.

In the case of iodides, the process breaks down, so another method was successfully tried. The alkaline solution is mixed with a known volume of potassium permanganate, previously standardised with a standard solution of arsenious acid, and, after a while, a slight excess of dilute sulphuric acid is added, with, if necessary, some more potassium iodide; after adding a slight excess of potassium hydrogen carbonate, the liberated iodine is titrated with the standard solution of arsenious acid, the end reaction being the disappearance of the yellow colour; starch need not be used as an indicator.

Supposing the two solutions balance each other—the difference in the two titrations equals the number of c.c. of permanganate consumed by the tellurous acid.

L. DE K.

Detection of Nitric Acid in Cadaveric Matter. By DIOSCORIDE VITALI (*Zeit. anal. Chem.*, 1899, 38, 539—541; from *Oesterr. Chemikerzeit.*, 1, 330).—For the detection of free nitric acid in animal matter in which nitrates may already be present, either as normal constituents or by introduction in food, it is useless to distil with water, for the mineral acids combine with albumin, forming acid-albumins, which in many cases are not decomposed at 190°. The substance is therefore digested on the water-bath with freshly precipitated barium carbonate, the solution evaporated to dryness, and the residue boiled repeatedly with absolute alcohol for the removal of calcium and magnesium nitrates. The alcoholic solution will also contain the soluble acid-albumin. It is evaporated to dryness, the residue dissolved in water, and exactly neutralised with barium hydroxide solution, which decomposes the acid-albumin. The solution is again evaporated and the nitrates separated by absolute alcohol. The residual barium nitrate is then dissolved in water, decolorised with lead acetate, freed from lead by hydrogen sulphide, and the concentrated solution finally crystallised in the desiccator. The residue from the first treatment with alcohol contains the barium nitrate derived from the presence of free acid as well as insoluble acid-albumin, and possibly some calcium nitrate. It is treated with a dilute solution of sodium carbonate until an alkaline reaction is just obtained. The acid-albumin and the barium nitrate are by this means converted into sodium nitrate, the calcium nitrate remaining undecomposed. The filtered solution is evaporated to dryness and the residue boiled with absolute alcohol. The sodium nitrate dissolves, but it is stated that the calcium nitrate remains undissolved. The sodium nitrate is purified and identified in the same way as the barium nitrate above. [W. Fresenius expresses grave doubts as to the correctness of some of the above reactions, and points out that the author contradicts himself, as well as established fact, in stating that calcium nitrate is undissolved by boiling alcohol.]

Another method consists in treating the animal matter with freshly precipitated strychnine, when strychnine nitrate is formed. This

can be purified by solution in boiling alcohol, the colour removed with lead acetate, and the nitrate finally obtained as crystals.

A very sensitive reaction for nitric acid is obtained by adding salicin and 8—10 drops of concentrated sulphuric acid to the residue of an evaporated solution. A blood-red coloration is produced, which becomes violet on dilution.

M. J. S.

Estimation of Arsenic in Paris Green. By THORN SMITH (*J. Amer. Chem. Soc.*, 1899, 21, 769—772).—Two grams of the sample are boiled with 100 c.c. of water and 2 grams of sodium hydroxide; when cold, the liquid is made up to 250 c.c., well shaken, and filtered through a dry filter. 50 c.c. are then concentrated to 25 c.c., and after cooling to 80°, 25 c.c. of hydrochloric acid and 3 grams of potassium iodide are added. After remaining for 10 minutes, any arsenic acid will be completely reduced to the arsenious state and the liberated iodine is removed by diluting with water and carefully decolorising with solution of sodium thiosulphate. After first neutralising with, and then adding an excess of sodium hydrogen carbonate, the arsenious acid is titrated in the usual manner with $N/10$ solution of iodine.

L. DE K.

Estimation of Boric Acid in Tourmaline. By GEORGE W. SARGENT (*J. Amer. Chem. Soc.*, 1899, 21, 858—887).—The paper contains a summary of all the chief methods proposed for the estimation of boric acid, and the author's opinion as to their respective merits.

When dealing with tourmaline and similar minerals containing aluminium, the chief difficulty arises from the incomplete separation of boric acid and alumina, the only way of effecting complete separation is by the method proposed by Gooch, namely, volatilisation of the acid by means of methyl alcohol, coupled with the titration of the volatilised acid by Thomson's glycerol method.

L. DE K.

Iodometric Method for the Estimation of Boric Acid. By LOUIS C. JONES (*Amer. J. Sci.*, 1899, 8, 127—132. Compare *Abstr.*, 1899, ii, 332).—Under certain definite conditions, a mixture of boric acid and mannitol possesses an acidic power sufficiently strong to liberate iodine from a mixture of potassium iodide and iodate. The iodine is readily estimated by means of sodium thiosulphate, and represents the amount of boric acid.

To obtain correct results, the following mode of procedure should be used: the borate is dissolved in the smallest possible quantity of hydrochloric acid and then diluted with water so that 50 c.c. of liquid shall contain about 0.1 gram of boric acid. The greater part of the free acid is then neutralised with sodium hydroxide and 5 c.c. of a 40 per cent. solution of potassium iodide and 10 c.c. of a 5 per cent. solution of potassium iodate are added and the liberated iodine at once removed by a few drops of a strong solution of sodium thiosulphate. After restoring a very faint yellow colour by means of standard iodine, 15 grams of mannitol are added, and when dissolved, a standard solution of sodium thiosulphate is added until the colour is bleached, when an extra 10 c.c. are added. A little more mannitol is added and after standing in a cool place for an hour, the excess of thiosulphate is carefully titrated by means of standard iodine solution.

L. DE K.

Stutzer and Hartleb's Process for the Estimation of Combined Carbon Dioxide (Calcium Carbonate) in Soils. By H. SCHÜTTE (*Zeit. angew. Chem.*, 1899, 854—858).—The author criticises this process (*Abstr.*, 1899, ii, 521) and states that, although good enough for marls, it is not sufficiently accurate for the estimation of small quantities of calcium carbonate in soils.

The chief objection to the process is that ammonium chloride also acts on calcium in combination with silicic acid, and so causes the results to be in excess of the truth. Ferrous carbonate is also stated to interfere with the accuracy of the method, and cannot always be completely decomposed by boiling.

L. DE K.

Gas Washing Apparatus: Rapid and Accurate Process for the Estimation of Carbon Dioxide. By ROBERT SCHALLER (*Zeit. angew. Chem.*, 1899, 878—880).—The apparatus is essentially a U-tube 17 cm. long, one side of which is very narrow and serves to admit the current of the gas. The other side is filled with glass beads 2 mm. in diameter, which are moistened with the absorbing liquid.

In the new apparatus for estimating carbon dioxide, the substance is decomposed in a kind of test-tube with hydrochloric acid, and the carbon dioxide is swept out by means of a current of air which has been freed from this gas by passing through two of the U-tubes containing a solution of potash. The gas then passes through a similar tube containing sulphuric acid before it reaches the absorber. The latter consists of one or two similar weighed U-tubes containing 10 c.c. of 50 per cent. solution of potassium hydroxide. These tubes are, in addition, fitted with a small test-tube 8 cm. long containing 1 c.c. of strong sulphuric acid, and provided with a doubly perforated rubber cork. Through one of the holes passes a tube with a bulb in its centre and drawn to a narrow point at the bottom, the object being to prevent any escape of moisture from the apparatus. The other hole is fitted with a small bent tube to allow the air to escape.

L. DE K.

Estimation of Calcium Carbonate in Marls. By HERMANN NOLL (*Zeit. angew. Chem.*, 1899, 859—860).—The process recommended by Tacke is found to answer for the estimation of calcium carbonate in marls, as it is not affected by the presence of small quantities of ferrous and aluminium compounds or of calcium silicate. The details of this process are briefly as follows: 0.2 gram of the powdered sample is mixed with 200 c.c. of warm water, 25 or 50 c.c. of *N*/5 normal sulphuric acid are added, and the carbon dioxide expelled by boiling. The excess of acid is then titrated with standard baryta, using phenolphthalein as indicator.

L. DE K.

New Volumetric Method for the Estimation of Magnesium. By RICHARD K. MEADE (*J. Amer. Chem. Soc.*, 1899, 21, 746—752).—The process is an indirect one. The ammoniacal solution free from calcium is precipitated with a solution of sodium arsenate, and the excess of the reagent removed by washing with dilute aqueous ammonia (1 : 3). The arsenical precipitate is then dissolved in 75—100 c.c. of dilute

hydrochloric acid (1:1), potassium iodide added, and the liberated iodine titrated with standard solution of sodium thiosulphate.

L. DE K.

Double Ammonium Phosphates of Beryllium, Zinc, and Cadmium in Analysis. By MARTHA AUSTIN (*Amer. J. Sci.*, 1899, 8, 206—216).—When salts of these three metals are precipitated by boiling with excess of sodium ammonium hydrogen phosphate, double ammonium phosphates are obtained, which, on ignition, yield the corresponding pyrophosphates.

It has, however, been found impossible to accurately estimate beryllium in this manner. Zinc may be estimated if care be taken to precipitate the metal from a neutral solution containing 10 per cent. of ammonium chloride. The process is also well adapted for cadmium; the solution should contain 10 per cent. of ammonium chloride, be practically neutral, and be allowed to remain several hours before filtering.

L. DE K.

Analysis of Zinc for Cadmium and Lead. By P. A. MACKAY (*J. Amer. Chem. Soc.*, 1899, 21, 940—941).—The metal is treated with dilute hydrochloric acid in sufficient quantity to dissolve the bulk of the zinc; the undissolved portion then contains all the lead and cadmium present.

After dissolving the residue in nitric acid, the lead is recovered in the usual way as sulphate, and in the filtrate the cadmium is precipitated by hydrogen sulphide; the cadmium sulphide is then collected, washed, and redissolved in boiling hydrochloric acid and titrated with potassium ferrocyanide. It has been noticed, however, that small quantities of cadmium can only be accurately estimated in the presence of zinc, and also that 1 gram-mol. of cadmium requires 3·676 gram-mols. of potassium ferrocyanide, instead of 3·767, as required by theory. A solution containing 10 grams of zinc per litre is prepared, and 50 c.c. of this titrated with a solution containing 36·76 grams of potassium ferrocyanide per litre, using uranium acetate as indicator. Another 50 c.c. is then added to the liquid containing the cadmium, and the titration is repeated; each c.c. excess of ferrocyanide solution used in this titration represents 0·01 gram of cadmium.

L. DE K.

Electrolytic Estimation of Zinc in the Presence of Manganese. By EMIL J. RIEDERER (*J. Amer. Chem. Soc.*, 1899, 21, 789—792).—Zinc may be conveniently separated from manganese by electrolysis. The solution, which should not contain chlorides or nitrates, but only sulphates, is mixed with 5 grams of ammonium lactate, 0·75 gram of lactic acid, 2 grams of ammonium sulphate, and then made up to 230 c.c.; the amount of zinc should not exceed 0·17 gram. The cathode, which should be 1½ cm. distant from the anode, should consist of a platinum dish on which silver has been deposited, and during the action of the current it is advisable to use a mechanical stirrer so as to obtain an even and uniform deposit of zinc; the current may vary from 0·20—0·26 ampères and the temperature from 15—26°.

The time required for the complete deposition of the zinc does not

exceed 5½ hours; the deposit is free from manganese. It is rapidly washed first with water, then successively with alcohol and ether, dried in the water oven for 5 minutes, and weighed.

L. DE K.

Direct Estimation of Aluminium in the Presence of Iron, Manganese, Calcium, and Magnesium. By WILLIAM H. HESS and EDWARD D. CAMPBELL (*J. Amer. Chem. Soc.*, 1899, 21, 776—780).—A convenient bulk of the liquid, preferably containing the metals as chlorides, is heated to boiling and dilute ammonia is added so long as the precipitate readily redissolves; to reduce the ferric salts, a saturated solution of ammonium hydrogen sulphite is added drop by drop until the liquid is colourless. The aluminium is now precipitated by adding a few c.c. of phenylhydrazine and is washed with hot water containing about 10 per cent. of phenylhydrazine hydrogen sulphite free from excess of sulphur dioxide. On ignition, it leaves pure alumina. Chromium may also be separated from iron, calcium, magnesium, cobalt, or nickel in this manner.

If, however, the mixture also contains phosphoric acid, the alumina will be contaminated with phosphoric oxide, which must be estimated and allowed for.

L. DE K.

Volumetric Estimation of Manganese. By RODOLFO NAMIAS (*Chem. Centr.*, 1899, i, 1224; from *Annuar. Soc. chim. Milano*, 1899, 54—56).—The author uses Volhard's process when estimating manganese in samples of iron or steel. Use is made of carefully selected crystals of potassium permanganate which are reduced by boiling with hydrochloric acid; the manganous chloride so obtained is precipitated with sodium carbonate, the precipitate is converted into manganoso-manganic oxide, and this is titrated with ferrous sulphate.

It is recommended to first dissolve the steel, or iron, in hydrochloric acid before oxidising with nitric acid to prevent the formation of organic compounds, which reduce permanganate.

L. DE K.

A Simplified Reductor. By PORTER W. SHIMEE (*J. Amer. Chem. Soc.*, 1899, 21, 723—724).—A new form of the reductor used in the estimation of iron and phosphomolybdate solutions. It is essentially a plain glass tube $\frac{3}{8}$ -inch in diameter and 20 inches long drawn out and out off at the lower end. It is united with a 4-inch funnel by means of wired rubber tubing fitted with a screw clamp. The lower end passes through a soft two-hole stopper of a thick-walled pint gas bottle connected with a filter pump through an intermediate safety bottle and valve. The passage of the solution through the reductor may be effected either by use of the pump or by Bunsen's device of condensing steam.

The tube is filled by placing a few small pieces of broken glass in the drawn out portion, then a little clean sand and finally about 3 ounces of amalgamated zinc. The speed of filtration is regulated by the upper clamp; a reduction takes about five minutes.

L. DE K.

Separation of Iron from Chromium, Zirconium, and Beryllium by the Action of Hydrogen Chloride on the Oxides. By FRANK S. HAYENS and ARTHUR F. WAY (*Am. J. Sci.*, 1899, 8, 217—218).—Gooch and Havens (Abstr., 1897, ii, 232) have shown that iron

le may be readily separated from alumina by heating the mixed des in a current of hydrogen chloride at a temperature of 450—500°; o the mixture of sodium chloride and sulphuric acid a small quantity manganese dioxide is added so as to also generate a little chlorine, ; decomposition may be effected at 200—300°.

The authors now state that this method may be used successfully for a separation of oxide of iron from the oxides of chromium, zirconium, d beryllium.

L. DE K.

Estimation of Nickel in Nickel-steel. By GEORGE W. SARGENT (*Amer. Chem. Soc.*, 1899, 21, 854—857).—The metal is dissolved in hydrochloric acid, oxidised with nitric acid, and the solution evaporated to dryness; the residue is taken up with a little dilute hydrochloric acid, and filtered into a separating funnel. The bulk of the ferric chloride is now removed by agitating the liquid with ether (Chase's method) and the solution, after removal of the dissolved ether, reprecipitated by bromine water and ammonia; the precipitate is freed from nickel by a second solution and precipitation. The combined filtrates containing the nickel are acidified with hydrochloric acid, freed from any copper by hydrogen sulphide, the filtrate boiled to expel hydrogen sulphide, and, when cold, a slight excess of ammonia added, and the liquid titrated with standard potassium cyanide, with silver iodide emulsion as indicator (Campbell and Andrew's method, *Abstr.*, 1895, ii, 421).

L. DE K.

[Estimation of Chromic Acid in Acetylene Purifiers.] By FRITZ ULLMANN and IRMA GOLDBERG (*Chem. Centr.*, 1899, ii, 19—20; from *J. Gasbel.*, 42, 374—377).—See this vol., i, 1.

Estimation of Antimony in Ores. By THOMAS BROWN, jun. (*J. Amer. Chem. Soc.*, 1899, 21, 780—789).—*Assay of soluble ores such as Stibnite and Senarmontite.*—1 gram of the finely powdered sample is boiled in a covered beaker with 25 c.c. of strong hydrochloric acid until about 15 c.c. are left. 2 grams of tartaric acid are then added, and when dissolved, about 4—6 drops of strong nitric acid are introduced, and the boiling continued for a minute. The mixture is then diluted with water, the insoluble residue well washed on a filter, and the filtrate diluted to about 250 c.c. The liquid is now saturated with hydrogen sulphide and gently heated, and after remaining for an hour, the antimony sulphide is collected and washed with cold water. If there is any probability of lead being present, the precipitate must be dissolved in ammonium sulphide and the filtrate reprecipitated with dilute hydrochloric acid. The precipitate is collected on a counterpoised (double) filter, washed, dried at 110°, and weighed; the bulk of the crude antimony sulphide is transferred to a weighed platinum boat, and then placed inside a piece of combustion tube and heated in a current of carbon dioxide, so as to convert it into black antimony sulphide, which is then weighed. A correction is finally made for the small amount of sulphide not removable from the filter.

Assay of insoluble ores such as Cervantite.—1 gram of the powdered ore is mixed in a covered porcelain crucible with 10 grams of a mixture of equal parts of sulphur and dry sodium carbonate, covered with a little more of this flux, and fused for 10 minutes in a muffle. The mass

is extracted with water, and in the filtrate the antimony is precipitated as sulphide by means of hydrochloric acid; the crude sulphide is then treated as previously directed.

Assay of partially soluble ores: Oxy-sulphides.—These are assayed by the combination of the two processes described.

The fire assay (fusion with potassium cyanide), although easy of execution, seldom agrees with the wet assays, and is particularly unsuitable for ores containing sulphur. L. DE K.

Apparatus for the Preparation of Plant-Ash for Analysis. By G. M. TUCKER (*Ber.*, 1899, 32, 2583—2585).—This is a simplified form of Shuttleworth's apparatus (*Diss. Göttingen*, 1899, and *J. Landwirthschaft*, 1899, 173) designed to give a control over any loss of potash, chlorine, &c., by volatilisation. The platinum vessel, in which the plant is burnt, is of a conical form and is provided with a closely-fitting cover having two apertures. In the central aperture is soldered a tube passing to the bottom of the vessel and down this tube, by means of which air enters, passes the handle of a stirrer. By means of the other aperture, the gases from the combustion chamber are led through a small wash-bottle, beyond which is an aspirator which draws air through the whole apparatus. Any ash mechanically carried by the air stream is stopped by a loose movable cap fitted to the exit tube. The conical shape of the vessel allows of more uniform heating, which is carried out first in a conical sand-bath, and, later, over a bare flame, the vessel being then fitted into a hole in an asbestos card. T. H. P.

Ammoniacal Copper Solutions and Hydroxylamine as a Test for Acetylene. By LUDWIG ILOSVAY VON NAGY ILOVA (*Ber.*, 1899, 32, 2697—2699).—Ammoniacal copper solutions decolorised by reducing with hydroxylamine can be used for detecting acetylene, but the value of the reagent and the colour of the precipitate depend on the proportions used. The quantities recommended are, for 50 c.c. of solution, (I) cupric chloride ($+ 3\text{H}_2\text{O}$), 0.75 gram; ammonium chloride, 1.5 grams; aqueous ammonia (20—21 per cent.), 3 c.c., hydroxylamine hydrochloride, 3 grams. (II) cupric nitrate ($+ 5\text{H}_2\text{O}$), 1 gram; aqueous ammonia, 4 c.c., hydroxylamine hydrochloride, 3 grams. (III) copper sulphate ($+ 5\text{H}_2\text{O}$), 1 gram; aqueous ammonia, 4 c.c., hydroxylamine hydrochloride, 3 grams. The reagent gives a splendid red precipitate with acetylene, but begins to deteriorate after three days. T. M. L.

A Colour Test for the Detection of Methyl Alcohol. By EDMOND JANDRIER (*Chem. Centr.*, 1899, i, 1296; from *Ann. chim. anal. appl.*, 4, 156).—Resorcinol recommended by Mulliken and Scudder (*Abstr.*, 1899, ii, 388) gives, with acetaldehyde, almost the same colour as with formaldehyde, and is consequently not a safe test for the detection of methyl alcohol; the test is also interfered with by the presence of furfuraldehyde. It is proposed to use gallic acid instead, as recommended by Barbet and Jandrier (*Abstr.*, 1898, ii, 265).

L. DE K.

Recognition of Marc Wines (Tresterweine). By WILHELM FRESSENIUS and LEO GRÜNHUT (*Zeit. anal. Chem.*, 1899, 38, 472—512).—Wines obtained by the fermentation of solutions of glucose in

contact with grape marc (*Trester*) have hitherto not been distinguishable with certainty by chemical analysis from natural wines. The authors believe they have discovered a trustworthy criterion of such wines in the fact that they contain little or no tartaric acid combined with alkaline earths, whilst natural white wines always contain calcium tartrate to an extent which permits a limit of about 0.1 gram of tartaric acid per 100 c.c. to be established. The recognition of this fact in their composition depends on the estimation of the ratio of the total tartaric acid to the total alkalinity of the ash and the alkalinity of the portion of the ash soluble in water. With reference to the observations of Kulisch, Kohlmann, and Höppner (*Abstr.*, 1899, ii, 341; also 1895, ii, 465) on this subject, they point out that, in the estimation of the soluble constituents of the ash, a very limited amount of washing (30—80 c.c. of hot water for the ash of 100 c.c. of wine) must be employed, so as to leave the calcium carbonate of the ash as far as possible undissolved. Formulæ are given for calculating the analytical data. An exception to the above rule occurs in the case of marc wines to which tartaric acid has been added during manufacture. Red wines also contain much smaller proportions of calcium tartrate than white wines. The above criterion must therefore in all cases be considered in connection with other characteristics of marc wines, namely, a high proportion of ash to total solids, high percentage of tannin, and occasionally also of volatile acids. It can likewise only be employed in cases where the ash of the wine exhibits a normal total alkalinity and the proportion of sulphate is not abnormal, since it is obvious that excessive sulphuring would disturb the relations of the various tartrates in the wine. The alkalinity factor of natural wines, that is, the alkalinity of 0.1 gram of the ash expressed in cubic centimetres of normal alkali, seldom exceeds 0.8 or 1.0. Wines exhibiting a much lower alkalinity factor should be examined for excessive sulphuration. A much higher factor would suggest a search for added organic acids. The ratio of glycerol to alcohol in marc wines seems generally to exceed the limit of 7:100 laid down for natural wines.

With regard to the use of the large proportion of tannin as a criterion of marc wines, it is evident that no limit can be laid down, since the proportion of tannin in natural wines varies widely. Barth has argued that the ratio of total extract (after deduction of sugar, ash, and non-volatile acids) to tannin may be regarded as constant, and employs the factor 5 for multiplying the tannin. The authors show, however, that in a great number of natural wines, even the factor 4 would be too high and point out the need for further investigations of this subject.

The authors also give a complete analysis of the ash of a marc wine prepared by themselves, and some analyses of raisin-wines, one of which they also manufactured.

M. J. S.

Volumetric Estimation of Alcohols, especially of Fusel-Oil in "Brandies." By FRANZ ADAM (*Chem. Centr.*, 1899, i, 1226—1227; from *Oesterr. Chem. Zeit.*, 2, 241—243).—A solution of acetyl chloride in chloroform, after it has been well shaken with water and so

decomposed into acetic and hydrochloric acids, is titrated with normal alkali. Another portion of the chloroform solution is allowed to act on the alcohol, whereby it is partly decomposed into hydrogen chloride and alkyl acetate; after decomposing the remainder with water, the titration is repeated, and the difference in alkali represents the amount of the alcohol. To estimate amyl alcohol in brandy, the sample is diluted to 20 per cent. strength by volume, and the fusel oil then extracted by repeated agitation with pure chloroform. This is repeatedly shaken with water, then dried over burnt gypsum and treated with standard solution of acetyl chloride, &c. The process is also suitable for the estimation of the alcohol number of ethereal oils.

L. DE K.

Action of Bromine on Phenol and Cresols with Reference to the Analysis of Mixtures of these Compounds. By HUGO DITZ and FRANZ CEDIWODA (*Zeit. angew. Chem.*, 1899, 873—877 and 897—903).—An alkaline solution of a phenol is mixed with a known excess of bromine dissolved in caustic potash, acidified with dilute HCl (1:1), shaken vigorously for 1 minute, and titrated with standard thiosulphate solution in the presence of potassium iodide; under these conditions, 1 mol. of *o*-cresol or *p*-cresol takes up 2 atoms of bromine, whilst *m*-cresol and phenol each combine with 3 atoms. In the case of *p*-cresol, it is essential that the duration of the experiment should not exceed the prescribed time limit, otherwise the amount of bromine required exceeds 2 atoms. When the alkaline solution of a phenol and excess of bromine is acidified with concentrated sulphuric acid, allowed to remain for 10 minutes, subsequently shaken for 5 minutes, and then filtered through glass wool or sand, it is found, by treating the filtrate with potassium iodide and titrating with thiosulphate, that the amount of bromine taken up corresponds with 3 atoms in the case of *o*-cresol and *p*-cresol, and with 4 for *m*-cresol and phenol. These results are applied to the analysis of mixtures of two or more of these constituents. The mixture of the phenols is separated from other impurities by extraction with ether; the ethereal extract is dried over calcium chloride or dry sodium sulphate, distilled up to 180° to remove ether and last traces of moisture, the fraction distilling over above this temperature is treated with bromine by the two methods just described, and the amount of phenol, *m*-cresol and mixed ortho- and para-cresol determined by means of the following equations: (i) $x + y + z = a$; (ii) $3\text{Br}/94 \cdot 06 \cdot x + 2\text{Br}/108 \cdot 08 \cdot y + 3\text{Br}/108 \cdot 08 \cdot z = b$; and (iii) $4\text{Br}/94 \cdot 06 \cdot x + 3\text{Br}/108 \cdot 08 \cdot y + 4\text{Br}/108 \cdot 08 \cdot z = c$, where x and z represent the amounts of phenol and *m*-cresol, y the amount of the mixture of the ortho- and para-isomerides, a the total quantity of phenolic compounds, b the amount of bromine absorbed when the solution is acidified with dilute hydrochloric acid, and c the amount taken up when concentrated sulphuric acid is employed, and the bromo-derivatives filtered off before titration.

G. T. M.

Simplification of the Phenylhydrazine Test [for Sugar in Urine.] By ALBERT KOWARSKY (*Chem. Centr.*, 1899, i, 1294; from *Berl. klin. Wochschr.*, 36, 412—414).—5 drops of pure phenyl-

hydrazine are mixed with 10 drops of glacial acetic acid and 1 c.c. of brine, and the mixture boiled for 2 minutes with 3 c.c. of the supposed diabetic urine and then allowed to cool slowly. If the characteristic osazone crystals form after a few minutes, the urine is practically free from sugar. If appreciable traces of albumin are present, these must be first removed by coagulation at the boiling heat.

L. DE K.

Stability of Gun-Cotton and Smokeless Powder. By C. HORTSEMA (*Zeit. angew. Chem.*, 1899, 705—710).—A review of the methods in use for testing these explosives as to their keeping powers.

The author thinks that at present there are not sufficient grounds for substituting the Simon-Thomas test for those of Abel and of Guttman. For comparison, a stock of materials of guaranteed make and of known age should be kept.

L. DE K.

Chemistry of Butter-Fat. II. Chemical Composition of Butter-Fat. By C. A. BROWNE, jun. (*J. Amer. Chem. Soc.*, 1899, 21, 807—827. Compare Abstr., 1899, ii, 709).—This is a long investigation as to the true composition of butter-fat; on the whole, the article does not lend itself to useful abstraction.

The following analysis of the fatty acids obtained from 100 grams of butter is interesting as it confirms the result of Hehner and Mitchell (Abstr., 1897, ii, 287) as to the small proportion of stearic acid contained in butter: dihydroxystearic, 1.00; oleic, 32.50; stearic, 1.83; palmitic, 38.61; myristic, 9.89; lauric, 2.57; capric (decoic), 0.32; caprylic (octoic), 0.49; caproic (hexoic), 2.09; butyric acid, 5.45; total, 94.75.

L. DE K.

The Reichert Number of Butter. By JAMES H. STEBBINS (*J. Amer. Chem. Soc.*, 1899, 21, 938—940).—From the result of 317 analyses of genuine butters, the author is in favour of placing the lowest allowable limit of the Reichert number at 11.5.

L. DE K.

Analysis of Bees Wax. By ANGIOLO FUNARO (*L'Orosci*, 1899, 22, 109—123).—The adulterants of bees wax are Japan and Carnaüba wax, animal fats, stearic acid, resins, cerasin, and paraffin wax. The various methods for detecting and estimating these impurities are described in detail and discussed.

T. H. P.

The Sesamé Oil Reaction and Sesamé Butter. By KARL BERNHARD SOHN (*Bied. Centr.*, 1899, 28, 298—299; from *Milchzeit.*, 1898, 498).—The employment of pure furfuraldehyde which has been recently distilled in a vacuum, and is colourless, is of great importance in testing for margarine by means of the Baudouin test. In case pure furfuraldehyde is not available, the employment of furfuramide is recommended.

The following process for detecting for sesamé oil is given: the melted filtered butter (10 c.c.) is extracted with hydrochloric acid of sp. gr. 1.125 three or four times or until the acid remains colourless. Five c.c. of the butter fat is then shaken with a solution of 1.08 grams of furfuramide in 100 c.c. of absolute alcohol (0.1 c.c.) and hydrochloric acid of sp. gr. 1.19 (10 c.c.) for at least half a minute. If the fat solidifies, it is heated at 60—70°. If the hydrochloric acid

shows a red coloration which does not soon disappear, sesamé oil is proved to be present; with small amounts of sesamé oil, the coloration takes hours to appear.

N. H. J. M.

[Testing Butter for Oil of Sesamé.] By H. WEIGMANN (*Bied. Centr.*, 1899, 28, 629).—See this vol., ii, 40.

Detection and Estimation of Formaldehyde in the Free State and in its Compounds. By G. H. A. CLOWES and BERNHARD TOLLENS (*Ber.*, 1899, 32, 2841—2848).—Formaldehyde is estimated by heating with phloroglucinol and hydrochloric acid at 70—80° and weighing the phloroglucide, $C_7H_5O_3$, which is produced under these conditions. In most of its compounds, the formaldehyde can be estimated in this way by using hydrochloric acid and water, but in some cases it is necessary to employ a more or less concentrated sulphuric acid to hydrolyse the methylene compound. A large number of analytical results are given.

T. M. L.

[Separation of Acetone from Acetoacetic and Acetonedicarboxylic Acids]. By LUIGI SABBATANI (*Chem. Centr.*, 1899, ii, 22—23; from *Atti Real. Accad. Torino*, 34).—See this vol., ii, 32.

New Reaction of Acetone and a New Method for the Detection of Aliphatic Amines. By ENRICO RIMINI (*L'Orosi*, 1899, 22, 40—44).—If to a mixture of an aliphatic monamine with a 10 per cent solution of acetone a few drops of a concentrated solution of sodium nitroprusside are added, a magenta coloration is formed, which gradually becomes more and more intense and lasts for several hours; the addition of a few drops of acetic acid changes it to an intense violet. When the hydrochloride of the amine is employed, too much alkali must not be added, as in this case the orange tint of Legal's reaction is obtained; this, however, vanishes much more quickly than the red coloration. By using aniline or phenylhydrazine in place of the aliphatic monamine, no coloration is obtained, whilst benzylamine gives a faint violet colour which forms slowly. With secondary aliphatic monamines, Legal's reaction takes place, whilst tertiary amines act simply as alkalis.

No coloration is obtained if, instead of acetone, one of the following substances is employed:—formaldedyde, acetaldehyde, paraldehyde, isobutaldehyde, or valeraldehyde, chloral, benzaldehyde, salicylaldehyde, anisaldehyde or cinnamaldehyde, furfuraldehyde, dextrose, acetophenone, benzophenone, ethyl acetoacetate, camphor, fenchone, or tanacetone; with concentrated solutions of pyruvic acid, a brown coloration forms and changes to green, whilst with dilute solutions a ponceau tint is developed.

The presence of 1/10 per cent. of acetone in a solution can be detected in this way, and the formation of the colour is not interfered with by the presence of alcohol or acetaldehyde.

Use is made of this reaction of acetone and of that of acetaldehyde formerly described (*Rendiconti Amministr. Civile. Ministero del Interno*, 1898) by the author to distinguish between primary and secondary aliphatic amines. The formation of an azure coloration on adding sodium nitroprusside and aldehyde to the solution of an amine, shows

that the base is secondary, whilst if acetone is added in place of the aldehyde, and a magenta tint is given to the liquid, the amine is primary. These reactions are obtained in mixtures of primary, secondary, and tertiary amines.

T. H. P.

Volumetric Estimation of Quinones Derived from Benzene. By AMAND VALEUR (*Compt. rend.*, 1899, 129, 552—553).—The method described is based on the reduction of quinones by hydriodic acid, all secondary reactions being avoided by operating in the following manner. A cooled mixture of 20 c.c. of concentrated hydrochloric acid with an equal volume of 95 per cent. alcohol is quickly added to 20 c.c. of a 10 per cent. aqueous solution of potassium iodide. The liquid is then poured into the alcoholic solution of the quinone and the iodine liberated is titrated with *N*/10 sodium thiosulphate solution. The process is expeditious, and is shown to give accurate results in the case of quinone, dichloroquinone, toluquinone, and thymoquinone; it is also applicable to unstable compounds of quinones, such as phenokinones and quinhydrone.

N. L.

A Colour Reaction to Distinguish the Hydrochlorides of *m*-Phenylenediamine and *p*-Phenylenediamine. By L. CUNIASSE (*Chem. Centr.*, 1899, i, 1297; from *Ann. chim. anal. appl.*, 4, 156—157).—The meta-compound, when heated in aqueous solution with a few drops of a 1 per cent. solution of acetaldehyde in proof-spirit slightly acidified with acetic acid, yields, when cold, a splendid yellow coloration with a strongly green fluorescence. The para-compound turns orange-red without any fluorescence.

L. DE K.

Estimation of Urea in the Tissues: and the Amount contained in the Liver. By RUDOLF GOTTLIEB (*Chem. Centr.*, 1899, i, 1298; from *Arch. Exp. Path. Pharm.*, 42, 238—249).—The urea is first isolated as a mercuric compound by von Schroeder's process; finally, the alcoholic solution of the urea is precipitated by an ethereal solution of oxalic acid and the acid contained in the urea oxalate found by titration.

The blood of starving dogs contains 0.011—0.02 per cent. of urea; when on meat diet, it increases to 0.033—0.056 per cent. The liver, contrary to expectation, contains only 0.008—0.02 per cent.

L. DE K.

Detection of "Saccharin" in Wines. By DIOSCORIDE VITALI (*Chem. Centr.*, 1899, i, 1297—1298; from *Boll. Chim. Farm.*, 38, 297—300).—The only trustworthy method is based on the conversion of the sulphur of "saccharin" into sulphate.

Small quantities of "saccharin" may be estimated by precipitation with mercuric nitrate. The precipitate is then weighed and the amount of mercuric oxide in it estimated, the difference representing the "saccharin."

L. DE K.

Employment of Chloral Hydrate in the Estimation of Alkaloids. By EDUARD SCHAEER (*Zeit. anal. Chem.*, 1889, 38, 469—472).—The author completely confirms Lenz's opinion (*Abstr.*,

1899, ii, 391) as to the value of chloral hydrate for the extraction of the vegetable alkaloids from plant products, especially when large proportions of resins and ethereal oils are present. A still more powerful solvent, especially for solid fats and waxes, is a concentrated alcoholic solution of chloral alcoholate. Mauch has made the observation that the salts of the alkaloids are dissolved by aqueous chloral hydrate as readily as the free bases. A difficulty is, however, encountered in the extraction of strychnine from nuxvomica seeds and Ignatius beans, in consequence of the presence of mucoid compounds, which (in common with certain varieties of starch and also animal gelatin) swell up in chloral hydrate, and render it viscous. Caoutchouc and gutta percha also resist completely the solvent action of chloral hydrate, and, when they are present to a large extent, no advantage results from the use of chloral.

Mauch asserts that when the chloral hydrate solutions of the bases are warmed, the bases are often converted into formates. So far as the author's experience extends, the chloral solutions of the alkaloid salts exhibit great permanence, and, may be heated on the water-bath without loss of alkaloid.

M. J. S.

The Chromic Acid Test for Cocaine. By GEORGE L. SCHAEFER (*J. Amer. Chem. Soc.*, 1899, 21, 936—938. Compare Abstr., 1899, ii, 715).—In reply to the criticisms of Squire (*Chemist and Druggist*, April 22), Cowmley (*Pharm. J. Trans.*, April 15), and Merck (*Pharm. Zeit.*, No. 42), the author upholds his own chromate process.

L. DE K.

The Active Principle of Cayenne Pepper. By KARL MICKO (*Chem. Centr.*, 1297; from *Zeit. Unters. Nahr.-Genußsm.*, 2, 411—412. Compare Abstr., 1899, i, 716).—Capsacutin described by Mörbitz is probably the same compound as the author's capsaicin, $C_{18}H_{18}O_3N$, the active principle of *Capsicum annuum*, L., and *Capsicum fastigiatum*, Bl.

Reactions of capsaicin.—When moistened with neutral solution of ferric chloride and a little alcohol, insoluble, greenish-blue drops are noticed, but this test is not particularly delicate. Strong sulphuric acid and a particle of sugar cause, after some hours, a fine violet coloration. When heated on the water-bath with strong hydrochloric acid, an alkaloidal substance is obtained which yields precipitates with platinic chloride, iodine, and potassium mercuric iodide.

L. DE K.

Detection of Nucleo-albumin in Urine by means of Tannin. By LÉON GARNIER and L. MICHEL (*J. Pharm.*, 1899, [vi], 10, 150—152).—The precipitate produced when tannin (Almén's reagent) is added to urine previously diluted with its own volume of a saturated solution of sodium chloride, consists chiefly of tannin with a small amount of sodium chloride and traces of nitrogenous substances. The phosphates present in the urine cause the precipitation of the tannin. Ott's statement (*Jahresber. für Thierchemie*, 1895, 567) that the formation of this precipitate is a sure test for the presence of nucleo-albumin is thus proved to be erroneous.

H. R. LE S.

Estimation of the Products of Digestion with Pepsin. By JEAN EFFRONT (*Chem. Zeit.*, 1899, 23, 770—771 and 783—784).—A solution of tannin in tartaric acid may be employed for separating proteoses and peptones, as proteoses are precipitated and peptones remain in solution; its use is suggested as a reagent in the analysis of the products of peptonisation. For a complete analysis, the following determinations should be made: 1, total nitrogen; 2, total proteids; 3, syntonins; 4, proteoses; 5, peptones. For the total proteids, the solution is precipitated with phosphotungstic acid, the precipitate washed with $N/2$ hydrochloric acid and dried without removal from the filter; the nitrogen in this precipitate is estimated, and the number thus obtained multiplied by 6.25 gives the total proteids. Syntonins may be estimated by exactly neutralising the solution with sodium hydroxide (1:10), or even more correctly by estimating the total proteids in the original solution and then in the neutralised solution, the difference between the two determinations giving the percentage of syntonins. Proteoses may be precipitated by a tartaric acid solution of tannin after the albumin is first removed by coagulation, and the syntonins by neutralisation. The solution is made by dissolving tannin (50 grams) in water (500 c.c.) adding N -sodium hydroxide (50 c.c.), making up to 1 litre, and then adding 15 c.c. of a 10 per cent. tartaric acid solution. The precipitate is well washed, then dried between filter-paper, and the percentage of nitrogen determined. The peptones which remain in solution may be precipitated by phosphotungstic acid.

The percentages of peptoses obtained by salting out with zinc sulphate, and by precipitating with a tartaric solution of tannin, are not concordant when the proteid solution has undergone an appreciable amount of peptonisation.

The results obtained also indicate that phosphotungstic acid is an uncertain reagent for estimating peptones. It appears that, after prolonged peptonisation, the peptones are no longer precipitated by this reagent, and it is concluded that the compounds known as peptones are really substances of very different characters, some of which are precipitated by the phosphotungstic acid reagent and others not, and, further, that peptones themselves are acted on by pepsin.

The process of analysis described above gives accurate results only when peptonisation has proceeded for a short time. J. J. S.

Analysis of Glue and Leather. By WILHELM FAHRION (*Chem. Zeit.*, 1899, 23, 452—453).—Glue and leather contain a small quantity of fatty matter, which, however, is partially oxidised, and incompletely soluble in light petroleum. To estimate fat in glue, 10 grams of the cut-up sample are heated with 40 c.c. of 8 per cent. alcoholic potash on the water-bath, adding some more alcohol if necessary, and finally evaporating to dryness. The residue is then dissolved in hot water and rendered acid with hydrochloric acid. The liquid is heated nearly to boiling for half-an-hour, then transferred to a separating funnel, and, when cold, shaken with ether and then left to settle overnight. The aqueous layer is drawn off, the ether poured off, and the hydroxy-acids which adhere to the sides of the funnel are dissolved in hot

alcohol. Both the ethereal and alcoholic solutions are then evaporated in the same tared dish.

Alcoholic potash is also useful in leather analysis. The rasped sample is first extracted with light petroleum to obtain the bulk of the fat. It is then treated with alcoholic potash as described, but on faintly acidifying with hydrochloric acid, a precipitate of tannin and its derivatives (phlobaphens) is obtained which occludes some more fat, and also any hydroxy-acids. The fat may be extracted with ether, but as yet a process is not known for the separation of fatty hydroxy-acids from the tannin precipitate. The latter may be dried and weighed, but as it always contains mineral matters, it must be finally burnt to ash.

L. DE K.

Estimation of Humus in Soils. By C. ASCHMAN and HAROLD FABER (*Chem. Zeit.*, 1899, 23, 61).—25 grams of the finely divided air-dried sample are put into a porcelain dish and heated for 1 hour on the boiling water-bath with 100 c.c. of aqueous caustic soda (50 grams per litre); the liquid is poured off and the extraction repeated several times. The whole, including the deposit, is then made up to 510 c.c. (10 c.c. being occupied by the insoluble matter) and after the supernatant liquid has become clear, an aliquot part is syphoned off and tested as follows: 0.125 gram of humic acid (*acid. huminic. pur.*) is dissolved in soda solution and diluted to 500 c.c.; 5 c.c. are diluted to 100 c.c., 10 c.c. of dilute sulphuric acid (1:5) added, and the liquid boiled with addition of solution of potassium permanganate (0.32 gram per litre) until the colour is no longer discharged. 10 c.c. of a solution of oxalic acid (0.63 gram per litre) are now added and the excess of oxalic acid titrated back with the permanganate solution. The usual blank experiment is then made, and having thus found the humic acid value of the permanganate, the amount of humic acid in the soil may be ascertained by titration. For the success of the experiment, it is necessary that the amount of the humic acid present in the aliquot part of the solution of the sample shall not materially differ from the amount used in the standardising experiment.

L. DE K.

Analyses of Ginger. By EDWY G. CLAYTON (*Analyst*, 1899, 24, 122—125).—The author has analysed 37 samples of ginger from various sources (some of them being again analysed after steeping in water or proof spirit) and has tabulated the results.

The analysis comprises the following estimations: soluble and insoluble ash; the extracts obtained with cold water, ether, absolute alcohol (after complete extraction with ether), and light petroleum respectively; essential oil; alkalinity calculated as potash, and chlorine in the soluble ash; in certain cases, the ash, alkalinity of the ash, chlorine in the cold water extract, water, and silica were also determined.

It appears that the commercial processes—washing, scraping, cutting, grinding, and separation of fibre—do not so alter the composition of genuine ginger as to convey the idea that it has been adulterated with spent ginger, except in some cases where excessive washing had occurred.

L. DE K.

General and Physical Chemistry.

Electrical Conductivity of Alkali Chlorides and Nitrates. By FRIEDRICH KOHLRAUSCH and MARGARET E. MALBY (*Chem. Centr.*, 1899, ii, 465—466; from *Sitz. Kgl. Akad. Wiss. Berlin*, 1899, 665).—With the view of testing the theoretical connection between molecular conductivity and ionic migration, the conductivities in dilute solution of the chlorides and nitrates of potassium, sodium, and lithium have been determined with the greatest care. The numbers in the following table give the equivalent conductivities at 18° for solutions of the concentration m , and represent the mean of several determinations, which agreed on the average to 1/4000th.

m .	KCl.	NaCl.	LiCl.	KNO ₃ .	NaNO ₃ .	LiNO ₃ .
0·0001	129·05	108·06	98·06	125·49	104·53	94·38
0·0002	128·76	107·80	97·78	125·18	104·18	94·07
0·0005	128·09	107·18	97·13	124·44	103·53	93·45
0·001	127·33	106·48	96·45	123·64	102·85	92·80
0·002	126·29	105·55	95·55	122·59	101·88	91·91
0·005	124·40	103·79	93·86	120·47	100·07	90·27
0·01	122·42	101·95	92·08	118·20	98·16	88·55
0·02	120·00	99·66	89·88	115·27	95·70	86·38
0·05	115·94	95·86	86·22	110·09	91·60	82·86
0·1	112·00	92·01	82·35	104·77	87·24	79·24
0·2	107·96	87·73	77·93	98·74	82·28	75·06
0·5	102·40	80·93	70·65	89·23	74·05	68·03
1·0	98·28	74·34	63·30	80·47	65·86	60·80

For solutions up to and including the concentration $N/500$, each ion has a specific conductivity, which depends on the concentration alone; up to $N/10$ solution, the deviations from this rule amount to ± 1 per cent. As a rule, the fall of ionic conductivity with increasing concentration is most rapid in the case of ions with high migration velocity, but no general and simple law can be laid down. Within the same limits, the fall of conductivity is, in the cases of potassium and sodium, more rapid for the nitrate than for the chloride; in the case of lithium, more rapid for the chloride than for the nitrate.

J. C. P.

Change of Free Energy in Fused Halogen Compounds of some Heavy Metals. By RICHARD LORENZ (*Zeit. anorg. Chem.*, 1899, 22, 241—255. Compare Abstr., 1899, ii, 269).—In determining the E.M.F. of polarisation for a number of fused salts (Abstr., 1899, ii, 267), Czepinski found the temperature coefficient abnormally large at higher temperatures. Further investigation by Weber (Abstr., 1899, ii, 724) has shown that this coefficient dE/dT is regular, even up to high temperatures, when the electrodes are kept far enough apart; the necessity for this is due to the diffusing and penetrating power of the halogen and the metallic vapour.

Differentiation of the equation $E = Q + T.dE/dT$ leads to the relation $-dQ/dT = T.d^2E/dT^2$. Thus, when dE/dT is constant, Q must also be constant. This relation is approximately fulfilled in the case of lead chloride, so that the molecular heat of the compound is very nearly the sum of the atomic heats of the components. On the assumption that this relation holds exactly, the E.M.F. may be extrapolated for ordinary temperatures. The value thus calculated for the E.M.F. of the system $Pb | PbCl_2 | Cl_2$ is 1.65 volts, agreeing with the value 1.59 volts for the E.M.F. of decomposition of lead chloride in solution, calculated by Bodländer from its solubility.

The paper also discusses the ionic concentrations in fused salts, leading to the conclusion that the dissociation of fused silver chloride is rather more than twice that of fused lead chloride. J. C. P.

Coagulative Power of Electrolytes. By W. C. DAMPIER WHETHAM (*Phil. Mag.*, 1899, 48, 474—477).—The coagulative power of an electrolyte may be taken as inversely proportional to the number of gram-equivalents necessary to produce immediate coagulation in a given solution of a colloid. The coagulative powers of sulphates with uni-, bi-, and ter-valent ions stand in the ratio 1 : 35 : 1023 (compare *Trans.*, 1895, 67, 63), those of chlorides in the ratio 1 : 30 : 1650. There is certainly an intimate connection between the coagulative power and the electrical properties of a solution, and it may be supposed that to produce coagulation a certain minimum electrical charge is necessary. Further, as the electrical charge on an ion is proportional to its valency, equal charges are carried by $2n$ triads, $3n$ dyads, or $6n$ monads. On this basis, it is shown that the coagulative powers of uni-, bi-, and ter-valent ions in equivalent solution are in the ratio $1 : x : x^2$, agreeing well with the numbers just quoted. If this view is correct, the coagulative power of a quadri-valent metallic sulphate would be about 30,000 times as great as that of a sulphate with a univalent ion. J. C. P.

Application of the Dissociation Theory to the Electrolysis of Aqueous Solutions of Two Electrolytes with One Common Ion. By JAMES G. MACGREGOR (*Chem. Centr.*, 1899, ii, 82; from *Trans. Roy. Soc. Canada*, [ii], 4, 117—148).—The author has calculated the values of the dissociation in solutions of mixed electrolytes with one common ion, and obtained from these values the ratio of the transference numbers of the other two ions, the values so resulting being compared with those obtained by Hopfgartner (*Abstr.*, 1898, ii, 151). The agreement was satisfactory in the cases of solutions of sodium and hydrogen chlorides, potassium chloride and iodide, and barium and hydrogen chlorides. Agreement was not obtained in the case of solutions of copper and hydrogen sulphates, but this is explicable by the dissociation of the acid into H and HSO_4 ions as well as into H_2 and SO_4 ions. L. M. J.

Theory of the Electrolytic Solution Pressure. By R. A. LEHFELDT (*Phil. Mag.*, 1899, 48, 430—433).—The electrolytic solution pressure, Π , of a metal is calculated from the observed E.M.F.

between the metal and the solution in which it is immersed by the equation $E = RT/\epsilon \log_e \Pi/P$, where ϵ is the quantity of electricity associated with 1 gram-equivalent, and P is the osmotic pressure of the metallic ions in the solution. For zinc, Π has the very high value 9.9×10^{13} atmospheres. An expression is obtained for the tension due to the electrical double layer between the metal and the ions in solution, leading to the equation, $x = \sqrt{D\Pi/2\pi\epsilon^2}$, where x is the number of gram-equivalents that go into solution per sq. cm. of surface, and D the dielectric constant of the medium. From this equation, it may be shown that in order to produce the solution pressure attributed to zinc, 1.27 grams of the metal would have to pass into the ionic form per sq. cm. immersed, a conclusion which is not borne out by observation. Besides this difficulty with regard to the electrolytic solution pressure of zinc, there is one of another kind in the case of palladium, for which $\Pi = 1.5 \times 10^{-36}$; the smallness of this value involves the rejection of the molecular theory of fluids.

J. C. P.

Thermal Conductivity in Gases. By M. SMOLUCHOWSKI R. VON SMOLAN (*Chem. Centr.*, 1899, ii, 353, from *Oesterr. Chem. Zeit.*, 2, 385).—It has been previously shown that, as foretold by Maxwell, the thermal conductivity of a gas is independent of pressure. The author shows, however, that this does not hold for very low pressures, and in this case a temperature difference occurs at the surface of gas and solid. When the mean wave-length is greater than the dimensions of the containing vessel, the phenomena are very complicated. Brush's assumption of the existence of etherion is not justified, and the author considers the supposed element to be merely aqueous vapour (compare Abstr., 1899, ii, 287).

L. M. J.

Thermal Capacity and Colour Changes of Solutions of Cobalt Chloride. By M. WREWSKY (*Chem. Centr.*, 1899, i, 1202; from *J. Russ. Chem. Soc.*, 1899, 31, 164—171).—Owing to difficulties in calorimetry at high temperatures, the changes in colour were brought about by the addition of alcohol. The change from a blue to a red solution is accompanied by an increase in the difference between the thermal capacities of solution and solvent. The author considers the results support Berthelot's hydrate theory. The decrease of thermal capacity by dissolution of salts is a function of both concentration and temperature, increase of both acting in the same sense.

L. M. J.

NOTE BY ABTRACTOR.—With regard to the comparison of the heat capacities of a solution and its components, see Tammann, Abstr., 1896, ii, 289.

Thermal Capacity of Solutions of Sulphuric Acid. By EUGEN VON BIRON (*Chem. Centr.*, 1899, i, 1202—1204; from *J. Russ. Chem. Soc.*, 1899, 31, 171—203).—The author has determined the mean specific heat between 18.6 and 21.8 for solutions of sulphuric acid of the composition $H_2SO_4 \cdot nH_2O$, where n varies from 0 to 1600, the extreme values for these liquids being 0.3352 and 0.99675. The molecular heat for the monohydrate is 51.17, that calculated from its

components being 50.9, and the difference is ascribed to the heat of dissociation of the hydrate. At dilutions greater than $\text{H}_2\text{SO}_4, 100\text{H}_2\text{O}$, a linear relationship is found to exist between the equivalent electrical conductivity and the difference between the found and calculated values for the molecular heat, so that it appears probable that both owe their origin to the same cause (compare Tammann, *Abstr.*, 1896, ii, 289).
L. M. J.

Some Boiling Point Curves. II. By JOHN K. HAYWOOD (*J. Amer. Chem. Soc.*, 1899, 21, 994—1001).—A continuation of the author's previous paper (*Abstr.*, 1899, ii, 632), the mixtures examined being benzene with chloroform, carbon tetrachloride, ether, acetone, and methyl alcohol; and methyl alcohol with ethyl alcohol, carbon tetrachloride, and ether. Minima were obtained in the following cases at the temperatures and composition given: benzene with methyl alcohol, 58.3° ; 53 to 67 per cent. of benzene; methyl alcohol with carbon tetrachloride, 55.95° , about 18.4 per cent. of alcohol. The law previously suggested that chemically similar substances yield similar boiling point curves again receives support, whilst it also appears that similarity of constitution of the two mixed compounds is unfavourable to the production of a minimum even when the boiling points are close together.
L. M. J.

Liquid Mixtures of Constant Boiling Point. By GARNETT RYLAND (*Amer. Chem. J.*, 1899, 22, 384—396).—A mixture of methyl alcohol and benzene containing 38 per cent. of alcohol distils at the constant temperature $57-57.5^\circ$; similarly, a mixture of ethyl alcohol and benzene with 32 per cent. of alcohol distils unchanged at $67-68^\circ$. The composition of the mixture with constant boiling point is in both cases dependent on the pressure.

Numerous binary mixtures of organic liquids have been examined with the view of discovering mixtures of constant boiling point. Forty-five have been found to boil at a constant temperature at or below the boiling point of the more volatile constituent, two above the boiling point of the less volatile constituent, and one between the boiling points of the constituents. For these mixtures of constant boiling point, the ratio of the two constituents in the distillate is approximately that of the products of their vapour density and vapour tension at the temperature of distillation, a result in accordance with earlier researches on the subject.
J. C. P.

Melting Points in Systems of Optical Isomerides. By H. W. BAKHUIS ROOZEBOOM (*Proc. K. Akad. Wetensch. Amsterdam*, 1899, 1, 466—468).—Melting point curves for mixtures of the racemic and dextro-compounds were examined in the case of dimethyl tartrate and dimethyl diacetyltartrate. In the first case, the racemic compound melts at 89.4° and the active compound at 43.3° , and a minimum of 41.6 is reached at 3 per cent. of racemic compound; in the second case, the melting point of the racemic compound is 83.8° and that of the active compound 104.3° ; the minimum of 83.4° is reached at about 86 per cent of the racemic compound. In both cases, the form of the curve is almost horizontal at the racemic compound, and indicates

considerable dissociation. The results confirm the author's previously published theoretical views (Abstr., 1899, ii, 401). L. M. J.

Freezing Point of Mixtures of Acetic Acid and Water. By ALBERT DAHMS (*Ann. Chim. Phys.*, 1899, [vii], 18, 140—142. Compare Abstr., 1897, ii, 245; 1899, ii, 546).—Coppet's determinations of the freezing points of dilute acetic acid agree closely with the values previously obtained by the author, who has also anticipated the theoretical conclusions deduced by this investigator. G. T. M.

Freezing Point of Mixtures of Acetic Acid and Water. A Reply. By LOUIS C. DE COPPET (*Ann. Chim. Phys.*, 1899, [vii], 18, 142—144).—The author, whilst admitting that Dahms first determined the freezing point of the eutectic mixture of acetic acid and water, claims to have discovered the lower freezing point of a superfused mixture at a temperature about 2° lower than the eutectic point. The author's conclusions were originally published over 27 years ago.

Since binary liquid mixtures having two eutectic points and three freezing points are known, it is highly probable that similar mixtures having three or more eutectic points should be capable of existence. G. T. M.

Test by Freezing Point Determinations of the Dissociation Values obtained by the Conductivity Method in the case of Solutions of Potassium and Sodium Sulphates. By E. H. ARCHIBALD (*Chem. Centr.*, 1899, ii, 7, and *Chem. News*, 1899, 80, 46, *et seq.*; from *Trans. Nova Scotia Inst.*, 10, 33).—Determinations were made of the electrical conductivity of solutions of each of the compounds at various dilutions at 18° and at 0°. In the case of potassium sulphate solutions at concentrations above 0.35, the dissociation is slightly greater at 0° than at 18°. The cryoscopic depressions of the solutions were also determined by the method adopted by Loomis, with whose results also the values are in good accord. Comparison of these depressions with those calculated from the dissociation values show the agreement to be close, the differences never exceeding 4 per cent., being, however, for the sodium chloride always in the same directions. For mixtures of equal volumes of solutions containing molecular proportions of the two salts, the depression is given by the expression $D = 1.86, (1 + a_1 + a_2)N/2$, where N is the number of gram-equivalents per litre of each salt in the solutions mixed, and a_1, a_2 the dissociation [this expression appears to involve the assumption that the salts are equally dissociated, which is, however, almost the case for the salts examined], and the depressions so calculated are found to agree well with those determined experimentally. L. M. J.

Cryoscopic Behaviour of Substances with Constitutions similar to that of the Solvent. V. By FELICE GARELLI and F. CALZOLARI (*Gazzetta*, 1899, 29, ii, 357—375. Compare Abstr., 1899, ii, 732).—The cryoscopic behaviour of various substances has been studied in solvents, from which they are derived by the substitution of an amino- or a hydroxyl group for a hydrogen atom. In the following cases, abnormal molecular weights were obtained, indicating the formation of solid solutions between the solvent and the solute; *p*-hydroxy-

azobenzene and *p*-aminoazobenzene dissolved in azobenzene; *m*-nitro- and *p*-nitro-phenol and *o*-nitro-, *m*-nitro-, and *p*-nitro-aniline in nitrobenzene; 2:4-dinitroaniline in *m*-dinitrobenzene; *p*-xylydine in *p*-xylene; *p*-hydroxyacetophenone in acetophenone; triphenylcarbinol in triphenylmethane; and glycollic acid in acetic acid. With solutions of *o*-nitrophenol in nitrobenzene, 2:4-dinitrophenol in *m*-dinitrobenzene, and *p*-aminoacetophenone in acetophenone, normal molecular weights are obtained.

T. H. P.

Influence of the Solvent on the Cryoscopic Behaviour of Phenols. By KARL AUWERS [with W. BARTSCH and H. M. SMITH] (*Zeit. physikal. Chem.*, 1899, 30, 300—340).—If the abnormal cryoscopic depressions of hydroxy-compounds are due to association, then an association constant should be obtainable by a calculation similar to that used for obtaining the dissociation constant. Experiments with acetoxime, benzophenoxime, *l*-camphoroxime, benzoic acid, and *o*-bromobenzoic acid, however, show that, except in the last case, no constant value for the association constant is obtained, at least not on the assumption of double molecules. Determinations with other compounds to high concentrations further show that the molecular weight does not, in general, tend to any constant value; the greatest value of association hitherto observed is about four, whilst cryoscopic depressions of ethyl alcohol in benzene give values leading to seven times the normal molecular weight. It appears, therefore, that the abnormal depressions are not due to association, but to some mutual influence of solvent and solute, and determinations were made of the depressions of a number of hydroxy-compounds in various solvents. The following were employed as solvents, and the cryoscopic constant obtained for each is added:—Nitrobenzene, 70; *m*-dinitrobenzene, 106; *p*-nitrotoluene, 78; 2:4-dinitrotoluene, 89; 2:4:6-trinitrotoluene, 115; *p*-chloronitrobenzene, 109; *p*-dichlorobenzene, 77; *p*-chlorobromobenzene, 92; *p*-dibromobenzene, 124; benzil, 105. In all these solvents, ortho-substitution derivatives of phenol were cryoscopically normal as in benzene or naphthalene; with para-compounds, however, this is not the case, *p*-nitrophenol, methyl *p*-hydroxybenzoate, and *p*-hydroxybenzaldehyde being abnormal in the halogen compounds, but almost normal in those solvents containing a nitro-group, so that the halogen increases and the nitro-group decreases the abnormalising influence in the solvent. Other substituted phenols dissolved in *p*-dichloro-, *p*-chlorobromo-, and *p*-dibromo-benzene were then investigated, and it was found that, as in naphthalene, para-compounds are more abnormal than meta-, and the order of the groups arranged according to their influence in giving abnormal values is: aldehyde, cyanide, substituted carboxyl, nitro-groups, whilst the abnormality is greatest in dichlorobenzene, and least in dibromobenzene. The abnormal cryoscopic depressions are hence the product of two factors, one dependent on the constitution of the solute, the other on that of the solvent (compare Abstr., 1896, ii, 293; 1897, ii, 476). L. M. J.

Influence of the Medium on the Heats of Solution of Salts. By N. GALITZKI (*Chem. Centr.*, 1899, ii, 469—470; from *J. Russ. Chem. Soc.*, 31, 536—540).—The effect of increasing quantities of alcohol on

the heats of solution of potassium nitrate and potassium carbonate in water has been investigated. By the addition of alcohol to water, the heat of solution is diminished, the diminution ultimately reaching a minimum, which depends on the nature of the dissolved salt. No connection could be traced between this phenomenon and the electrical conductivity of the solutions.

J. C. P.

The Critical State. By KONRAD DIETERICI (*Ann. Phys. Chem.*, 1899, 69, 685—705).—For most substances hitherto investigated, the ratio of the actually observed critical density to the ideal density (the density which the substance would have if the law $pv = RT$ held for the critical pressure and temperature) is nearly constant, and equal to 3.75; for ethylene, nitrous oxide, nitrogen, and oxygen, the ratio differs considerably from 3.75, but this is probably due to deficient experimental methods.

In van der Waals' equation, the cohesion pressure is equal to a/v^2 , and the correction for the molecular volume is a constant b ; in these circumstances, the ratio v_0/v_k (ideal volume : critical volume) has the value 2.67. This want of correspondence between experiment and van der Waals' equation remains, even when b is regarded as a function of v .

If the equation $(p + \pi)(v - b) = RT$ be accepted, and the cohesion pressure $\pi = a/v^{5/3}$ instead of a/v^2 , the ratio v_0/v_k is equal to 3.75. This purely empirical law regarding the cohesion pressure, although it brings van der Waals' equation into agreement with the critical phenomena, is without theoretical basis.

Other theoretical considerations lead to the equation $p = RT/(v - b) \cdot e^{-A/RT}$, where A is a function of v , and represents the work to be done by a molecule against the forces of cohesion. On the supposition that $A = C/v$, the ratio v_0/v_k is equal to 3.695, a value agreeing closely with that given by experiment.

J. C. P.

Hydrolytic Dissociation in Salt Solutions. By HEINRICH LEY (*Zeit. physikal. Chem.*, 1899, 30, 193—257).—In a salt solution, besides the electrolytic dissociation, hydrolysis may occur with the formation of acid and base which further undergo electrolytic dissociation. The concentrations of the various molecular groupings present in the solution are determined by the equilibrium constants for the hydrolytic dissociation and for the electrolytic dissociation of salt, acid, base, and water. The author first investigates theoretically the necessary equations for the cases where (1) either base or acid is weak; (2) both acid and base are weak. For the determination of the hydrolysis, the method of sugar inversion was found suitable, and the author obtains the value 16.8 for the inversion constant at 100°, which is thus intermediate between the values 17.9 found by Trevor (*Abstr.*, 1893, ii, 62) and 16.0 found by Smith (*Abstr.*, 1898, ii, 155). The variation of the constant with temperature was also determined and found to be given by the expression $K_{T_1} = K_{T_0} e^{A(T_1 - T_0)/T_1 T_0}$, where A is a constant. Some salts were found to cause an irregular increase of inversion, apparently not due to hydrolysis, as, for example, lanthanum chloride. Lithium and magnesium salts have no effect, but beryllium and aluminium cause considerable inversion, and for these the hydrolytic constant was calculated at dilutions from 32 to

512. The values do not remain constant, but the author considers the agreement to be satisfactory, owing to the complicated equations and the fact that they are rigorously valid for only binary electrolytes. From the values of the dissociation, the basicity of the hydroxides may be compared, and it is thus found that beryllium hydroxide is about eleven times as strong a base as aluminium hydroxide. Salts of cerium, copper, and zinc are only very slightly hydrolysed; lead causes greater inversion, but still far less than the aluminium salts. The hydrolysis of methyl acetate was also employed for the determinations, and the values for the hydrolysis of aluminium chloride by this process agree well with those obtained by the inversion method. Conductivity determinations may also serve for the calculation of hydrolysis; the acetates of manganese, cobalt, zinc, and nickel exhibit a perfectly normal change of conductivity with dilution, and are hence not hydrolysed. With acetate of lanthanum, cerium, and lithium, this is not the case, whilst acetates of lead, beryllium, aluminium, and mercury give very abnormal results, indicating considerable hydrolysis. Where quantitative results were obtained, the values of percentage hydrolysis at $v=1024$ and 25° are: beryllium sulphate, 5 per cent.; aluminium chloride, 4.5 per cent.; lead chloride, 4.4 per cent.; uranium nitrate, 5.9 per cent.; mercuric perchlorate ($v=512$), 37 per cent. (Abstr., 1898, ii, 66).

L. M. J.

Determination of Solubility Coefficients of Liquids. By A. AIGNAN and E. DUGAS (*Compt. rend.*, 1899, 129, 643—645).—When aniline and water are mixed, there is no alteration of total volume consequent on the reciprocal solubility of the liquids, and in this case it is possible to determine the solubilities by observation of the volumes of the two layers before and after agitation, in two different experiments. The values so obtained in c.c. per cubic centimetre are: (1) aniline in water, 0.036; (2) water in aniline, 0.042. In the case of water and fermentation amyl alcohol, however, the total volume does not remain constant, and very diverse values for the solubilities, sometimes even negative, are obtained, so that in this case the author considers the case is not one of simple solubility, and the results may be due to the fact that one of the alcohols present in the fermentation amyl alcohol is capable of combining with water.

L. M. J.

Equilibrium between Manganous Salts and Ammonia. By W. HERZ (*Zeit. anorg. Chem.*, 1899, 22, 279—284).—The results previously obtained (Abstr., 1899, ii, 752) were not in harmony with the law of mass action, but it is now found that at lower concentrations the equation $K = [\text{Mn}^{++}][\text{NH}_3]^2/[\text{NH}_4]^2$ gives fairly constant values of K : in this equation, the symbols in square brackets indicate the concentrations of the respective molecules or ions. With the mean value of $K = 1.6 \times 10^{-3}$, and the dissociation constant of ammonia = 0.000023, the solubility of manganous hydroxide is calculated to be 0.6×10^{-4} , a value of the same order as that obtained by Bodländer from other considerations.

J. C. P.

Fusion of Sodium Thiosulphate. Hydrates. By FRIEDRICH WILHELM KÜSTER and A. THIEL (*Zeit. anorg. Chem.*, 1899, 21, 401—404).—Fused sodium thiosulphate might be regarded either as

a definite liquid compound, or as a reciprocal solution of the decomposition products of the crystallised salt. In the first case, excess of water or anhydrous thiosulphate in the fused hydrate would give two distinct series of solutions, the properties of which might be represented by two curves, cutting each other at the point corresponding with the composition $\text{Na}_2\text{S}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$. If, on the other hand, the fused hydrate is merely a reciprocal solution of water and anhydrous salt, its properties ought to be intermediate between those of solutions with excess of water and anhydrous salt respectively. The latter behaviour has been observed in the case of the conductivity. As the number of water molecules to one molecule of anhydrous salt rises from 4.69 to 6.65, the conductivity increases proportionally, and there is no discontinuity whatever corresponding with the composition $\text{Na}_2\text{S}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$.

J. C. P.

Molecular State of Ammonia and of Amines in Aqueous Solutions. By ARTHUR HANTZSCH and F. SEBALDT (*Zeit. physikal. Chem.*, 1899, 30, 258—299).—In the hope of solving this question, the author determined the partition ratio of ammonia and amines between water and other solvents. Ammonia in water and chloroform was first examined; if it exists as hydroxide, the scheme of dissociation is $\text{NH}_4\text{HO} \rightleftharpoons \text{NH}_3 + \text{H}_2\text{O} \rightleftharpoons \text{NH}_4^+ + \text{HO}^-$, and as ammonia is but a weak base, the latter dissociation is very slight. The calculation of the partition ratio is made on the assumption that the hydroxide itself is insoluble in chloroform, and as the concentration of the gaseous ammonia in the aqueous phase is proportional to that of the hydroxide, the total concentration may be, and is, employed instead of that of the gaseous ammonia only. The value for the partition ratio, water/chloroform at 25° , is about 25, and remains constant for varying concentrations, but it increases with fall of temperature. The values were not affected by the addition of ammonium chloride, a result the authors consider to be surprising, although, in view of the slight electrolytic dissociation of ammonium hydroxide, it might have been expected. The partition of piperidine between benzene and water and the effect of addition of piperidine hydrochloride, were next examined; the addition of sodium hydroxide was found to cause considerable decrease in the partition ratio, which was also found to decrease with increase of temperature. The partition at various temperatures was also determined for trimethylamine and triethylamine between water and toluene; acetic acid, pyridine, hydrogen cyanide, and cyanacetic acid between water and benzene; and for acetic acid, cyanacetic acid, ferric thiocyanate, and mercurous chloride between water and ether. With the amines, in every case the partition ratio decreases with rise of temperature; this was also the case in a few other systems, but in most the converse obtained. This seems to indicate the existence of hydroxides and an increase of molecular dissociation at higher temperatures, but the authors consider it more probable that hydrates, and not hydroxides, exist in the solutions. In ammonia solutions, the temperature coefficient is very small, and here especially the quantity of hydroxide must be very small.

L. M. J.

Conversion of Mixed Crystals into a Compound. By H. W. BAKHUIS ROOZEBOOM (*Proc. K. Akad. Wetensch. Amsterdam*, 1899, 2, 74—77).—No difference is observable in the melting points of dextro-lævo-, and inactive camphoroxime, or of mixtures in any proportions; the solid mass is further perfectly homogeneous, so that the existence of mixed crystals is confirmed (Forster and Pope, *Trans.*, 1897, 71, 1049), and the melting point curve for the mixture is hence a horizontal line. The transition point to monoclinic crystals varies from 112.6° for 100 per cent. of either compound to 109.4° for the inactive mixture, and the curve is quite symmetrical, and here also mixed crystals are again formed. By cooling still more, a further change takes place, and this occurs at 103° for the inactive mixture, but the temperature is considerably reduced by excess of either component, and could not be observed at all when the percentage rose above 75. In this case, therefore, the mixed crystals become converted into a compound, and the views of Pope (*loc. cit.*) are confirmed (see *Abstr.*, 1899, ii, 401).

L. M. J.

Mixed Crystals of Mercuric Iodide and Bromide. By W. REINDERS (*Proc. K. Akad. Wetensch. Amsterdam*, 1899, 2, 146—148).—The melting point curve of mixed crystals of mercuric iodide and bromide is continuous between the temperatures 236.5° and 255.4° , the melting points of the bromide and iodide respectively. It passes through a minimum at 216.1° , corresponding with a mixture containing 59 per cent. of mols. of the bromide, and at this temperature the crystals deposited have the same composition as the molten mixture; if the latter contains more (or less) bromide than the above-named quantity, the crystals deposited are richer (or poorer) in bromide than the mixture. Below 216° , mixed crystals in all proportions can exist.

At 127° , yellow mercuric iodide is converted into the red modification. By admixture of the bromide, this transition point is lowered and also widened out into a transition-interval determined by two limiting curves, one for the yellow, and the other for the red, crystals. The former of these runs from 127° when no bromide is present to a point on the 0° abscissa corresponding with 33 per cent. of mols. of the bromide; whilst that for the red crystals proceeds from the same starting point and cuts the 0° abscissa in a point indicating the presence of 8.6 per cent. of the bromide molecules. The transition interval was determined partly by observation of the colour change, as this made it possible to determine the composition of red crystals which at a definite temperature change completely into the yellow variety; further, solutions were found by trial, each of which deposits at a particular temperature, both red and yellow mixed crystals. These curves could not be continued below 0° , but their direction shows that, if there is a transition point for mercuric bromide, it must be at a very low temperature; at -83° , no indications of such transition could be found.

Solid mercuric bromide and iodide diffuse into one another at ordinary temperatures, and more so when heated, and the transition temperature of a finely-powdered mixture of them agrees very nearly with that of the mixed crystals of the same composition. T. H. P.

Properties of Flames. By NICOLA TECLU (*J. pr. Chem.*, 1899, [ii], 60, 396—399).—I. A stream of coal gas is allowed to issue from a platinum tube about 12 mm. in length and 2 mm. in diameter, so as to afford a flame of definite dimensions, the pressure of the gas at the point where it enters the tube being registered by means of an alcohol manometer. It is found that on heating the platinum tube by means of a flat flame bunsen burner, if the gas supply is taken directly from the main, the flame suffers a contraction of about 70 per cent., whilst the manometer registers only a small increase in pressure (about 40 mm.). If, on the other hand, the gas is supplied from a small laboratory gas-holder, the flame suffers no appreciable contraction when the tube is heated, but the manometer registers an increase in pressure nearly three times as large as in the former case (about 110 mm.).

The explanation offered is that the disturbances, set up by the sudden increase in bulk which the gas undergoes in coming into contact with the heated tube, are propagated backwards with the velocity of compression waves, and suffer reflection in the small laboratory apparatus, producing pressure in the mass of gas and thus affecting the manometer and serving to maintain the size of the flame; where the enormous technical gasometers are involved, the energy of the waves is minimised or dissipated.

II. An apparatus is described which consists of a modification of that used in the ordinary lecture experiment for demonstrating the reciprocal nature of combustion. A. L.

A Dissolver. By ARTHUR JOHN HOPKINS (*Amer. Chem. J.*, 1899, 22, 407—410).—In this apparatus, a glass tube passing through a doubly-bored indiarubber stopper, fitted to a tall glass cylinder, is connected near the bottom of the latter with one limb of a Y-tube, the lower limb of which is open, whilst the third is connected to a vertical glass tube which reaches up nearly to the stopper, and is there curved downwards. Through the second hole in the stopper passes a tube connected with a filter pump which serves to draw a current of air through the apparatus, the rate of this being regulated by a stop-cock on the tube open to the air. The crystals to be dissolved are placed at the bottom of the cylinder; the saturated solution formed there is withdrawn continuously by the suction in the Y-tube and discharged upon the less saturated solvent at the top, fresh solvent thus being brought continuously in contact with the substance to be dissolved. W. A. D.

Inorganic Chemistry.

Biological and Chemical Purification of Water. By A. TIXIER (*J. Pharm.*, 1899, [vi], 10, 297—300).—In order to avoid the liberation of free alkali which occurs when potassium permanganate or calcium permanganate is used for the purification of water, the

author uses a solution containing aluminium permanganate and barium permanganate. The solution employed has a specific gravity of 35° B., and contains 290 grams of permanganic acid per litre, and 7 per cent. of alumina. It is added to the water to be purified until a persistent pink coloration is produced; the water is allowed to remain for 24 hours, and after filtration through a carbon or other filter is fit for consumption. H. R. LE S.

New Ozone Apparatus. By NICOLA TECLU (*J. pr. Chem.*, 1899, [ii], 60, 402—403).—Several new forms of apparatus for exhibiting the phenomenon of ozone production during electric discharge are figured. A. L.

Spectrum of Chlorine. By JOSEF M. EDER and EDUARD VALENTA (*Chem. Centr.*, 1899, ii, 358).—The spectrum of chlorine was examined at pressures varying from 10 to 100 mm., a concave grating being employed. The authors confirm Ciamician's observation of the broadening of many lines and increase of brightness of the continuous spectrum by increase of pressure, but no band spectrum was obtained. Very characteristic lines were those of wave-length 4132 in the violet and 3860 in the ultra-violet, and the wave-length of many lines are given which at low pressures are seen to be doubled or trebled; a line at 3750 does not become broader by increased pressure. L. M. J.

Colour of Chlorine Solutions. By E. H. SARLES (*J. Amer. Chem. Soc.*, 1899, 21, 1038).—When chlorine is passed into ethyl alcohol, the liquid finally separates into a lower yellow layer and an upper layer having a grass-green colour. The green solution has bleaching properties which it, however, loses when uncombined chlorine is removed by a current of air or carbon dioxide. The solvent, which gives a green solution of chlorine, has not been isolated; it is either easily decomposed or very volatile, since when the liquid has been fractionated several times, the green colour is completely lost and cannot be regained by passing fresh chlorine into the liquid. J. J. S.

Theory of the Electrolytic Formation of Hypochlorite and Chlorate. By FRITZ FÖRSTER (*Zeit. anorg. Chem.*, 1899, 22, 1—32).—Investigation of the formation of hypochlorite and chlorate as a purely chemical process (Abstr., 1899, ii, 278) has prepared the way for a theory of the electrolytic preparation of these substances. A review of the work dealing with the electrolysis of alkali chlorides (compare Oettel, Abstr., 1896, ii, 517; Haber and Grinberg, Abstr., 1898, ii, 215 and 365; Wohlwill, Abstr., 1899, ii, 213) shows that the following conclusions may be regarded as established. Hypochlorite is formed chiefly by the interaction of the chlorine liberated at the anode with the alkali produced during the electrolysis or previously present: in alkaline solution, hypochlorite can be oxidised to chlorate by a primary anode process; the formation of chloric acid in the electrolysis of dilute hydrochloric acid is due to the direct oxidation of Cl ions at the anode.

A theory of the secondary electrolytic formation of chlorate is discussed, based on two suppositions; (1) that in the electrolysis of

neutral alkali chloride solutions, chlorine is continually being liberated at the anode, (2) that the hypochlorite takes part in the electrolysis, and that its ions are discharged at the anode with evolution of oxygen. The known facts regarding the influence of current density, temperature, acidity, and alkalinity, on the formation of chlorate, are largely in harmony with the theory; further experiments to determine the exact nature of the process have been made by Müller (see following abstract). J. C. P.

Formation of Hypochlorite and Chlorate in the Electrolysis of Alkali Chlorides. By ERICH MÜLLER (*Zeit. anorg. Chem.*, 1899, 22, 33—90. Compare Abstr., 1899, ii, 742).—The supposition that in the electrolysis of neutral alkali chloride solutions the formation of hypochlorite and chlorate depends on the same purely chemical process as in the non-electrolytic formation of these compounds, has several consequences. Experiment on the whole confirms these consequences, and shows that the electrolytic formation of chlorate in neutral alkali chloride solutions consists in the following processes; chlorine is discharged at the anode, and unites with the alkali from the cathode to form hypochlorite; even while the hypochlorite concentration is still small, ClO^- ions are discharged at the anode, forming hypochlorous acid, which in its turn oxidises hypochlorite and chloride to chlorate; at low temperatures, hypochlorite is to a small extent oxidised by anode oxygen.

Experiments in acid and alkaline solutions of the alkali chlorides lead to the conclusion that the electrolytic process in these does not differ essentially from that in neutral solution. The electrolytic formation of chlorate may thus be referred in general to four equations: (1) $\text{Cl}^- + 3\text{HClO} = \text{ClO}_3^- + 3\text{H}^+ + 3\text{Cl}^-$; (2) $\text{ClO}^- + 2\text{HClO} = \text{ClO}_3^- + 2\text{H}^+ + 2\text{Cl}^-$; (3) $\text{Cl}^- + 3\text{O} = \text{ClO}_3^-$; (4) $\text{ClO}^- + 2\text{O} = \text{ClO}_3^-$. In dilute hydrochloric acid, the existence of ClO^- ions is excluded, and in this case the formation of chlorate must take place according to equation (3). In other cases, the processes may be represented in varying degree; thus, when there is no appreciable evolution of oxygen, the chief processes are those indicated by equations (1) and (2); when the evolution of oxygen is considerable, as in strongly alkaline solutions, the formation of chlorate will take place chiefly according to equations (3) and (4). J. C. P.

Molecular Weights of some Elements and their Derivatives. By GIUSEPPE ODDO and E. SERRA (*Gazzetta*, 1899, 29, ii, 343—353).—The molecular weight of iodine has been determined by the boiling point method, the solvents employed being tetrachloromethane, carbon disulphide, benzene, and ethyl alcohol. The numbers obtained with the first two solvents are sensibly the same as those of Beckmann and Stock (Abstr., 1895, ii, 382). Benzene and ethyl alcohol yielded the respective values 273—279 and 265—327, Beckmann and Stock's numbers being 335—360 and 330—342; the latter results, being corrected for the volatility of iodine, give the values 233—255 and

233—241 respectively. The authors' object to this very large correction being applied, as with slow boiling, the amount of iodine volatilised is very small and scarcely sufficient to colour the vapour of the solvent.

In boiling tetrachloromethane, the sulphur molecule contains 8 atoms up to concentrations of about 3 per cent.; beyond that strength of solution, the results obtained are not concordant.

Phosphorus pentachloride has the normal molecular weight in boiling tetrachloromethane.

Solutions of iodine mono- or tri-chloride in tetrachloromethane give lower boiling points than that of the pure solvent. In the case of the trichloride, this is due to the fact that it sublimes at 70—75°. With the monochloride, dissociation takes place according to the equation $9\text{ICl} = \text{I}_2 + \text{I}_4 + 3\text{ICl}_3$, and the effect of the trichloride in lowering the boiling point is greater than that of the iodine in raising it.

T. H. P.

Action of Arsenious and Antimonious Oxides on Sulphur Monochloride. By GIUSEPPE ODDO and E. SERRA (*Gazzetta*, 1899, 29, ii, 355).—When arsenious oxide and sulphur monochloride are heated together in a reflux apparatus, they react according to the equation: $\text{As}_2\text{O}_3 + 6\text{S}_2\text{Cl}_2 = 4\text{AsCl}_3 + 3\text{SO}_2 + 9\text{S}$. The reaction is complete in about an hour, and on cooling, nearly all the sulphur formed crystallises out and the arsenic trichloride can be separated by decantation.

Analogous reactions take place when antimony or bismuth sesquioxide is substituted for the arsenic compound.

T. H. P.

Hydrates of Sulphuric Acid. By EUGEN VON BIRON (*Chem. Centr.*, 1899, ii, 467—468; from *J. Russ. Chem. Soc.*, 31, 517—522).—The author has succeeded in crystallising the hydrate $\text{H}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$, predicted by Mendeléeff. A solution of the composition $\text{H}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$, cooled with liquid air, solidifies to an amorphous mass. This mass, if rubbed at rather a higher temperature with a glass rod, becomes crystalline, the thermometer rising at the same time to -35° . The crystals thus obtained may be used to start crystallisation in a solution of the composition $\text{H}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$ cooled merely to -75° with solid carbon dioxide and ether. Cooling with liquid air is detrimental to the formation of the crystals.

The freezing point of the hydrate was determined in a Beckmann's apparatus of small size, well protected by surrounding tubes, and cooled in a mixture of carbon dioxide and ether. During solidification, the thermometer remained steady for about 10 minutes, until practically no liquid was left, showing that the separation of the solid did not alter the freezing point of the remaining liquid. In solutions which deviated from the composition $\text{H}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$, the thermometer was steady for only 1—2 minutes. The freezing point of the hydrate is -38.9° ; with the same apparatus, the hydrate $\text{H}_2\text{SO}_4 \cdot 4\text{H}_2\text{O}$ solidified at -69° .

J. C. P.

Polymerisation of Inorganic Chloro-Anhydrides. I. By GIUSEPPE ODDO and E. SERRA (*Gazzetta*, 1899, 29, ii, 318—329. Compare this vol., i, 92).—Determined by the boiling point method, the

molecular weight of phosphorus oxychloride in various solvents is as follows: In tetrachloromethane, 325—362; benzene, 283—309; carbon disulphide, 214—244; chloroform, 159—164; ether, 147—157. The cryoscopic method gives a value 149—152 in benzene. The number corresponding with the formula POCl_3 is 153.5.

The molecular weight of thionyl chloride in boiling chloroform is 229—235 and in freezing benzene 108—110; the formula SOCl_2 requires 119.

Phosphorus oxybromide has a molecular weight of 287—310 in boiling tetrachloromethane and 334—352 in boiling benzene; the cryoscopic method gives a value 293—308 in benzene. The calculated value for POBr_3 is 287. Phosphorus thioclchloride gives the following molecular weights. In boiling tetrachloromethane, 209; in boiling benzene, 236—247; in freezing benzene, 158—161. The calculated number is 169.5.

For sulphur monochloride, the values obtained are, in boiling tetrachloromethane, 169—173, and in boiling benzene, 180—193; the formula S_2Cl_2 requires 135.

Chromyl chloride in boiling tetrachloromethane gives the molecular weight 225—243; in boiling benzene, 441—528; and in freezing benzene, 165—175. The formula CrO_2Cl_2 corresponds with a value 155.5.

The cryoscopic method gives for the molecular weight of sulphuryl chloride in benzene the number 131, the value for SO_2Cl_2 being 135.

T. H. P.

Properties of Solutions of Sodium Nitrite. By JOSEF JURI BOGUSKI (*Chem. Centr.*, 1899, ii, 470; from *J. Russ. Chem. Soc.*, 1899, 31, 543—551).—Sodium nitrite, prepared from the commercial article by crystallising from solutions saturated at 125° , has a yellowish tinge which disappears, however, when the salt is dried over sulphuric acid or washed with alcohol, but even then the colourless salt still forms yellowish solutions. This coloration is due to the presence of a foreign substance. The variation of the sp. gr. with the concentration of solutions of the nitrite is represented by a curve which is very nearly a straight line. The specific refractive index of solutions at 20° may be calculated from the formula $[n]_D = 1.33336 + 0.0011559 P$, where P = percentage of nitrite dissolved. The original paper contains copious data and many tables. E. W. W.

NOTE.—As to the colour of sodium nitrite and its solutions, compare Divers (*Trans.*, 1899, 75, 86), Groves (*Proc.*, 1898, 222).—EDITORS.

Preparation of Cæsium from the Carbonate. By EDMUND GRAEFE and MORITZ ECKARDT (*Zeit. anorg. Chem.*, 1899, 22, 158—160).—A repetition of Winkler's experiments (*Abstr.*, 1890, 331) on the reduction of alkaline carbonates proves Beketoff's assertion that the reduction to metal takes place more easily as the atomic weight increases. The preparation of cæsium is effected at a lower temperature than that of rubidium or potassium. A mixture in the proportion $\text{R}_2\text{CO}_3 : 3\text{Mg}$ is heated in an iron tube, free from rust, in a slow current of dry hydrogen and the metal, which distils

collected under petroleum; a theoretical yield is obtained. Metallic caesium is silver-white with a yellow tinge, retains its lustre under petroleum, oxidises with development of heat on exposure to the air, then melts and explodes, swims on water, and burns with a reddish-violet flame with liberation of hydrogen. E. C. R.

Calcium and its Compounds. By HENRI MOISSAN (*Ann. Chim. Phys.*, 1899, [vii], 18, 289—343).—A detailed account of work already published (compare Abstr., 1894, i, 313; 1898, ii, 116, 161, 578; 1899, ii, 25, 152, 153, 155, 219, 241, and 418). G. T. M.

Setting of Gypsum. By KARL ZULKOWSKI (*Chem. Centr.*, 1899, ii, 602—603; from *Chem. Ind.*, 22, 349—352).—The setting of the ordinary roasted gypsum is due to the formation of the calcium salt, $\text{S}(\text{OH})_4 \cdot \text{O}_2\text{Ca}$, of hexabasic sulphuric acid by the action of water (2 mols.). Gypsum which has been roasted at a moderate red heat is also capable of taking up water, but on account of its greater density it only combines with 1 mol. of water, forming the calcium salt, $\text{SO}(\text{OH})_2 \cdot \text{O}_2\text{Ca}$, of tetrabasic sulphuric acid. The water has a twofold action, first dissolving the more soluble calcium compound, and then combining with it to form a less soluble compound which separates in a crystalline form and sets to a compact mass. E. W. W.

Preparation and Properties of Crystallised Barium and Strontium Phosphides. By A. JABOIN (*Compt. rend.*, 1899, 129, 762—765).—Crystallised strontium phosphide is obtained by heating a mixture of lampblack and strontium phosphate for 3 or 4 minutes in an electric furnace with a current of 45 volts and 950 ampères, and the barium compound is obtained in a similar way. *Strontium phosphide*, Sr_3P_2 , burns in fluorine at the ordinary temperature, in chlorine at about 30° , in bromine at 170 — 175° , in iodine at a red heat, in oxygen above 300° , and in sulphur vapour at a higher temperature. It is decomposed by carbon at a high temperature, but not by sodium at a red heat; by dilute acids and gaseous hydracids, but not by concentrated acids, nor by hydrogen sulphide or ammonia, nor by organic solvents. It alters rapidly in moist air, is decomposed by water with liberation of hydrogen phosphide, and is violently attacked by oxidising agents. Its sp. gr. is 2.68 and it melts only in the electric furnace. *Barium phosphide*, Ba_3P_2 , has similar properties, but is not so readily attacked; it burns in chlorine at 90° and in bromine at 260 — 300° . Its sp. gr. is 3.183. C. H. B.

Formation of Oceanic Salt Deposits, Particularly of the Stassfurt Beds. XIV. Influence of Pressure on the Formation of Tachyhydrite. By JACOBUS H. VAN'T HOFF and H. M. DAWSON (*Chem. Centr.*, 1899, ii, 401—402; from *Sitzungsber. Akad. Wiss. Berlin*, 1899, 557—562. Compare Abstr., 1899, 759).—The effect of increase of temperature and pressure on the evaporation of sea-water is to cause the separation of new compounds, for when the change of the solubilities of the various compounds affected by the alteration of conditions exceeds certain limits, supersaturation with new compounds is rendered possible. Increase of temperature and pressure results in the formation of kieserite, löweite, kainite, and langbeinite, none of

these compounds being formed when sea water is evaporated at 25° under the ordinary pressure. The salt basins of Besançon have a temperature of 62° at a depth of 1.35 metres, and reckoning on this basis the variations of temperature and pressure in the case of the Stassfurt beds which have a maximum depth of 1500 metres amount to 40 and 180 atmospheres respectively.

The effect of changes of temperature and pressure has been investigated in the case of the formation of tachyhydrite ($\text{MgCl}_2 \cdot \text{Ca} \cdot 12\text{H}_2\text{O}$), which easily separates from mixed solutions of the hexahydrates of magnesium and calcium chlorides at 22°. Experiments with the manocryometer and Beckmann's thermometer show that an extra pressure of one atmosphere only raises the temperature of the formation of tachyhydrite by 0.017°. This effect is comparable with that of pressure on melting points; it lies between the raising of the melting point of ice by 0.0073° and that of paraffin by 0.035° caused by a pressure of one atmosphere. Hence, since an increase of pressure of 180 atmospheres would only raise the temperature of formation by 3°, the effect of increase of temperature must be of much greater importance.

E. W. W.

Solution of Copper in Gelatin Solutions. By ALEXANDER P. LIDOFF (*Chem. Centr.*, 1899, ii, 471; from *J. Russ. Chem. Soc.*, 1899, 31, 571—572).—From the results of experiments on the action of copper salts on alkaline solutions of albumin, it appears that the biuret reaction really depends on the dissolution of copper, the copper salt being reduced to soluble colloidal copper. An alkaline solution of gelatin in which copper gauze was placed had acquired a violet coloration after remaining a day, and after 48 days 3.54 per cent. of the copper was found to have been dissolved.

E. W. W.

Manganese Trichloride and Tetrachloride. By RICHARD JOS. MEYER and HANS BEST (*Zeit. anorg. Chem.*, 1899, 22, 169—191).—The dark green solution of oxides of manganese in hydrochloric acid contains manganese trichloride. Each of the oxides, Mn_2O_3 , Mn_3O_4 , or MnO_2 , when dissolved in absolute alcohol or ether saturated with hydrogen chloride, yields a solution of manganese trichloride which is decomposed by water and also by evaporation in a vacuum over sulphuric acid, and consequently the trichloride cannot be isolated. It, however, yields very characteristic double salts with pyridine and quinoline hydrochlorides which crystallise in lustrous needles.

The action of hydrogen bromide on the oxides of manganese results in the formation of the dibromide which yields a crystalline double salt with pyridine hydrobromide.

When potassium permanganate is boiled with acetic acid, carbon dioxide is evolved and a brown solution obtained, which on cooling deposits the salt, $3\text{MnO}_2 \cdot \text{Mn}_2(\text{C}_2\text{H}_3\text{O}_2)_6 + 2\text{C}_2\text{H}_4\text{O}_2$, and if a small quantity of water is added to the mother liquor, Christensen's triacetate, $\text{Mn}_2(\text{C}_2\text{H}_3\text{O}_2)_6 + 4\text{H}_2\text{O}$, crystallises out. The solution obtained by reducing potassium permanganate with acetic acid with the addition of 1 mol. of potassium acetate, when saturated with hydrogen chloride yields the double salt $\text{MnCl}_2 \cdot 2\text{KCl}$ (Rice, *Trans.*, 1898, 75, 258). If, however, the solution is only partially saturated with

hydrogen chloride, the salt $\text{MnCl}_4 \cdot \text{MnCl}_2 \cdot 5\text{KCl}$ is obtained. When the acetic acid solution of potassium permanganate, without the addition of potassium acetate, is saturated with hydrogen chloride, a small quantity of the salt $\text{MnCl}_4 \cdot 2\text{KCl}$ is obtained as a black, crystalline precipitate, and the mother liquors contain large quantities of manganese trichloride. The corresponding ammonium salts could not be isolated, although the reaction proceeds apparently in a similar manner. Cæsium permanganate, under similar conditions, yields the salt $\text{MnCl}_4 \cdot 2\text{CsCl}$. Thallium permanganate does not yield a double salt.

The double sulphate, $\text{Mn}_2(\text{SO}_4)_3 \cdot \text{K}_2\text{SO}_4$, is precipitated quantitatively by adding sulphuric acid to the solution of potassium permanganate in acetic acid.

The higher chlorides of iron, cobalt, and nickel are not obtained by the above method. Lead dioxide, when dissolved in cold alcohol saturated with hydrogen chloride, is converted into the tetrachloride, which yields crystalline double salts with pyridine, di- and tri-methylamine hydrochloride, and tetramethylammonium chloride.

Thallium permanganate, TlMnO_4 , forms large, nearly black prisms.

E. C. R.

Atomic Weight of Cobalt. III. Analysis of Cobaltous Chloride and Cobaltous Oxide. By THEODORE W. RICHARDS and GREGORY P. BAXTER (*Zeit. anorg. Chem.*, 1899, 22, 221—234. Compare Abstr., 1898, ii, 377, and 1899, ii, 753).—The authors have determined the weight of the cobalt obtained from a known weight of cobaltous chloride by reducing it in a current of hydrogen. The methods employed are essentially the same as those previously described. The mean of the two experiments gives for the atomic weight $\text{Co} = 59.045$. The cobaltous chloride was prepared by decomposing purpureo-cobalt chloride at 200° and eliminating the remaining ammonium chloride by heating in a current of nitrogen and hydrogen chloride. The cobaltous chloride was found to contain small quantities of ammonium chloride, alkali salts, and silica.

Cobaltous oxide is prepared by precipitating a solution of pure cobalt in nitric acid with ammonia, and after heating the precipitate over a spirit burner, decomposing the resulting black oxide at a red heat in a vacuum. The reduction of the cobaltous oxide by means of hydrogen gave for the atomic weight $\text{Co} = 58.954$ (mean of three experiments). An examination of the cobaltous oxide shows that it contains a small quantity of a higher oxide; also, by heating the oxide in a vacuum at 800° , a partial reduction takes place into metal and oxygen, and since a perfectly constant oxide could not be obtained, the authors have abandoned the experiments.

The results of all the experiments show that the atomic weight of cobalt lies between 58.93 and 59.06 and the most probable value is $\text{Co} = 58.995$ when $\text{O} = 16$.

E. C. R.

Occlusion of Hydrogen by Cobalt and other Metals. By GREGORY P. BAXTER (*Amer. Chem. J.*, 1899, 22, 351—364).—Although cobalt in the form of ingots, which therefore presents a minimum amount of surface, is known to occlude practically no hydrogen, it is

found that when reduced from the oxide, and therefore in a very finely divided condition, it occludes relatively large amounts of this gas. Electrolytic foil, which although somewhat porous lies between the two modifications in relative surface, falls between them also in its occluding power. The volume of occluded hydrogen varies, in the case of metal reduced from the oxide, with its purity and the temperature of reduction; it is remarkable that the metal reduced from cobalt bromide occludes practically no hydrogen; this appears to be due to its being deposited in a more compact form than that reduced from the oxide, as the presence of sodium bromide has no perceptible effect on the amount of occluded gas. Since the occlusion of hydrogen progresses very slowly at the ordinary temperature and is practically negligible at the temperature of reduction ($400-500^{\circ}$), it must be a maximum at some intermediate temperature; the time during which the metal is in contact with hydrogen determines largely the amount of gas taken up. Although practically none of the hydrogen occluded is given off in a vacuum at the ordinary temperature, yet on heating in a vacuum nearly the whole is evolved.

The occlusion of hydrogen by nickel appears to be governed by similar conditions to those dealt with in the case of cobalt; with pure copper and silver, the occlusion is practically *nil*. W. A. D.

Chromyl Chloride, Chlorochromic Acid, and Aminochromic Acid. By RICHARD JOS. MEYER and HANS BEST (*Zeit. anorg. Chem.*, 1899, 22, 192—199).—Chromyl chloride is obtained by the action of hydrogen chloride on a solution of chromic acid in acetic acid, but cannot be separated from the acetic acid solution. When pyridine, dissolved in acetic acid, is added to the solution, chlorine is evolved, and the *pyridine* salt of hexachlorotrichromyl chloride, $\text{Cr}_2\text{O}_3\text{Cl}_6 \cdot 3\text{PyHCl}$, is obtained, which crystallises in brownish-gold leaflets. The same salt is also obtained by adding pyridine hydrochloride to a solution of pure chromyl chloride in acetic acid.

Pyridine and quinoline, when added to a solution of potassium chlorochromate in acetic acid, yield pyridine and quinoline chlorochromates respectively, which separate in yellowish-red crystals, are stable, and can be recrystallised from dilute hydrochloric acid.

No evidence of the formation of aminochromic acid was obtained by the action of ammonia on a solution of potassium chlorochromate in dry acetone. E. C. R.

Recovery of Chromic Acid from Chromium Residues. By FRIEDRICH REGELSBERGER (*Zeit. angew. Chem.*, 1899, 1123—1128).—Various methods have been suggested for recovering chromic acid (compare Häussermann, *Dingl.*, 268, 163; Lorenz, *Abstr.*, 1896, ii, 265; Heibling, French Pat. 275274; Fitzgerald, Eng. Pat. 1896, 5542; Dercum, Eng. Pat. 1898, 3801; Meister, Lucius, and Brünig, German Pat. 103860). Two different electrolytic methods are described in the paper. The one consists in oxidation in alkaline solution: a current is passed through a saturated solution of an alkaline chloride containing an amount of chromic oxide or chromium salt equivalent to the current in unit time. When potassium chloride is employed, potassium dichromate crystallises from the hot solution

after some time, and chlorine is liberated. The metal vessel in which the electrolysis was conducted served as the cathode, and platinum gauze as the anode, and, to ensure complete admixture, air was blown through. The method may be of practical use when the chromium liquors contain considerable amounts of organic matter, or when solid chromium residues have to be dealt with.

The second method consists in the use of lead anodes in acid solution, either with or without a diaphragm; the lead is first converted into peroxide, which then oxidises the chromium compounds. The electrolysis proceeds best in hot solution, and almost any metal may be employed as cathode. Iron salts must not be present in the liquid.

J. J. S.

Preparation of Molybdenum and Uranium with the Aid of Liquid Air. By ALFRED STAIVENHAGEN (*Ber.*, 1899, 32, 3065. Compare next abstract but one).—The yield of molybdenum from a mixture of molybdic acid, aluminium, and liquid air is poor, owing to the volatility of molybdic oxide. A mixture of uranic acid and aluminium explodes with great difficulty, but when liquid air is added, the reaction is very violent, and a thoroughly fused uranium regulus is obtained.

G. T. M.

Molybdenum Dioxide. By MARCEL GUICHARD (*Compt. rend.*, 1899, 129, 722—725).—Various oxides of molybdenum, intermediate in composition between MoO_2 and MoO_3 , have been described by former observers as being produced by heating molybdenum trioxide with ammonium molybdate and by the electrolysis of fused molybdenum trioxide. Both these reactions have been studied by the author, who finds that the sole product, after excess of molybdenum trioxide has been removed by successive washing with soda and hydrochloric acid, is in each case molybdenum dioxide, which was obtained in a pure, crystalline state.

N. L.

Preparation of Tungsten with the Aid of Liquid Air. By ALFRED STAIVENHAGEN (*Ber.*, 1899, 32, 3064—3065).—The addition of liquid air to the mixture of aluminium and tungstic acid employed in the preparation of tungsten (*Abstr.*, 1899, ii, 489), produces, on explosion, so great a rise of temperature that a completely fused regulus of tungsten is obtained which contains only traces of aluminium. The author was unable to obtain the element by Hallepeau's electrolytic method (*Abstr.*, 1899, ii, 158). When molten lithium paratungstate is electrolysed with a current of 3.5 ampères and an E.M.F. of 12 volts, bluish-black crystals of lithium-tungsten bronze are produced.

G. T. M.

Tungsten. By EDGAR F. SMITH (*J. Amer. Chem. Soc.*, 1899, 21, 1007—1008).—An introductory paper, referring to those treated in the following abstracts and in this vol., i, 76, 89.

J. J. S.

Atomic Weight of Tungsten. By EDGAR F. SMITH and WILLETT L. HARDIN (*J. Amer. Chem. Soc.*, 1899, 21, 1017—1027. Compare *Abstr.*, 1898, ii, 336).—Recent experiments prove that practically no hydrogen is occluded when metallic tungsten is allowed to cool in an atmosphere of this gas (compare Waddell, *Abstr.*, 1887, 112; Derenbach,

Inaug. Diss. Würzburg, 1892). It has been proved that tungsten trioxide exists in two varieties, crystalline and amorphous. These differ in specific gravity and also in their solubility in sulphur monochloride; they may be converted into one another. If the insoluble oxide is converted into ammonium tungstate and then ignited, the oxide which is formed dissolves in sulphur chloride at 145° , and when the metal obtained from the oxychloride is heated in a current of oxygen, the oxide formed is insoluble in sulphur chloride at 145° .

The authors conclude that, so far, there is no trustworthy method for the determination of the atomic weight of tungsten. The methods they have employed are (1) heating pure tungsten in air or in pure oxygen; (2) precipitating metallic silver from silver nitrate solution by the aid of metallic tungsten (compare Smith, *Abstr.*, 1893, ii, 170); (3) estimating the water of crystallisation in barium metatungstate (compare Scheibler, *J. prakt. Chem.*, 1861, 83, 324). In no case were concordant results obtained.

J. J. S.

Action of Sulphur Monochloride on Tungsten Trioxide. By EDGAR F. SMITH and HERMANN FLECK (*J. Amer. Chem. Soc.*, 1899, 21, 1008—1013).—When tungsten trioxide, the dioxide, or the mineral wolframite or scheelite is heated with sulphur monochloride, a red solution of tungsten oxychloride, $WOCl_4$, is obtained, together with a small amount of a brown, insoluble substance. The trioxide obtained by heating ammonium tungstate, or the trioxide which has been heated for some time in the air, is not completely acted on by sulphur chloride, whereas the trioxide obtained by heating the oxychloride is practically all dissolved by it. This difference is not due to the presence of a nitride or oxynitride. Tungsten itself is not acted on by pure sulphur monochloride, but if free chlorine is present, tungsten hexachloride is formed.

J. J. S.

Rays Emitted by Uranium and Thorium Compounds. By SKŁODOWSKA CURIE (*Compt. rend.*, 1898, 126, 1101—1103).—The electrical conductivity of air, when induced by the Becquerel rays emitted by uranium compounds, varies directly with the amount of this element present in the active substance. All uranium compounds are active, and the metal itself more so than any of its derivatives, except pitchblende and native chalcocite (copper uranylphosphate); the latter substance, however, when prepared artificially, is less active than the metal; these results seem to indicate that the two minerals contain an element far more active than uranium. Thorium compounds are very active, the action of thoria being more pronounced than that of metallic uranium; cerium, niobium, and tantalum compounds are slightly active. Yellow phosphorus is extremely active, but its action is probably of a nature different from that of uranium and thorium; in the allotropic form and in the phosphates, it is quite inert; the compounds of all other elements do not appreciably influence the electrical conductivity of air. The effects produced by the rays vary directly with the thickness of the layer of active substance; the rays traverse thin sheets of glass, ebonite, paper, and the metals. The rays emitted by thoria are more penetrating than those from uranium, and the penetrative power is augmented by increasing the layer of the oxide.

Distinct photographic impressions are obtained in the case of uranium, uranous oxide, pitchblende, chalcocite, and thorium, but those produced by thorium sulphate and potassium fluoroxytantalate are very faint. When uranium and thorium compounds are subjected to the influence of Röntgen rays, they emit secondary rays, which produce a more intense effect than those emitted by lead under similar conditions.

G. T. M.

New Radio-active Substance contained in Pitchblende. By P. CURIE and SKŁODOWSKA CURIE (*Compt. rend.*, 1898, 127, 175—178. Compare preceding abstract).—A specimen of pitchblende, having $2\frac{1}{2}$ times the emissive power of uranium, was examined chemically with a view of isolating the radio-active principle which produces the abnormal activity. The mineral was dissolved in acids and treated with hydrogen sulphide, the thorium and uranium remain in solution, whilst the active substance is precipitated with the sulphides insoluble in ammonium sulphide; after separating these in the usual manner, it is found that the substance in question remains with the bismuth.

When the sulphides are treated with nitric acid, the less active portion dissolves more readily; and when the solution of the nitrates is diluted with water the more active portion is first precipitated; the progress of the separation is controlled by determining the electrical conductivity of air induced by the various fractions. An extremely active product can be isolated from pitchblende by sublimation, and when the sulphides of bismuth and the active substance are heated in a vacuum at 700° , a sublimate is obtained, the activity of which is 400 times that of uranium. It is believed that the extremely active substance obtained from pitchblende contains an unknown metal to which the name *polonium* is given. Spectroscopic examination of the substance, however, has not revealed the existence of any characteristic lines indicating the presence of a new element.

G. T. M.

An extremely Radio-active Substance contained in Pitchblende. By P. CURIE, SKŁODOWSKA CURIE, and GUSTAVE BÉMONT (*Compt. rend.*, 1898, 127, 1215—1217. Compare preceding abstracts).—In the course of their researches on radio-active substances, the authors have obtained a product having all the properties of barium chloride, and, in fact, consisting mainly of this compound, but differing from the ordinary chloride in being extremely active. By repeated fractional precipitation of the active chloride from its aqueous solution by alcohol, a product is obtained which is 900 times more active than uranium. Ordinary barium salts are never radio-active, and, moreover, spectroscopic examination of the active substance has revealed the presence of a well-defined line not belonging to any known element (compare following abstract); the distinctness of the line increases with the radio-activity of the fraction under inspection. For these reasons, it is supposed that the active barium chloride contains another radio-active element for which the name *radium* is proposed. The atomic weight of barium in the active salt is not markedly different from that of the element in its inactive compounds.

The compounds of uranium, thorium, polonium, and radium all give photographic effects on sensitive plates, and in this respect

polonium and radium are far more active than the other two; the rays emitted by the new elements render barium platincyanide fluorescent, but the effect is less marked than with Röntgen rays.

G. T. M.

Spectrum of a Radio-active Substance [in Barium Chloride]. By EUGÈNE DEMARÇAY (*Compt. rend.*, 1898, 127, 1218. Compare preceding abstract).—The spectrum of the radio-active barium chloride, together with distinct indications of barium and faint lines due to lead, calcium, and platinum (from electrodes), contains a well-defined line of wave-length 3814·8 (Rowland's scale) which appears between the platinum lines 3819·9 and 3801·5; this line has not been noticed in the spectra of any of the known elements.

G. T. M.

Spectrum of Radium. By EUGÈNE DEMARÇAY (*Compt. rend.*, 1899, 129, 716—717).—The following lines characteristic of radium were obtained from the photographed spectrum of a specimen of barium chloride containing that element. The numbers 1 to 16 indicate the order of intensity. λ , 4826·3, (10); 4726·9, (5); 4699·8, (3); 4692·1, (7); 4683·0, (14); 4641·9, (4); 4627·4, (4), the centre of a nebulous band; 4600·3, (3); 4533·5, (9); 4458·0, (3), the centre of a nebulous band; 4436·1, (8); 4364·2, (3); 4340·6, (12); 3814·7, (16); 3649·6, (12). A number of feeble lines of uncertain origin were also observed.

N. L.

Atomic Weight of the Metal in Radio-active Barium Chloride. By SKŁODOWSKA CURIE (*Compt. rend.*, 1899, 129, 760—762).—Radio-active barium chloride obtained from a large quantity of uranium residues was fractionally crystallised, and the radio-active constituent was found to accumulate in the less soluble portions; when the latter were dissolved in water and fractionally precipitated by alcohol, the active substance was concentrated in the first precipitates. The atomic weight of the radio-active barium increases with the intensity of the radiation; with an intensity 3000 times as great as that of uranium, the atomic weight is 140·0; 4700 times as great, 140·9, and 7500 as great, 145·8. The radio-activity of the crystallised or precipitated compounds increases in a marked manner for several weeks after their preparation, but eventually attains a limiting value which may be five or six times as great as the value immediately after their preparation (compare Giesel, *Ann. Phys. Chem.*, 1899, [ii], 69, 91).

C. H. B.

Enantiotropy of Tin. By ERNST COHEN and C. VAN EYCK (*Proc. K. Akad. Wetensch. Amsterdam*, 1899, 2, 77).—It is well known that at low temperatures tin becomes converted into a grey powder, but the change has been but little investigated, and various reasons have been assigned for it. The authors find that at -83° the change occurred in about 24 hours, and the reverse transition could not be observed below 30° . At temperatures between these limits, the velocity of the change becomes so small as to be incapable of measurement. By the addition of a few drops of a 10 per cent. solution of ammonium stannic chloride, however, the reaction is considerably accelerated, and dilatometric observations employing this liquid for measurement purposes indicated

a temperature of between 10° and 20° for the transition. Determinations of the E.M.F. of the cell: white tin/10 per cent ammonium stannic chloride/grey tin, gave 20° for the temperature of transition. It hence appears that all tin exists, save in exceptionally warm weather, in the metastable condition. L. M. J.

Thio- and Seleno-antimonites. By ISIDORE POUGET (*Ann. Chim. Phys.*, 1899, [vii], 18, 508—571. Compare Abstr., 1897, ii, 499).—The following salts are described for the first time. *Lithium orthothioantimonite*, $\text{Li}_3\text{SbS}_3 + 3\text{H}_2\text{O}$, forms white, deliquescent crystals; the *para-salt* $\text{Li}_4\text{Sb}_4\text{S}_7 + 3\text{H}_2\text{O}$, is a dark red, gelatinous precipitate which has not been obtained crystalline.

Ammonium orthothioantimonite, $(\text{NH}_4)_3\text{SbS}_3$, is precipitated as a white, crystalline powder on adding alcohol to the mother liquor from the meta-salt; it readily decomposes and is only stable in the presence of ammonium sulphide.

Barium metathioantimonite, $\text{Ba}(\text{SbS}_2)_2 + 4\frac{1}{2}\text{H}_2\text{O}$, is an amorphous, brown precipitate.

Triargentic thioantimonite, Ag_3SbS_3 , is obtained as an amorphous, black precipitate by the addition of silver nitrate to a dilute solution of potassium orthothioantimonite; the double salt, Ag_2KSbS_3 , is a yellow, crystalline precipitate produced by the action of silver nitrate on concentrated solutions of the potassium ortho- or pyro-salt (Sommerlad, Abstr., 1897, ii, 500). A series of double salts of the formula RAg_2SbS_3 is obtained from sodium, lithium, and ammonium thioantimonites; these compounds are all decomposed by water into triargentic thioantimonite and the corresponding alkali salt.

Zinc orthothioantimonite, $\text{Zn}_3(\text{SbS}_3)_2$, forms a yellow, crystalline precipitate, produced by the action of zinc salts on dilute solutions of potassium thioantimonite; the *double salt*, ZnKSbS_3 , is obtained when concentrated solutions are employed.

The corresponding *manganese* salts, $\text{Mn}_3(\text{SbS}_3)_2$ and MnKSbS_3 , are produced in a similar manner; they form pale red, crystalline precipitates.

The *lead* salts, $\text{Pb}_3(\text{SbS}_3)_2$ and PbKSbS_3 , are brown precipitates. The reaction between potassium orthothioantimonite and cadmium, nickel, cobalt, and ferrous salts, follows the same course as in the preceding examples, but the products are very unstable.

Cuprous potassium orthothioantimonite, $\text{Cu}_2\text{KSbS}_3 + 3\text{H}_2\text{O}$, is a yellow, crystalline precipitate obtained by treating a cupric salt with excess of a concentrated solution of potassium orthothioantimonite; *cuprous orthoantimonite*, Cu_3SbS_3 , is produced by treating the preceding double salt with water; it is a red, crystalline precipitate. A black precipitate of *cupric thioantimonite* is formed when cupric salts are treated with a dilute solution of potassium orthothioantimonite; if, however, the latter reagent is in excess, it gradually reduces the cupric salt and the precipitate then consists of a mixture of this compound with the cuprous salt.

When mercurous salts are added to solutions of the alkali orthothioantimonites, the yellow precipitate at first produced is rapidly converted into a black deposit of mercury; mercurous salts react in a

similar manner. Gold chloride, when mixed with a concentrated solution of thioantimonite, produces a brown precipitate; this redissolves on agitation, and the solution, when warmed, deposits metallic gold.

Potassium orthoselenoantimonite, K_3SbSe_3 , is obtained in the form of orange crystals on evaporating a solution of antimony selenide in potassium selenide in a current of hydrogen; the salt is extremely unstable and its solution rapidly deposits selenium. The *para*-salt $K_2Sb_4Se_7 + 3H_2O$, separates as a gelatinous, brown precipitate on cooling a saturated solution of its generators.

Sodium orthoselenoantimonite, $Na_3SbSe_3 + 9H_2O$, crystallises in yellow needles from a solution of antimony selenide in sodium selenide; it is even more oxidisable than its potassium analogue, and its solution deposits red, tetrahedral crystals of sodium selenoantimonate, $Na_3SbSe_4 + 9H_2O$.

By the joint action of selenium and antimony dissolved in potassium sulphide, the mixed *salt*, $K_{10}Sb_5S_5Se_6 + 4H_2O$, is produced; it separates from the concentrated solution in small, yellow crystals. When a solution of sodium selenide is employed as the medium, two compounds are produced; the less soluble is a complex *salt* having the composition $Na_3SbS_{1.5}Se_{2.5} + 9H_2O$, which corresponds with the thioantimonate, $Na_3SbS_4 + 9H_2O$; the more soluble *salt*, $Na_3SbS_{1.5}Se_{1.5} + 9H_2O$, forms yellow needles and is analogous to the orthoantimonite, $Na_3SbS_3 + 9H_2O$.

Tellurium derivatives, analogous to the preceding compounds, could not be prepared; antimony telluride does not dissolve in a hot solution of potassium telluride, K_2Te , or potassium hydrotelluride, $KHTe$, and tellurium itself is insoluble in alkali sulphides. G. T. M.

Derivatives and Atomic Weight of Palladium. By WILLETT LEPLÉY HARDIN (*J. Amer. Chem. Soc.*, 1899, 21, 943—955. Compare Rosenheim and Maass, *Abstr.*, 1899, i, 163).—Palladobis-phenylammonium chloride, $Pd(NH_2PhCl)_2$, is obtained as a voluminous yellow precipitate when a slight excess of aniline is added to a hydrochloric acid solution of palladious chloride, it is insoluble in hydrochloric acid, but dissolves in ammonium hydroxide solution; the *bromide*, $Pd(NH_2PhBr)_2$, resembles the chloride. *Palladodiquinolinium chloride*, $Pd(C_9NH_7Cl)_2$, the corresponding *bromide* and *palladodipiperidium chloride*, $Pd(C_5NH_{11}Cl)_2$, all form pale yellow precipitates. They are not acted on by hydrogen at the ordinary temperature, but are readily reduced to metallic palladium when heated in hydrogen and the product allowed to cool in a current of air. A compound, $PdCl_2 \cdot 2NH_2Et \cdot 2HCl$, crystallising in brownish-red scales has also been prepared.

The atomic weight of palladium has been determined by various authorities (Berzelius, 1828; Keiser, *Abstr.*, 1890, 17; Keller and Smith, *ibid.*, 1893, ii, 73; Bailey and Lamb, *Trans.*, 1892, 61, 745; Joly and Leidie, *Abstr.*, 1893, ii, 284; Keiser and Breed, *ibid.*, 1894, ii, 141) and has now been determined by analysing diphenylpalladodiammonium chloride (seven experiments) and bromide (five experiments), and also ammonium palladium bromide (four experi-

ments), all of which were prepared from carefully purified palla. The mean result obtained was 107.014 ($O=16$), which is some above that given by other authorities. J. J

Mineralogical Chemistry.

Libollite. By JACINTO PEDRO GOMES (*Comm. Direc. Tra Geol. Portugal*, 1898, 3, 244—250, 290—291).—Libollite is the given to an asphalt resembling albertite which is found near Li province of Angola, in Portuguese West Africa. Analysis gave

Limonite Pseudomorphs from Dutch Guiana. By ROBERT W. RAYMOND (*Trans. Amer. Inst. Mining Eng.*, 1899, 28, 235—).—The auriferous alluvial deposits in the Saramacca district of I Guiana contain cubes of limonite pseudomorphous after pyrites; these are sometimes hollow and are partly filled with a reddish po. Analyses by A. R. Ledoux of the outer light red crust gave I, and the interior darker red material gave II.

	Fe ₂ O ₃	Al ₂ O ₃	SiO ₂	H ₂ O.	Total
I.	42.90	17.70	30.44	5.90	96.94
II.	87.94	0.90	2.34	7.50	98.68

A small amount of gold is present in II, but not in I. L. J.

Chromite from Newfoundland. By GEORGE W. MAY (*Trans. Amer. Inst. Mining Eng.*, 1898, 27, 283—288).—Deposits of chromite are found in serpentine at Port-au-Port Bay, on the coast of Newfoundland. Analysis by E. Waller of a selected sample of the ore gave:

Cr ₂ O ₃	FeO.	MgO.	Al ₂ O ₃	SiO ₂	Total.
49.23	17.21	18.66	7.50	6.51	99.11

Also traces of calcium, vanadium, copper and manganese.

L. J.

Occurrence of Nickel in Silesia. By O. H. ASCHERMANN (*Kryst. Min.*, 1899, 32, 106; from *Inaug. Diss. Breslau*, 1897, 43).—Nickel occurs at Frankenstein, Silesia, as silicates in a red deposit, a product of serpentine (Abstr., 1895, ii, 514). The unaltered serpentine contains, according to two determinations, 0.0866 and 0.148 per cent. of nickel. L. J.

Leverrierite. By PIERRE TERMIER (*Bull. Soc. franç. Min.*, 1902, 27—31).—Previous analyses of this mineral are unsatisfactory owing to the presence of admixed quartz and clay. A new analysis made on more pure material from Rochebelle, Gard, gave the following results. Sp. gr. 2.598.

SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	MgO.	CaO.	K ₂ O.	Loss on ignition.	Total.
49.90	37.02	3.65	0.30	trace	1.13	8.65	100.65

The material analysed was dried at 110°. The loss on ignition is mainly water with a very little carbonaceous matter. The colourless crystals become white at 500°. This analysis agrees approximately with the formula $(\text{H}, \text{K})_2\text{O} \cdot (\text{Al}, \text{Fe})_2\text{O}_3 \cdot 2\text{SiO}_2$. The mineral therefore differs from kaolinite ($2\text{H}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$), and resembles muscovite, but has water largely replacing potash.

Optical determinations are also given.

L. J. S.

Minerals of Japan. By KOTORA JIMBŌ (*J. Sci. Coll. Imp. Univ. Tokyo*, 1899, 11, 213—281).—A description, dealing mainly with occurrences, is given of 128 mineral species found in Japan. Some of the information has been previously published in Japanese journals. Analyses are given of the following.

Topaz. Good crystals of topaz are found at Takayama, &c., in province Mino, and at Tanokamiyama in province Ōmi. The crystals from Ōmi are usually brownish and occur with flesh-red felspar; analyses by Takayama gave the results under I and II.

Olivine in brown crystals occurs with crystals of augite in a basalt at Nishinotake in Hizen; analysis III by Kondō.

	SiO ₂	Al ₂ O ₃	MgO.	FeO.	CaO.	F.	Total.

Biotite? The pegmatite at Tanokamiyana in Ōmi contains several varieties of mica. Analysis V, by Kodera, is of dark green plates of biotite (?) which is nearly optically uniaxial.

Zinnwaldite (?), from the same place, is reddish-brown to nearly colourless; the plane of the optic axes is parallel to the plane of symmetry, and the axial angle is large. Analysis VI by Kodera.

A dirty, dark brown mica from Kai gave VII, by Hida.

	SiO ₂	TiO ₂	Al ₂ O ₃	Fe ₂ O ₃	FeO.	MnO.	CaO.	MgO.	K ₂ O.	Na ₂ O.	H ₂ O.	F.	Total.

L. J. S.

New Minerals from Franklin, New Jersey. By SAMUEL L. PENFIELD and CHARLES H. WARREN (*Amer. J. Sci.*, 1899, [iv], 8, 339—353).—The new minerals were found in the zinc mines at Franklin, in association with native copper and lead (Abstr., 1898, ii, 602), clinohedrite (Abstr., 1898, ii, 607), roëblingite (Abstr., 1897, ii, 563), axinite, willemite, datolite, garnet, phlogopite, &c. They are probably of metamorphic (pneumatolitic) origin.

Hancockite. This occurs as brownish-red, cellular masses of minute, lath-shaped crystals, which are monoclinic, and have nearly the same habit and angles as epidote. Single crystals are yellowish-brown with a vitreous lustre, and are pleochroic. Sp. gr. 4.030. Analysis by Warren gave:

SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	Mn ₂ O ₃	PbO	MnO	MgO	CaO
30.99	17.89	12.33	1.38	18.53	2.12	0.52	11.50
SiO	H ₂ O	Total					
3.89	1.62	100.77					

This gives the epidote formula, $H_2R''R'''Si_6O_{26}$, or $R''_2(R'''OH)R'''_2(SiO_4)_3$;

but the mineral differs from epidote in containing lead and strontium isomorphous with calcium. Like epidote, the mineral is decomposed by hydrochloric acid only after ignition.

Glaucokhroite. This occurs embedded in nasonite as columnar, orthorhombic crystals of a bluish-green colour. Twins are sometimes present with individuals intercrossing at angles of about 60°. The parameters are approximately $a:b:c=0.440:1:0.566$; these ratios, as well as the optical characters, indicate that the mineral belongs to the olivine group. Sp. gr. 3.407. Analysis I, by Warren, gives the formula $CaMnSiO_4$, showing that the mineral takes a place next to monticellite ($CaMgSiO_4$).

Nasonite. This is white and massive, with a greasy to adamantine lustre. Thin sections under the microscope show the mineral to be crystalline and optically uniaxial; the system is probably tetragonal. Sp. gr. 5.425. After deducting 2.16 per cent. of clinochrodite ($\text{H}_2\text{CaZnSiO}_5$), analysis II (by Warren) gives the formula $\text{Pb}_6\text{Ca}_4\text{Cl}_2(\text{Si}_2\text{O}_7)_3 = \text{Pb}_4(\text{PbCl})_2\text{Ca}_4(\text{Si}_2\text{O}_7)_3$. This is closely related to the tetragonal ganomalite from Sweden, of which the formula is usually given as $\text{Pb}_5\text{Ca}_2\text{Si}_3\text{O}_{11} = \text{Pb}_4(\text{Pb}_2\text{O})''\text{Ca}_4(\text{Si}_2\text{O}_7)_3$. Lindström's analysis (1883) of ganomalite shows the presence of small quantities of water and chlorine, and it agrees with the formula

which is now proposed for ganomalite. Nasonite therefore differs from ganomalite in containing chlorine in place of hydroxyl.

The acid, $\text{H}_6\text{Si}_2\text{O}_7$, of which nasonite and ganomalite, as well as cordierite, barysilite ($\text{Pb}_3\text{Si}_2\text{O}_7$) and hardystonite (Abstr., 1899, ii, 435) are salts, is intermediate between ortho- and meta-silicic acids, or it may be considered as $2\text{Si}(\text{OH})_4 - \text{H}_2\text{O}$. For this acid, which is usually called diorthosilicic, the name *mesosilicic acid* is proposed.

Leucophaenicite. This is of a purplish-red or raspberry colour; it has a crystalline structure, though the crystal system, probably monoclinic, could not be determined. Sp. gr. 3.848. Analysis III (also Na_2O , 0.39; K_2O , 0.24), by Warren, agrees with the formula $\text{H}_2\text{R}_7\text{Si}_3\text{O}_{14}$, or, as the water is not expelled below a red heat, $\text{R}_5(\text{R}\cdot\text{OH})_2(\text{SiO}_4)_8$. This represents a basic orthosilicate, and the mineral is therefore a manganese humite with hydroxyl in place of fluorine.

L. J. S.

Hydrated Aluminium Silicates and Clays. By KONSTANTIN D. GLINKA (*Zeit. Kryst. Min.*, 1899, 32, 79—81; from *Mém. Inst. agron. forest. à Novo-Alexandria* [Gouv. Lublin], 1899, 12, 41—84).—Various clays were found to contain quartz, orthoclase, muscovite, rutile, zircon, tourmaline and garnet, together with kaolin, bauxite and diaspor, but no zeolites. Quartz and aluminium hydroxides may occur together, and in this case their presence will not be indicated by a bulk analysis of the clay. Their presence is, however, indicated when the material, after ignition, is treated with a 33 per cent. solution of potassium hydroxide; under these circumstances, most of the silica, but very little of the alumina, goes into solution. Several other experiments of a similar nature were made on clays and various silicates, the object being to determine the constituent minerals of clays. L. J. S.

Stokesite, a New Mineral from Cornwall. By ARTHUR HUTCHINSON (*Phil. Mag.*, 1899, [v], 48, 480—481).—A preliminary notice is given of a new mineral, of which only a single crystal, about 10 mm. long, has been found. It is colourless and transparent. System, orthorhombic [$a:b:c = 0.3479:1:0.8117$]. Sp. gr. 3.185,

H=6. The lustre is vitreous. Analysis gives the formula $\text{CaO}, \text{SnO}_2, 3\text{SiO}_2, 2\text{H}_2\text{O}$ (compare *Nature*, 1899, 61, 119). L. J. S.

Andesites from Maine. By HERBERT E. GREGORY (*Amer. J. Sci.*, 1899, [iv], 8, 359—369).—A description is given of the andesites of the Aroostook volcanic area of northern Maine. An analysis by Hillebrand is quoted. L. J. S.

Hot Sulphur Spring of Deutsch-Altenburg. By ERNEST LUDWIG and THEODOR PANZER (*Chem. Centr.*, 1899, ii, 402; from *Wien. klin. Wochensch.*, 12, 708—710).—The hot sulphur spring of Deutsch-Altenburg belongs to the same type as the hot salt-sulphur springs of Aachen and of the Hercules bath in Mevania. It is a clear water, with a strong odour of hydrogen sulphide, and becomes turbid on keeping and deposits sulphur. It has a sp. gr. 1·00289 at 18·70° and contains traces of caesium, rubidium, titanic oxide and formic acid. A full analysis is given. E. W. W.

Origin of Graubünden Mineral Waters. By GUSTAV NUSSBERGER (*Jahresber. Naturforsch. Ges. Graubündens*, 1899, 42, 1—35. Compare Abstr., 1897, ii, 569).—A detailed account is given of the mineral waters of the Canton Graubünden (= Grisons), Switzerland, and their origin discussed. Several analyses are quoted. L. J. S.

Mineral Waters of Lutraki, Greece. By ANASTASIOS K. DAMBERGIS (*Chem. Centr.*, 1899, ii, 568; from *Oesterr. Chem.-Zeit.*, 2, 437).—The mineral waters of Lutraki, on the north coast of the Gulf of Corinth, consist of three groups, which differ in temperature and quantity, but have an almost identical composition. The clear, odourless water has a sweet taste, with a somewhat saline after-taste, does not become turbid on exposure to air, and leaves no residue as it flows from the spring. The group containing the most dissolved matter contains 1·912 grams of dissolved substances per litre, has a temperature of 31°, and a sp. gr. 1·0018. An analysis is quoted. The springs belong to the class of alkaline calcareous hot springs. E. W. W.

The Water of Monsummano. By PIETRO ALBERTONI and GIUSTO CORONEDI (*Chem. Centr.*, 1899, ii, 591—592; from *Ann. Farm. Chim.*, 1899, 214—235).—The water of Monsummano has a temperature of 32° and a sp. gr. 1·000154, and 10,000 parts leave a residue of 13·012 dried at 180°. An analysis of the residue is quoted. In the original paper, the action of this water is discussed on the basis of the ion theory and clinical experiments on its therapeutic and physiological effects are also described. The small amount of calcium and magnesium salts present, and its power of dissolving uric acid, are remarkable. Uric acid dialyses much more readily into this water than into distilled water. E. W. W.

Physiological Chemistry.

Influence of Bile, of Acid, and of Alkalis on the Proteolytic Action of Pancreatic Juice. By BENJAMIN K. RACHFORD (*J. Physiol.*, 1899, 25, 165—178. Compare Abstr., 1899, ii, 567).—Experiments were made with the pancreatic juice (not extracts, as Chittenden used) and bile of the rabbit. These confirm the conclusion arrived at previously, although denied by Chittenden, that bile much favours the proteolytic action of the juice. Bile, however, retards the albuminous fermentations carried on by organised ferments. When pancreatic juice is added to fibrin half saturated with hydrochloric acid, it does as much work as on neutral fibrin. If the fibrin is nine-tenths saturated with the acid, proteolysis is retarded; this retardation also occurs in the presence of bile. Free hydrochloric acid greatly inhibits, but does not destroy, the proteolytic action, whilst sodium carbonate is favourable, especially in dilute solutions of pancreatic juice. The general conclusion is drawn that the conditions in the entire small intestine are favourable to the proteolytic activity of pancreatic juice.

W. D. H.

The Influence of Removal of Water on Metabolism and Circulation. By WALTHER STRAUB (*Zeit. Biol.*, 1899, 33, 537—566).—The effect of sodium chloride in producing a slight increase of proteid katabolism is attributed to its diuretic action, water being removed from the tissues. The present experiments on dogs were designed to test this theory by a removal of water from the food; this was found to increase proteid katabolism, but to have no influence on fat. The blood pressure is not altered, but the quantity of water lost by skin and lungs is slightly lessened.

W. D. H.

Influence of the Kind and Amount of Nutriment on Metabolism. By EDUARD PFLÜGER (*Pflüger's Archiv*, 1899, 77, 425—482).—The object of the paper is to show that proteid is the great source of energy; it increases metabolism, and raises the resistance and power of the animal; it does so by increasing the substance of the living cells, sometimes even doubling their weight. Fat and carbohydrate have no such power. Fat never arises from proteid in the animal body. Man cannot take all his nutriment in the form of proteid simply because of the limitation which exists in his digesting power.

W. D. H.

Metabolism of Nucleins. By T. H. MILROY and J. MALCOLM (*J. Physiol.*, 1899, 25, 105—130. Compare Abstr., 1899, ii, 479).—In a case of lymphatic leucocythæmia, the phosphoric oxide excreted was diminished both absolutely and relatively to the nitrogen excreted, whilst the excretion of uric acid and alloxuric bases was hardly affected. In a case of medullary leucocythæmia where the number of leucocytes was falling, the excretion of phosphoric oxide underwent no diminution, whilst the alloxuric excretion varied greatly. An investi-

gation of the characters of the granules in the colourless corpuscles of marrow and blood was carried out by micro-chemical means. Nucleic acid, and its principal decomposition products (thymic acid, adenine, guanine, cytosine) alter the staining affinities of oxyphil granules, making them finally basophil. The granules are nucleoproteid, and the action of the nucleic acid is to cause the cell to give up the albumin and leave a more acid residue, nuclein. The subsequent discharge of the residue leads to an increase of excreted phosphoric anhydride; this probably occurs in the body when nucleic acid is liberated. The granules readily undergo changes, and a study of them is important, for these affect the general metabolism.

W. D. H.

The Proteid-sparing Action of Alcohol. By RUDOLF ROSEMAN (Pflüger's Archiv, 1899, '77, 405—424).—Miura, Schmidt, and Schönesseffen found that alcohol has no proteid-sparing action. The present paper confirms this, and criticises Neumann's recent work, which appeared to show the contrary.

W. D. H.

Koppe's Theory of the Formation of Hydrochloric Acid in the Stomach. By JOHN A. WESENER (Pflüger's Archiv, 1899, '77, 483—484).—Koppe's theory of the formation of hydrochloric acid in the stomach is that ionisation of the sodium chloride in the stomach, and of the acid carbonates and phosphates in the blood, occurs, and that an exchange of the hydrogen ions in the blood, and sodium ions of the stomach then takes place. The following experiments show this cannot be the case, but that the acid is the result of cell activity. If the stomach is well washed out, and a 0.7 per cent. solution of sodium chloride introduced, there is no formation of free acid, but if the stomach be irritated by the rotation of a revolving sound in its interior, whether the sodium chloride solution be there or not, free hydrochloric acid appears, reaching a percentage of 0.1 in a few minutes.

W. D. H.

Origin of Fat from Proteid. By EDUARD PFLÜGER (Pflüger's Archiv, 1899, '77, 521—554).—Polemical. Pflüger is well known to be an unbeliever in Voit's doctrine that fat can originate from proteid in the body; his remarks here are mainly directed against Max Cremer, the latest exponent of Voit's theory.

W. D. H.

Phosphorus in Muscle. By J. J. R. MACLEOD (Zeit. physiol. Chem., 1899, 28, 535—558).—By muscular work, the organically united phosphorus in aqueous extracts of muscle is greatly diminished but the inorganic phosphates are increased. The lessening is due partly to a diminution of phosphorus in nucleon, but especially to that in organic phosphorus compounds other than nucleon.

W. D. H.

Sodium Chloride in Cartilage. By GUSTAV VON BUNGE (Zeit. physiol. Chem., 1899, 28, 452—458).—Cartilage, one of the oldest tissues, phylogenetically, is the richest of the tissues in sodium. A number of analyses of cartilage from mammals show that the sodium is most abundant in embryonic life, and least so in old animals. Com-

paring the cartilage of adult selachians with that of adult and embryonic mammals, the former is richest in sodium; doubtless the sodium is principally present as chloride.

W. D. H.

The Lactase of the Pancreas. By ERNST WEINLAND (*Zeit. Biol.* 1899, 38, 607—617).—In both young and adult dogs, the pancreas in virtue of a lactase converts lactose into dextrose and galactose, this power being increased by a milk diet. By prolonged boiling with citric acid, lactose is similarly acted on. There is no evidence of any intermediate substance between lactose and its hydrolytic products.

W. D. H.

The Retention of Phytosterol in the Animal Body after Feeding with Cotton-seed Oil. By C. VIRCHOW (*Chem. Centr.*, 1899, ii, 395; from *Zeit. Unters. Nahr. u. Genussmittel.*, 2, 559—575. Compare Abstr., 1899, ii, 689).—The results of experiments in which dogs and pigs were fed with cotton-seed oil showed that phytosterol did not pass into the fat, so that the presence of phytosterol in lard is important evidence of adulteration.

It was found that glycerides of hydroxy-fatty acids passed into the fatty tissues.

N. H. J. M.

Albumin in the Cell of the Queen Bee. By P. SÜSS (*Chem. Centr.*, 1899, ii, 560; from *Pharm. Centr.-H.*, 40, 458).—More than a gram of a yellowish-white, rather transparent mass with the appearance of salve was found on the floor of a queen bee cell and proved to be albumin. A. KLETT (*ibid.*, 502) points out that it has been long known that the cell of the queen bee contains albumin, and, indeed, differs from those of the working bees only in containing a larger proportion of it.

E. W. W.

Death Temperature of Marine Organisms. By HORACE M. VERNON (*J. Physiol.*, 1899, 25, 131—138).—In a number of marine animals belonging to various groups, the death temperature is generally a little higher than the paralysis temperature, and varies from 32·5° to 43·5°. Even among transparent pelagic animals, the differences are nearly as great. The differences can only be partly explained by the differences in the amount of solids in the tissues, hence protoplasm must vary chemically as well as physically. From observations on the death temperature of echinoid embryos, it is shown that it rises with the progress of development.

W. D. H.

Degradation of Caffeine in the Organism of the Dog. By MARTIN KRÜGER (*Ber.*, 1899, 32, 3336—3337. Compare Abstr., 1898, i, 699; 1899, ii, 233, and this vol., ii, 30 and 31).—Caffeine (1:4:6-trimethylxanthine) was given to a rabbit during 22 days in daily doses of 0·1 gram, the animal being fed on oatmeal and cabbage; the urine was found to contain paraxanthine (1:6-dimethylxanthine), heteroxanthine (1-methylxanthine), and 6-methylxanthine. In the systems of the rabbit and man, the methyl group in position 4 appears to be most labile, whilst in the dog the alkyl radicle in position 1 is most readily removed.

G. T. M.

Influence of Theine on the Excretion of Alkalis in the Urine. By K. KATSUYAMA, T. KUWAHARA, and K. SENO (*Zeit. physiol. Chem.*, 1899, 28, 587—594).—Experiments on rabbits show that the administration of theine increases the output of alkali in the urine; there is increase in sodium, but not in potassium. W. D. H.

Estimation of the Reducing Substances in Urine by Peške's Method. By A. GREGOR (*Chem. Centr.*, 1899, ii, 231; from *Centr. Krank. Harn. und Sexualorgane*, 10, 240).—The method of Peške (*Proc.*, 1895, 11, 43) for the estimation of dextrose is equally applicable to urine. The urine requires to be diluted. Normal urine shows a reducing power varying from 0.0825 to 0.347 per cent. It rises after a meal, more strongly after an amylaceous than after a flesh diet. It is constant during the night, having the same value (0.085 per cent.) as when fasting or employing a pure flesh diet. Excessive use of carbohydrates does not increase it; alcohol does so. It is lowered by hard, muscular work. M. J. S.

Relations between the Diuretic Effects and Osmotic Properties of Sugars. By E. HÉDON and J. ARBOUS (*Compt. rend.*, 1899, 129, 778—781).—Sugars are toxic only in very large doses, and can be injected into the animal system without producing either immediate or subsequent accidents. The maximum diuretic effect is produced by a particular dose at a particular degree of concentration, which varies with different sugars. There is an approximately constant relation, the *diuretic coefficient D*, between the quantity of sugar solution injected and the volume of urine eliminated, but this coefficient varies with the concentration of the solution; with dextrose solution containing 25 per cent. it is 2.8, with 50 per cent. 4.8, and with 10 per cent. 1.0. The coefficient also varies with different sugars at the same degree of concentration; with dextrose at 25 per cent. it is 2.8; levulose and galactose, 2.4; sucrose, 2.0; lactose and maltose, 2.2; raffinose, 0.9; arabinose, 3.4; erythritol, 4.0. It follows that the diuretic coefficients of these sugars vary inversely as their molecular weights, but directly as their osmotic pressures. Some sugars of the same molecular weights and osmotic pressures have not, however, exactly the same diuretic coefficients, but these differences are probably due to the different chemical functions of the sugars or to the fact that different proportions of them are consumed by the organism.

The toxic effect of the sugars generally follows the same order as their diuretic coefficients. The toxic dose is 30—35 grams per kilogram of body weight in the case of sucrose; 20—25 grams with dextrose; and 5 grams with arabinose and erythritol. C. H. B.

[Physiological Action of] Cyanotetramethylpyridone. By LUIGI SABBATANI (*Chem. Centr.*, 1899, ii, 528; from *Atti Real. Accad. Torino*, 34).—A 1 per cent. solution of the 3-cyano-1:2:3:4-tetramethylpyridone, prepared by Guareschi (*Atti Real. Accad. Torino*, 34), has an extremely bitter taste, which is similar to that of quinine and magnesium sulphate. With Bouchardat's reagent, this compound forms a reddish-brown precipitate which easily decomposes and with Nessler's reagent, even in very dilute solutions, it gives a lemon-yellow,

amorphous precipitate, but its presence in urine could not be detected by means of these reactions. Physiologically it proved to be very active, but comparatively harmless, its operation being of short duration and chiefly affecting the spinal marrow. When dropped into the eye, it induces myosis and subcutaneous injections have a purgative action. Dilute solutions of the pyridone cause more or less violent contraction of the muscles.

E. W. W.

Physiological Action of Quinosol [*o*-Hydroxyquinoline-sulphonic Acid]. By CARL BRAHM (*Zeit. physiol. Chem.*, 1899, 28, 439—451).—The urine of animals (dogs and rabbits) which had been dosed with quinosol deposits crystals of *o*-hydroxyquinoline-glycuronic acid, $C_{15}H_{15}O_7N + 2H_2O$, and this does not show a definite melting point, but turns yellow at 102—105° and decomposes at 151°; it dissolves in 815 parts of water at 15°, but readily in hot water, the solution being strongly acid; it does not reduce Fehling's solution. The cadmium, strontium, barium, and potassium salts were prepared; an aqueous solution of the latter is laevorotatory $[\alpha]_D^{20}$ 83.83—76.59°. When boiled with dilute acids, the acid is resolved into *o*-hydroxyquinoline and glycuronic acid.

Nothing certain is known of the origin of glycuronic acid in the body; the administration of α -methylglucoside did not lead to its appearance in the urine.

W. D. H.

Action of Lymphagogues on the Proteids of Blood and Lymph. By DMITRI J. TIMOFÉFFSKY (*Zeit. Biol.*, 1899, 38, 618—651).—The percentage of globulin in relation to the total proteid is higher in normal blood than in lymph. Lymphagogues of Heidenhain's first kind increase this relationship, either only in the lymph (for example, with toxins and crayfish extract), or in both lymph and blood (as when peptone is used); this, however, lasts but a short time, the normal ratio being quickly re-established. The change in the proteids has no direct relation to the increase of lymph secretion, or the rise in the total proteids of the lymph.

W. D. H.

Acute Alcoholism: Estimation of Alcohol in the Blood and the Tissues. By NESTOR GRÉHANT (*Compt. rend.*, 1899, 129, 746—748).—A 10 per cent. solution of alcohol was introduced into the stomach of dogs, in quantity corresponding with 5 c.c. of absolute alcohol per kilogram of body weight. After half-an-hour, 10 c.c. of arterial blood were withdrawn, and the alcohol in it estimated by distillation and titration with potassium dichromate, this operation being repeated every half-hour. After an hour and a half, the quantity of alcohol in the blood becomes constant and is 0.57 c.c. per 100 c.c. of blood. After four-and-a-half to five hours, the quantity of alcohol begins to be less and the animal slowly recovers. In the case of a dog killed by bleeding from the carotid artery, the following quantities of alcohol were found in the various tissues: brain, 0.41 c.c.; muscles, 0.33 c.c.; liver, 0.325 c.c.; kidneys, 0.39 c.c. per 100 grams of tissue in each case.

C. H. B.

Effect of Poisons on the Eye-Muscles. By GUILLERY (*Pflüger's Archiv*, 1899, 77, 321—404).—A considerable number of measure-

ments of the movements of the ocular muscles were made under normal circumstances, and these were compared with others made under the influence of various poisons. Alcohol lessens the contractive-energy: this is principally manifested by the internal recti. The paralysing action of morphine falls also chiefly on the same muscles; the action on the external muscles begins later. The action of chloral hydrate on the eye-muscles is shown by quite small doses; the pupil is enlarged, and the near point is made more distant. Much larger doses of paraldehyde are necessary to produce corresponding effects; the action of sulphonal and trional is small but unmistakable. Cocaine has little or no action beyond that on the pupil. Chloroform is the most active of the inhalation poisons examined.

W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

Do the Bacteria of Alinit assimilate Atmospheric Nitrogen? By JULIUS STOKLASA (*Chem. Centr.*, 1899, ii, 132; from *Centr. Bakt. Parasit.*, II., 5, 350—354).—Whilst Lauck (*Chem. Centr.*, 1899, i, 443 and 858, and *Centr. Bakt. Parasit.*, II., 5, 20, 54, and 87) believes that the alinit bacteria are *Bacillus subtilis*, the author considers them to be *B. megatherium*. The two bacilli differ essentially; the former converts nitrates into nitrites, the latter into nitrites and ammonia.

In a mixture of xylose and galactose (3 : 1) with mineral matter and a little nitrogen (as peptone) the alinit bacteria develop quickly and fix free nitrogen. In presence of much combined nitrogen there is no fixation. In the same mixture, *B. subtilis* grows less and there is only a slight fixation of free nitrogen.

N. H. J. M.

Influence of Organic Substances on the Work of Nitrifying Organisms. By SERGEI WINOGRADSKY and V. OMELIANSKY (*Chem. Centr.*, 1899, ii, 132—133, 217, and 264; from *Centr. Bakt. Parasit.*, II., 5, 329—343, 377—387, and 429—440).—Sodium carbonate is essential for the growth of nitric and nitrous organisms.

In the case of nitrate organisms, the oxidation of the nitrite and the growth of the microbe are inseparable. Peptone in excessive amount cannot alter the specific function of the microbe, but destroys or completely checks it under certain conditions. Addition of 0.025 per cent. of dextrose is favourable; the limit of favourable action is reached when 0.3 per cent. is present. Urea is without effect when the amount is only 0.05 per cent.; 0.5—0.8 per cent. hinders nitrification; asparagine (0.05 per cent.) is injurious, and glycerol behaves similarly.

Infusion of hay (14 per cent.) is beneficial; addition of urine (2 per cent.) resulted in the time required for oxidation being increased five times. Broth (8 per cent.) had no effect. Urea is without action

and it is to ammonia that the depressing effect of urine is attributed (compare Warington, Trans., 1891, 521). Sodium acetate (2 per cent.) checked oxidation, whilst the butyrate had only a slight effect. Iron salts seem to assist the process.

The nitrite bacterium is much more sensitive to nitrogenous substances such as peptone and asparagine than the nitrate bacterium. The more complex, unstable, and, for most microbes, the more assimilable the substance, the more injurious is its effect on nitric organisms. The following arrangement of nitrogenous substances, according to their nutritive value, also corresponds with their anti-nitrifying effect: peptone, dextrose, asparagine, urea, acetates, and butyrates.

N. H. J. M.

Nitrification of Organic Nitrogen. By V. OMELIANSKI (*Chem. Centr.*, 1899, ii, 347—348; from *Centr. Bakt. Parasit.*, II., 5, 473—490).—Experiments with amides, proteids, urine, &c., showed that the nitrifying organisms are not able to attack organic nitrogen; the nitrogen must be first converted into ammonia.

A cultivation containing an ammonia microbe (*Bacillus ramosus*), a nitrite bacterium, and a nitrate bacterium converted organic nitrogen successively into ammonia, and nitrous and nitric acids. If the nitrite bacterium is omitted, only ammonia is formed, whilst if the nitrate bacterium is omitted, the change stops after production of nitrites.

N. H. J. M.

Micro-organisms observed in the Formation of Nitrates. By ALBERT STUTZER and R. HARTLEB (*Chem. Centr.*, 1899, ii, 448—449; from *Mitt. landw. Inst. k. Univ. Breslau*, Heft. 2).—A nitric organism, *Nitromicrobium germinans*, which is not a bacterium, was obtained from soil. It only oxidises nitrites to nitrates. As nitrogenous food, it can utilise ammonium compounds and nitrates as well as nitrites, but not complex compounds such as peptone and the constituents of broth. It utilises free carbon dioxide, but not carbonates, and it cannot assimilate the carbon compounds, such as sugars, usually employed for bacteria.

N. H. J. M.

Action of *Bacillus Coli* and *Bacillus D'Eberth* on Nitrates. By LÉON GRIMBERT (*Ann. de l'Inst. Pasteur*, 1899, 13, 67—76).—Nitrogen is not evolved, and only a trace of nitrite is formed, when *Bacillus coli* and *B. d'Eberth* are cultivated in a 1 per cent. peptone solution containing 1 per cent. of a nitrate. If, however, they are cultivated in peptonised broth containing a nitrate, then a part of this nitrate is decomposed, nitrogen and carbon dioxide are evolved, and a considerable amount of nitrite remains in solution. With *B. pyocyaneus* the whole of the gas evolved consists of nitrogen, no carbon dioxide being formed. Similar results are obtained with a peptone solution containing extract of meat and a nitrate. The evolution of nitrogen is no doubt due to a secondary reaction between the nitrous acid produced by the reduction of the nitrate by the bacillus, and the amino-nitrogen contained in the broth or extract, for the amount of nitrogen evolved is twice that corresponding with the amount of nitrate decomposed and half that corresponding with the aminic nitrogen

contained in the broth or extract. Peptone itself contains a small amount of aminic nitrogen, and it is therefore possible for *B. coli* and *B. d'Eberth* to evolve nitrogen from a 5 per cent. peptone solution, for the amount of peptone in the solution is sufficient to furnish the aminic nitrogen required. Nitrogen is evolved when *B. d'Escherich* and *B. d'Eberth* are cultivated in a peptone solution containing potassium nitrite. H. R. LÆ S.

Denitrification. By KURT WOLFF (*Chem. Centr.*, 1899, ii, 133—134; from *Hygien. Rundsch.*, 9, 538—547).—Besides the eleven known denitrifying organisms, *Bacillus fluorescens liquefaciens* possesses this property, although it will not reduce nitrates in pure well or river water, or in milk.

As regards the question whether denitrifying organisms obtain oxygen wholly, or in part, from nitrates, it was found that the same amount of atmospheric oxygen was absorbed whether nitrates were present or not.

On inoculating peptone containing calcium nitrate with *B. fluorescens*, nitrogen was eliminated, nitrous anhydride being formed as an intermediate product. Calcium carbonate was formed; the liberation of nitrogen cannot therefore be the result of the interaction of nitrate and amino-compounds in acid solution, as Marpmann suggested (*Chem. Centr.*, 1899, i, 702, and *Centr. Bakt. Parasit.*, II, 5, 67). The fact that with abundant aëration nitrogen is not liberated may be due to the removal of most of the carbon dioxide. Other examples of microbes which only denitrify in presence of plenty of carbon dioxide are given.

Ordinary pressed yeast destroys nitrates completely both in broth containing sodium nitrate or with calcium nitrate. This is not a case of action of pure yeast, as numerous bacteria are present. Fermentation can take place without liberation of free nitrogen from the nitrate present. N. H. J. M.

Which forms of Carbohydrates do Denitrification Bacteria require for their Vital Processes? By JULIUS STOKLASA (*Bied. Centr.*, 1899, 27, 707—708; from *Zeit. landw. Versuchswesen Oesterr.*, 1898, i, 371).—The activity of denitrification bacteria was found to be greatest in presence of xylose; arabinose is a less suitable food. Experiments were also made with pure dextrose, lævulose, galactose, and sucrose.

In experiments with *Bacillus denitrificans*, it was found that oats grew normally in presence of dextrose, whilst with xylose the yield was reduced to about one-fourth as compared with that of pots manured with nitrate and superphosphate. With arabinose, the results were similar to those obtained with glucose.

Bacillus megatherium and *B. mycoides* had no effect on the growth of oats in presence of xylose, nitrate, and phosphoric acid. It is probable that both bacteria reduce the nitrate to ammonia and also accumulate atmospheric nitrogen in the soil. N. H. J. M.

Fermentation Experiments with Trehalose. By ARMINIUS BAU (*Chem. Centr.*, 1899, ii, 130—131; from *Woch. Brauerei*, 16, 305—306).—The constituent of certain yeasts which causes the break-

ing up of trehalose into dextrose must be of a nature differing from that of ordinary enzymes. Invertin has no effect on trehalose. It cannot be assumed that trehalose, which Bourquelot found in mould fungi, occurs in genuine yeasts. The hydration of trehalose is attributed to the living protoplasm or its constituents.

Trehalose is not suitable for distinguishing between different yeasts.

N. H. J. M.

Cellulose Enzymes. By FREDERICK C. NEWCOMBE (*Chem. Centr.*, 1899, ii, 129; from *Annals of Bot.*, 13, No. 49).—The extract of *Aspergillus Oryzae* attacks reserve cellulose more vigorously than starch; the enzymes of *Lupinus albus* and of *Phoenix dactylifera* behave similarly, but the latter hydrolyses somewhat more starch than *Lupinus albus*, whilst the enzyme acts very strongly on cellulose and less on starch than the extracts of *Lupinus* and *Phoenix*. The enzymes of barley malt, besides those already mentioned, attack cellulose when very much diluted. The effect of all these ferments is to render the cell-walls more and more transparent. The enzymes of *Lupinus* and *Phoenix* may be considered as cytase, and are not to be regarded as diastase.

N. H. J. M.

Raffinose as a Carbohydrate for the Nutrition of *Aspergillus Niger*. By HENRI GILLOT (*Chem. Centr.*, 1899, ii, 129—130; from *Bul. Acad. roy. Belg.*, 1899, 221—226).—When sucrose is employed for the nutrition of *Aspergillus niger*, it is inverted by a diastase before being assimilated, oxalic acid being formed as an intermediate product. In a similar manner, raffinose is inverted; the melibiose produced is further hydrolysed to dextrose and levulose. Like sucrose, raffinose is completely utilised, and to the same extent in a given length of time. Oxalic acid is formed.

N. H. J. M.

Nitrogen Nutrition of Leguminous Plants. By JAN LUTOSLAWSKI (*Bied. Centr.*, 1897, 27, 688—689; from *Ber. physiol. Lab. landw. Inst. Univ. Halle*, 1898).—Peas were grown in pots containing sandy loam (6·6 kilograms) from a field on which peas had been grown the year before. Mineral manure was given to each pot, and to some sodium nitrate (1·277 grams) as well. Plants were taken up at five periods, (1) after the end of the germinating process (8th to 10th leaf), (2) commencement of flowering, (3) full flower, (4) after flowering, (5) ripe. The balance of nitrogen, taking into account the amounts in produce and in soil, gave the following gain per cent. of the original nitrogen in soil and seed (9·269 grams), (1) without, and (2) with nitrate at the different periods:

	I.	II.	III.	IV.	V.
1.	1·0	1·65	3·14	5·17	3·40
2.	0·0	1·45	1·89	2·95	2·20

in absence of nitrate, fixation of nitrogen commenced soon after the germinating period, whilst with nitrate it was later. For green manuring and for feeding, peas should be ploughed in or cut when fruit begins to be formed; or, in unfavourable weather, at earlier periods. Similar experiments with vetches failed in absence of nitrate.

N. H. J. M.

Chemistry of the Cell. By JAN SOSNOWSKI (*Chem. Centr.*, 1899, ii, 587; from *Centr. physiol.*, 13, 267—270).—The infusoriæ obtained from ordinary hay infusion are for the most part easily soluble in a 0.2 per cent. solution of an alkali hydroxide and in a 0.3 per cent. solution of sodium carbonate, only a few lustrous granules remaining undissolved. The solutions give the biuret reaction and the *Paramæcium* gives Millon's reaction. They are only attacked by pepsin-hydrochloric acid with difficulty. The extracts obtained by grinding the infusoriæ with quartz and treating with water, contain albumin which cannot be coagulated when the solutions are neutral, but is partly precipitated by adding sodium chloride or acids. The proteids are completely precipitated from the aqueous extract by barium hydroxide, and the precipitate contains phosphorus even after repeated treatment with dilute hydrochloric acid, alcohol, and ether. When the fat, lecithin, &c., have been removed from the cells by means of alcohol, only a portion of the residue is soluble in a 0.2 per cent. solution of sodium hydroxide, and the precipitate obtained by acidifying the alkaline solution with acetic acid contains phosphorus, gives the biuret reaction, and when boiled with phloroglucinol dissolved in hydrochloric acid exhibits the bands characteristic of the pentoses.

E. W. W.

Absorption of Iodine by Plants. By PAUL BOUBCET (*Compt. rend.*, 1899, 129, 768—770).—Twenty-eight plants belonging to nine different natural orders were grown in carefully prepared soil containing 0.83 mg. of iodine per kilog., and when the plants reached maturity they were cropped, and the proportion of iodine in them was determined. It was found to vary from *nil* (potato, gherkin, black radish, parsley, carrots, chicory, endive) to 0.32 (green haricots), 0.38 (*Beta cycla*), and even 0.94 (garlic) mg. per kilogram. Certain families, such as *Liliaceæ* and *Chenopodiaceæ*, absorb more iodine than others, such as *Solanaceæ* and *Umbelliferae*, but different species of the same order show considerable differences.

C. H. B.

Physiological Importance of Furfuroids in Sugar Beet. By JULIUS STOKLASA (*Chem. Centr.*, 1899, ii, 57—58; from *Zeit. Zucker-Ind. Böhmen*, 23, 387—397. Compare Abstr., 1899, ii, 792).—Inasmuch as pentosans are important constituents of the cell membranes, it may be concluded that they are formed from sucrose. As new organs containing pentosans develop in the second year of vegetation, the sucrose gradually disappears from the roots. In water-culture experiments with peas and maize, it was found that only a slight excess of furfuroids was produced in presence of sucrose as compared with dextrose; when, however, root heads of beet were fed under conditions of sterilisation with sucrose and dextrose respectively, in absence of carbon dioxide, it was found that a far greater amount of furfuroids was produced with sucrose than with dextrose. Potassium chloride assists the production of furfuroids.

Furfuroids are essential in the building up of cell membranes. The celluloses of the embryo are hydrolysed, and thus furnish the material for the production of the new hemicellulose group of the

seedlings. The hemicelluloses are transformed into lignocelluloses (which protect the roots from infection by parasitic fungi) and lignin substances.

N. H. J. M.

Occurrence of Indican in the Chlorophyll Grains of the Indigo Plants. By HANS MOLISCH (*Chem. Centr.*, 1899, ii, 482; from *Ber. deutsch. bot. Ges.*, 17, 228—233).—Indican is usually found in the mesophyll and external skin of the leaves of the indigo plant. Inside the green cell itself, it occurs mainly in the chlorophyll grains. It is best detected by converting it into indigo-blue by means of alcohol, ammonia, or chloroform vapour. The discovery of indican in the chlorophyll grains is the first proof of the presence of a glucoside containing nitrogen in the chlorophyll grains of the indigo plants.

E. W. W.

Histidine and Lysine in the Decomposition Products of the Proteid of Conifer Seeds. ERNST SCHULZE and ERNST WINTERSTEIN (*Zeit. physiol. Chem.*, 1899, 28, 459—464).—The proteid material of the seeds of various conifers has been shown to yield arginine on decomposition. The present research shows that, on decomposing the proteid with hydrochloric acid, histidine and lysine are also obtained. From 300 grams of dry material, 3 grams of histidine chloride, 19 grams of arginine nitrate, and 3 grams of lysine picrate were obtained.

W. D. H.

Histidine and Lysine in Seedlings. By ERNST SCHULZE (*Zeit. physiol. Chem.*, 1899, 28, 465—470).—From the present and previous work it is shown that from the seedlings of *Lupinus luteus* eight nitrogenous derivatives of proteid are obtainable, namely, asparagine, leucine, aminovaleric acid, tyrosine, phenylalanine, arginine, histidine, and lysine.

W. D. H.

Progressive Development of Essence of Bergamot. By EUGÈNE CHARABOT (*Compt. rend.*, 1899, 129, 728—731).—Analyses of two samples of essence of bergamot, one prepared from the green but fully developed fruit, and the other from the ripe fruit of the same trees, show that during the process of ripening, the free acids, calculated as acetic acid, decrease from 0.289 to 0.283, the total linalool from 40.5 to 35.5, the free linalool from 13.9 to 5.9, and the bergaptene from 5.9 to 5.5 per cent., whilst the linalyl acetate increases from 33.8 to 37.3 per cent. An increase is also observed in the terpenic constituents of the oil, but the relative proportions of limonene and dipentene remain unchanged. From these results, it is concluded that the primary development of the fruit is characterised by the active formation of linalool, and that during the subsequent ripening this reacts with the free acetic acid and is partly converted into linalyl acetate, partly dehydrated with the production of limonene and dipentene.

N. L.

Hazelnut Oil. By JOS. HANUŠ (*Chem. Centr.*, 1899, ii, 557—558; from *Zeit. Unters. Nahr.-Genussm.*, 2, 617—622).—From the ripe fruit of *Corylus avellana*, L., 50—60 per cent. of a clear, golden-yellow oil may be extracted by means of ether. It has a pleasant taste, an odour like

that of fresh butter, and the following constants: sp. gr., 0.9169 at 15°; saponification number, 193.7; iodine number, 90.2; Hehner's number, 95.6; Reichert-Meissl number, 0.99, and acetyl number, 3.2. The insoluble fatty acids have: saponification number, 200.6; iodine number, 90.6, and mean molecular weight of 279.0. The unsaturated fatty acids have: saponification number, 198.5; iodine number, 91.3; Maumene's number, 36.2, and mean molecular weight of 282. The oil does not give characteristic reactions with the usual reagents, but yields a greenish, semi-solid elaidin, and consists of 85 per cent. of oleic acid, 10 of palmitic and stearic acids, 10.41 of glycerol, and 0.5 of phytosterol. Oleic acid is the only unsaturated acid present, and the oil does not contain arachic acid.

E. W. W.

Cortex Lokri. By W. P. H. VAN DEN DRIESSEN MAREEUW (*Chem. Centr.*, 1899, ii, 589; from *Ned. Tijds. Pharm.*, 11, 227—234).—The bark, *Cortex Lokri*, is obtained from *Hymenaea Courbaril*; it contains 2.7 per cent. of catechin, 23.6 of catechu-tannic acid, 0.6 of fat, and 7.6 of ash.

E. W. W.

Saw Palmetto. By P. L. SHERMAN and C. H. BRIGGS (*Pharm. Archives*, 1899, 2, 101—116).—The saw palmetto (*Sabal serrulata*) is a tree which is found along the S.E. coast of the United States; the fruit is dark purple in colour, about the size of an olive, and consists of a juicy pulp and a very hard seed or nut. The fruit is pressed in a hydraulic press; when the juice is allowed to remain, an oil rises to the surface, in amount equal to about 1.5 per cent. of the fruit. This oil consists of acids, chiefly hexoic, octoic, decoic, lauric, palmitic, and oleic, and their ethyl esters, about 37 per cent. consisting of esters, the remainder of the free acids.

The dry nuts form 17.5 per cent. of the fruit; they were cracked, and the very hard kernels broken, ground to a meal, and extracted with boiling benzene; in this way, an oil was obtained in amount equal to about 2 per cent. of the fruit. This oil contained about 97.7 per cent. of glycerides of octoic, decoic, lauric, palmitic, stearic, and oleic acids, the rest consisting of the free acids.

The fruit contains in addition about 5.4 per cent. of sugar, estimated by its cupric reducing power, and calculated as invert sugar; also a small amount of pentoses. No alkaloid could be detected.

C. F. B.

Presence of an Oxidising Enzyme in the Vine. By CHARLES CORNU (*J. Pharm.*, 1899, [vi], 10, 342—343).—The vine contains an oxidising enzyme which belongs to the class of "aéroxydases," or enzymes, which only cause oxidation in the presence of air. The activity of the ferment is greater in the spring than in the autumn.

H. R. LÉ S.

Accumulation of Nitrogen by the Cultivation of Intermediate Crops on Loamy Soil. By MAX MAERCKER (*Bied. Centr.*, 1899, 27, 655—656; from *Landw. Jahrb.*, 1898, 27, 157).—A mixture of beans (50), peas (100), and vetches (50 kilos. per hectare) accumulated 154.4 kilos. of nitrogen, whilst as much as 4624 kilos. of organic matter was produced on a hectare. The least favourable results

showed an accumulation of nitrogen corresponding with 5—6 cwt. of sodium nitrate. A mixture of lupins and lathyrus proved to be unsuitable for the soil.

In the dry season of 1898, the effect of the intermediate crop on the succeeding crop of oats was very striking, partly owing to the water supplied by the deep roots of the *Leguminosæ*.

N. H. J. M.

Experiments with Different Lupins. By A. SEMPOLOWSKI (*Bied. Centr.*, 1899, 27, 716; from *Fühling's Landw. Zeit.*, 1898, 47, 517).—The yield of corn (I) in kilos. per hectare, and (II) the percentage of alkaloids, was determined in the following varieties of lupins:—(1) *Lupinus angustifolius*, var. *fl. roseo*; (2) var. *fl. albo*; (3) *L. hirsutus*; (4) var. *fl. cœruleo*; (5) *L. angustifolius*; (6) *L. hirsutus*, var. *fl. albo*; (7) *L. albus*; (8) *L. luteus*, var. *semine nigro*; (9) var. *semine albo*; (10) *L. luteus*; (11) *L. perennis*.

	1.	2.	3.	4.	5.	6.	7.	8.	9.	10.	11.
I.	3321	3310	3236	3154	3088	2924	2708	1736	1717	1550	823
II.	0.430	0.345	0.378	0.378	0.641	0.378	0.250	0.290	0.788	0.833	—

The narrow leaved varieties gave the greatest yields; yellow lupins gave the least, and contained most alkaloids. *L. angust.* var. *fl.*, gave a high yield of corn, with a comparatively low percentage of alkaloids.

N. H. J. M.

[Experiments with] Cows at Lauchstädt, 1896—1897. By FRIEDRICH ALBERT (*Bied. Centr.*, 1899, 27, 663—667; from *Landw. Jahrb.*, 1898, 27, 188. Compare *Abstr.*, 1899, ii, 689).—Experiments were made with 10 cows (two kinds) to ascertain the effect of food-fats on the production of milk and of milk fat. There were five experimental periods of 7—14 days, with longer intermediate periods for gradually changing the foods. The amounts of fat in the concentrated foods were as follows:—Period preceding the experiment (0.504 kilogram); (1) palm cake, 0.937 kilogram of fat; (2) lupins, 0.297; (3) cocoa nut cake, 0.747; (4) cocoa nut cake, (1.706); (5) lupins, 0.297 kilogram of fat.

Increasing the amount of fat in the food had no effect on milk production so long as the amount of fat did not exceed 1 per thousand of the live weight of the cows; with 1.706 kilograms of fat to 1000 kilograms of live weight the production of milk was considerably diminished.

Palm cake and cocoa nut cake increased the percentage of fat in the milk; with the largest amount of fat, the average increase was 0.75 per cent.; with rations (1) and (3) the percentage increase of fat in milk was 0.36 and 0.28.

The rations with low percentage of fat had very little effect on the percentage of fat in the milk, and the lupins affected the taste of the milk.

Feeding with large amounts of fat increased the live weight of the cows considerably; in the case of one breed, the cows became unwieldy and had to be killed. The rations with low percentage of fat caused great loss of weight,

N. H. J. M.

Experiments on Feeding Cows with Brewery Residues. By EBERH. RAMM and E. MÖLLER (*Bied. Centr.*, 1899, 27, 668—670; from *Milchzeit.*, 1899, 97).—The food contains brewery refuse and other materials, and consists of brown, worm-shaped lumps as hard as glass. It contains 42·48 per cent. of digestible proteids, 0·8 per cent. of fat, 26·96 per cent. of non-nitrogenous extract, and 1·3 per cent. of woody fibre.

Feeding experiments were made in which the cows received hay (14), straw (4·5), roots (50), and dried brewers' grains (4 kilograms for 1000 kilograms of live weight). In addition, they received either earth-nut cake (containing 6·5 per cent. of fat), or brewery residues (6 kilograms). After 14 days, the cows which had brewery residues weighed rather more than the others (average 1·97 kilograms), and had yielded 94 grams more milk but 33 grams less fat and 45 grams less dry matter in the milk per head per day. The percentage of fat in the milk was: with earth-nut cake 3·322, and with brewery residues 3·062. The butter, after feeding with (1) earth-nut cake and (2) brewery residues, contained: water, 27·7 and 16·0; fat, 70·91 and 82·10; casein, &c., 1·22 and 1·76; ash, 0·17 and 0·14 per cent. The examination of the fat showed the butter in both cases to be normal.

N. H. J. M.

Amounts of Plant Food withdrawn from Peaty and Sandy Soil by cutting Heather and Turf. By HEINRICH IMMENDORFF (*Bied. Centr.*, 1899, 27, 649—652; from *Landw. Jahrb.*, 1898, 27, iv, 503).—In order to ascertain the losses which moor-land undergoes where turf and heather are cut for litter, samples were taken from measured areas, both from peaty and sandy soil, the ordinary implements being employed. Determinations of the different constituents were then made. The results calculated to kilograms per hectare are as follows: (1) sandy soil, and (2) peaty soil:

Fresh substance.	Dry matter.	N.	K ₂ O.	CaO.	MgO.	Fe ₂ O ₃ . Al ₂ O ₃ .	P ₂ O ₅ .	SO ₂ .
32,500	20,858	179·7	53·4	72·7	31·0	64·6	22·4	40·4
48,750	21,231	201·5	34·0	89·2	40·3	78·6	19·1	53·1

The dry substance removed from the sandy soil consisted of vegetable matter (18,222) and humous sand (2636 kilograms).

Assuming the cutting to take place about every 15 years, it is seen that the land must be impoverished in a comparatively short time, and it is concluded that the benefits resulting from the practice by no means compensate for the injury done to the land.

N. H. J. M.

Amount of Humus in Soils, and the Percentage of Nitrogen in the Humus, as affected by the Application of Air-slaked Lime and other Substances. By HOMER J. WHEELER, C. L. SARGENT, and B. L. HARTWELL (*J. Amer. Chem. Soc.*, 1899, 21, 1032—1037).—Zinc vessels, with holes for drainage, were filled with soil, (254 lbs.), to which different manures were added. Maize was grown the first year, oats the second, and rye the third year. At the end of the experiment, humus, and nitrogen in the humus, were

determined. Nitrogen, as ammonia or nitrate, was applied to some pots at the rate of 2.65 grams per pot, lime at the rate of 4 tons per acre (147.2 grams per pot), and gypsum in amounts corresponding with the lime. All the manured pots had potassium chloride and dissolved bone black.

The percentage amounts of (1) humus nitrogen, and (2) humus in the dry soil, and (3) nitrogen in dry humus, were as follows :

No	Am ₂ SO ₄	Am ₂ SO ₄	Am ₂ SO ₄	No N or	NaNO ₃	NaNO ₃	NaNO ₃	NaNO ₃
manure.	Am ₂ SO ₄	CaO.	CaO.	CaSO ₄	CaO.	CaO.	NaNO ₃	CaO.
1. 0.130	0.128	0.133	0.126	0.139	0.129	0.139	0.143	0.133
2. 3.86	3.93	3.77	3.63	3.65	3.75	3.51	3.93	3.42
3. 3.37	3.26	3.53	3.47	3.81	3.44	3.68	3.64	3.89

The results in the third column were obtained with 36.8 grams of CaO instead of 147.2 grams.

Potassium chloride and phosphoric acid alone (column 6) slightly decreased the humus and humus nitrogen. Lime and gypsum lowered the humus, but increased the nitrogen in the humus. Ammonium sulphate, without lime, reduced the nitrogen in the humus, whilst nitrate increased it.

It would seem that lime increased the amount of humus nitrogen, notwithstanding that the lime pots had yielded the heaviest crops. Although there was also a decrease in the amount of humus, there is probably no danger of injuring soil by the application of lime, as lime gives rise to greatly increased root production, when the land is laid down to grass for a few years.

It is thought probable that nitrates become converted into soluble organic compounds, probably by the intervention of denitrifying organisms. In presence of lime, as well as nitrate, the increase in humus nitrogen was less than with nitrate alone, owing, perhaps, to the destruction of denitrifying organisms by the lime.

N. H. J. M.

Losses of the Nitrogen of Stable Manure in Covered and Uncovered Stalls. By MAX MAERCKER and W. SCHNEIDEWIND (*Bisd. Centr.*, 1899, 27, 656—657; from *Landw. Jahrb.*, 1898, 27, 215); Conservation of Manure. By W. SCHNEIDEWIND (*ibid.*, 658; from *Landw. Jahrb.*, 1898, 27, 234).—The loss of nitrogen in manure in stalls where animals are fattened was comparatively slight (13.2 per cent.) so long as they remain on it, but rose to 34.8 per cent. when the manure remained for 4 weeks without the animals. Manure should therefore be spread on the fields, or treated with a preservative, as soon as the animals leave the stalls.

The loss of nitrogen in uncovered and covered manure heaps was 37.4 and 36.9 per cent. respectively. The higher result, with covered heaps, is attributed to loss of moisture, greater concentration, and increased temperature. Heaps under cover should be kept moist and compact. Addition of slight excess of 0.5 per cent. sulphuric acid causes production of ammonia compounds from proteids.

In fattening experiments with sheep in stalls, the loss of manure nitrogen was again satisfactory, but the manure lost considerably after the sheep were removed.

As regards preservatives, it was found that marl (30 per cent.) reduced the loss of nitrogen from 22.6 to 9.9 per cent.; with marl (30) and peat litter (2 per cent.), the loss was 6.1 per cent. Sodium hydrogen sulphate (6 per cent.) reduced the loss of nitrogen to 1.3 per cent. and at the same time rather improved the quality of the manure by increasing the nitrogen directly available. N. H. J. M.

Bat Guano found at Cagliari, Sardinia. By GIULIO PARIS (*Chem. Centr.*, 1899, ii, 65; from *Staz. sper. agrar. ital.*, 32, 176—185. Compare *Abstr.*, 1897, ii, 383).—The guano has the following percentage composition:—Moisture, 13.85; organic matter, 58.78; ammonia, 1.32; nitric acid, 0.75; uric acid, 0.63; Na_2O , 3.10; K_2O , 1.77; CaO , 1.72; MgO , 0.48; Fe_2O_3 and Al_2O_3 , 5.20; P_2O_5 (organic, citrate soluble, and insoluble respectively), 0.50, 4.20, and 0.66; SO_3 , 2.28; SiO_2 (soluble and insoluble in HCl , sp. gr. 1.11), 1.17 and 3.65; CO_2 , 1.80. N. H. J. M.

Value of Lime Compounds in Phosphatic Manures. By O. BÖTTCHER (*Bied. Centr.*, 1899, 27, 662—663; from *D. Landw. Presse*, 1899, 91, 222).—In reply to Ullmann (*ibid.*, No. 13), it is stated that the value of basic slag as a lime manure is not less at the present time than formerly; the amount of free lime is usually only slightly less.

Citric acid (2 per cent.) dissolved, in half an hour, 42—45 per cent. of lime; and in 12 hours, 45—52 per cent. N. H. J. M.

Analytical Chemistry.

Estimation of Oxygen in Water. By L. MUTSCHLER (*Chem. Centr.*, 1899, ii, 225; from *Zeit. Unters. Nahr.-Genussm.*, 2, 481).—The method consists in enclosing in a bottle of about a litre capacity three sealed glass tubes, one of which contains an alkali, the second a known volume of $N/10$ ferrous ammonium sulphate, and the third an excess of 50 per cent. sulphuric acid. The acid tube is attached to the caoutchouc stopper, the others lie at the bottom. After filling the bottle with the water, the two former are fractured by a glass ball and the ferrous hydroxide diffused through the water. After a sufficient time, the acid tube is also fractured and the unoxidised ferrous salt titrated with $N/10$ permanganate. M. J. S.

Estimation of Sulphur in Pig Iron. By M. J. MOORE (*J. Amer. Chem. Soc.*, 1899, 21, 972—975).—In the estimation of sulphur in pig iron, much less sulphur is always obtained by the volumetric process than by the gravimetric method.

The practice of pouring the molten metal into water and obtaining a "shot sample" is not a good one; it is preferable to catch a small test in a sand mould. L. DE K.

Estimation of Sulphur in Petroleum. By SIEGFRIED FRIEDLÄNDER (*Chem. Centr.*, 1899, ii, 406—407; from *Arbb. Kais. Ges.-A.*, 15, 365—372).—The sample is burnt in an Ohlmüller lamp, which is weighed before and after the experiment, the products of combustion being drawn through two wash-bottles containing a 5 per cent. solution of potassium hydrogen carbonate. The solution is then oxidised by means of potassium permanganate and hydrochloric acid, and the sulphuric acid estimated as usual.

L. DE K.

Estimation of Sulphur in Petroleum. By SIEGFRIED FRIEDLÄNDER (*Chem. Centr.*, 1899, ii, 629—630; from *Chem. Ind.*, 22, 343—349).—Equally good results are obtained by the use of the apparatus and processes of Heusler, Engler, Kiessling, or Ohlmüller, but the latter is by far the quickest, it being possible to effect an analysis in half an hour. Attention is called to the occasional presence of sulphur compounds in the air, and to the means for removing them.

L. DE K.

Estimation of Sulphur in Naphtha. By ALEXANDER P. LIDOFF (*Chem. Centr.*, 1899, ii, 493; from *J. Russ. Chem. Soc.*, 1899, 31, 567—570).—1 gram of the sample is dissolved in ether and carefully mixed with 30 grams of a mixture of 17 parts of potassium nitrate and 13 parts of sodium carbonate. When the ether has completely evaporated, the mixture is put by small degrees into a platinum dish heated to redness. The fused mass contains the sulphur as sulphate, which is then estimated in the usual way.

L. DE K.

Estimation of Sulphur in Organic Substances. By ROBERT HENRIQUES (*Chem. Zeit.*, 1899, 23, 869).—The process recommended for the estimation of total sulphur in rubber wares may be safely used for the analysis of other not readily volatile organic substances (compare this vol., ii, 123).

L. DE K.

Detection of Nitrogen in Organic Compounds containing Sulphur. By ERNST TAUBER (*Ber.*, 1899, 32, 3150—3154).—Jacobsen's method (*Ber.*, 12, 2318) which consists in adding iron-powder to the substance before heating with potassium, is entirely untrustworthy, since the addition of the iron greatly facilitates the absorption of nitrogen from the air, and cyanides are formed even when the substance contains no nitrogen; the method is useless unless carried out in a stream of hydrogen. Magnesium has a similar, but very slight, effect in facilitating the absorption of nitrogen; tungsten, chromium, and nickel are still less effective, and copper produces no effect at all. The method recommended consists in using a large excess of potassium and then an excess of ferric chloride to oxidise the potassium sulphide which is formed.

T. M. L.

NOTE.—The inaccuracy of Jacobsen's method was pointed out at the time by Remsen (*Abstr.*, 1880, 473).—EDITORS.

New Method for Estimating Nitric Acid. By J. F. POOL (*Chem. Centr.*, 1899, ii, 227; from *Nederl. Tijdschr. Pharm.*, 11, 171).—The nitrate is evaporated to dryness with excess of sodium chloride

in a flask. The air is expelled by carbon dioxide, and concentrated sulphuric acid is introduced; water is added and the gases are driven over by boiling into a solution of potassium iodide. The liberated iodine is then titrated. M. J. S.

Estimation of Phosphorus by Reed's Method. By D. GERHARDT (*Chem. Centr.*, 1899, ii, 227; from *Nederl. Tijdschr. Pharm.*, 11, 174).—Reed's method (Abstr., 1899, ii, 451) depends on the fact that phosphorus dissolved in carbon disulphide combines with 5 atoms of bromine in presence of alcohol. The author finds that the presence of alcohol is not necessary; in a simple carbon disulphide solution 5 atoms of bromine are absorbed, not 3, as stated by Reed. The method is useless in presence of fats. M. J. S.

Estimation of Phosphorus in Organic Compounds. By CH. MARIE (*Compt. rend.*, 1899, 129, 766—767).—The substance is oxidised by nitric acid and potassium permanganate, the phosphoric acid precipitated with ammonium molybdate, the precipitate washed until quite free from manganese, redissolved in ammonia, and precipitated with magnesia mixture. The ammonium magnesium phosphate should be washed until the filtrate gives no coloration when treated with excess of hydrochloric acid, a small quantity of ammonium thiocyanate, and a fragment of zinc.

15 to 20 c.c. of concentrated nitric acid are used for each gram of substance, heated on a water-bath, and from 5 to 6 grams of finely powdered potassium permanganate are added in successive small portions until the liquid remains red for several minutes. Excess of permanganate is decomposed by adding a small quantity of sodium or potassium nitrite. Even compounds difficult to oxidise by Carius' method are readily dealt with in this way. C. H. B.

Separation of Barium, Strontium, and Calcium by Mixed Carbonate and Sulphate Solutions of varying Composition. By FRIEDRICH W. KÜSTER (*Zeit. anorg. Chem.*, 1899, 22, 161).—A short criticism of Morgan's theoretical calculations (Abstr., 1899, ii, 627). The author points out that in the calculation of the solubility product, Morgan has entirely neglected the effect of the hydrolysis on the barium carbonate solution. E. C. R.

Composition of Ammonium Magnesium Phosphate. By HUGO NEUBAUER (*Zeit. anorg. Chem.*, 1899, 22, 162), and by FRANK A. GOOCH and MARTHA AUSTIN (*ibid.*, 163).—Neubauer claims priority in determining the composition of the magnesium ammonium phosphate precipitated in the usual method of estimation, and Gooch and Austin admit the justness of his claim (compare Neubauer, Abstr., 1893, ii, 236, 489; 1896, ii, 73, 674). E. C. R.

Analysis of "Weissmetall." By H. NISSENSON (*Chem. Zeit.*, 1899, 23, 868—869).—This alloy consists chiefly of lead with tin and antimony. It is dissolved in dilute nitric acid containing tartaric acid, sulphuric acid added, and the nitric acid expelled by heat, taking care not to char the tartaric acid. It is then diluted with water and the undissolved lead sulphate collected, the filtrate rendered alkaline

with aqueous caustic soda, excess of sodium sulphide added, and the whole boiled and filtered from any copper sulphide. The liquid is then electrolysed at 80°, using a current of 3 volts and 1.5 amperes, when the antimony is deposited. To obtain the tin, sufficient ammonium sulphate is added to convert all the sodium sulphide into the ammonium compound and the liquid again electrolysed. L. DE K.

Electrolysis of Metallic Phosphate Solutions. By HARRY M. FERNBERGER and EDGAR F. SMITH (*J. Amer. Chem. Soc.*, 1899, 21, 1001—1007).—The best conditions for the separation of copper from iron, aluminium, chromium, cobalt, zinc, nickel, or manganese in phosphoric acid solution have been determined.

In every case, a solution containing a little over 0.1 gram of each metal was employed, the phosphate was precipitated by adding 30—60 c.c. of disodium hydrogen phosphate solution of sp. gr. 1.0358, then dissolved by adding 5—10 c.c. of phosphoric acid solution of sp. gr. 1.347, and the solution electrolysed with a normal current density of from 0.035—0.072 ampere and a voltage of 1.5—2.6. In each case, the amount of liquid was 225 c.c., the time occupied 5 to 7 hours, and the temperature was kept at 60—70°.

Nickel may also be deposited from phosphoric acid solution by employing a current of 0.5 ampere and 7—8 volts. It has been found impossible to completely separate nickel from manganese, chromium, or zinc, mercury from cadmium or uranium, and copper from uranium. Mercury may, however, be separated from zinc. J. J. S.

Analysis of Bronzes. By A. FOMIN (*Chem. Centr.*, 1899, ii, 495—496; from *J. Russ. Chem. Soc.*, 31, 565—567).—About 0.3 gram of bronze filings, freed from iron particles by aid of a magnet, is treated with nitric acid. Ammonium nitrate is added and the whole evaporated to dryness. The residue is treated with water, neutralised with ammonia, and again acidified with nitric acid, and the insoluble matter, consisting of tin oxide slightly contaminated with antimony, iron, and traces of copper, is removed by filtration.

The filtrate, measuring about 100 c.c., is mixed with 30 drops of nitric acid and submitted to electrolysis by means of a current of 0.14—0.34 ampere and 2 volts. After 3—4 hours, 5 c.c. of saturated solution of ammonium nitrate are added, and in 24 hours the operation is finished. The electrodes are washed twice with water and once with alcohol. The one with the copper deposit is dried quickly, and the other, coated with lead dioxide, is dried for 15 minutes at 180°. Iron is then searched for in the usual way. L. DE K.

Estimation of Manganic Acids in the presence of Manganese Salts or of both Manganese Compounds in the presence of each other, by means of an Alkaline Solution of Arsenious Acid. By C. REICHARD (*Chem. Zeit.*, 1899, 23, 867—868).—Aqueous sodium hydroxide is added in sufficient quantity to precipitate the manganese salts as manganous or manganic hydroxide. Standardised alkaline solution of arsenious acid is then added and the operation is conducted as previously described (*Abstr.*, 1899, ii, 813).

The residue left on the filter is then ignited and weighed; the difference in the total manganese and that found by titration represents the manganese salts.

Two other processes are also suggested, but not supported by experiments.

L. DE K.

Estimation of Chromium in Iron and Steel. By E. DÖHLER (*Chem. Zeit.*, 1899, 23, 868).—The sample is dissolved in hydrochloric acid, and from this solution the chromium is precipitated by repeated treatment with excess of barium carbonate in a closed flask. The precipitate is then fused in a porcelain crucible with potassium nitrate and potassium sodium carbonate, and the chromium estimated in the aqueous extract in the usual manner.

L. DE K.

Estimation of Chromium in Steel. By R. W. MAHON (*J. Amer. Chem. Soc.*, 1899, 21, 1057—1060).—This is a slight modification of McKenna's process based on the oxidation of chromium to chromic acid by means of nitric acid and potassium chlorate, and titration with ferrous sulphate and potassium permanganate.

Nitric acid and potassium chlorate are employed in greatly reduced quantities, and paper instead of asbestos is used as a filtering medium.

L. DE K.

Detection of Alkali Chromates in Milk. By ALEXANDRE LEYS (*J. Pharm.*, 1899, [vi], 10, 337—340).—The white ash obtained by the evaporation and subsequent ignition of 100—150 c.c. of the milk is moistened with distilled water and filtered. A portion of this filtrate is added to 5 c.c. of pure concentrated hydrochloric acid, previously coloured with indigo-carmin, when, if a chromate is present, the solution will be immediately decolorised. A second portion of the filtrate is added to 5 c.c. of an acetic acid solution of pure aniline and commercial toluidine, when, if a chromate is present, a cherry-red coloration, due to magenta, will be produced on heating. These reactions only prove the presence of an oxidising substance, and in order to further identify the chromate, the rest of the filtrate is acidified with dilute sulphuric acid and a few drops of a solution of hydrogen peroxide added, when the production of a blue coloration fully proves the presence of a chromate.

H. R. LE S.

Iodometric Estimation of Gold. By FRANK A. GOOCH and FREDERICK H. MORLEY (*Amer. J. Sci.*, 1899, 8, 261—266).—Contrary to Peterson's statement that gold chloride cannot be estimated by the iodine set free when it is treated with potassium iodide, the authors have found this to be a very accurate method for the estimation of very small quantities of gold.

The gold, which should be in the metallic state and not exceed 0.01 gram, is dissolved in chlorine water, and the excess of chlorine is then removed by adding ammonia, boiling and acidifying with hydrochloric acid; this treatment should be repeated. After diluting to 200 c.c., 10 c.c. of the liquid are mixed with 0.02 gram of potassium iodide, and the liberated iodine then found by titrating with *N*/1000 solution of sodium thiosulphate, using starch as indicator; it is advisable

to add a very slight excess and then to titrate back with *N/1000* solution of iodine.

L. DE K.

Parting of Gold Platinum Alloy. By EDUARD PŘIWOZNIK (*Chem. Centr.*, 1899, ii, 539; from *Oesterr. Zeit. Berg.-Hütt.*, 47, 356—358).—The following process is used in the imperial Austrian assay office. The alloy is first treated with nitric acid of sp. gr. 1.199, which also dissolves a little of the platinum if silver is present. The mass is then treated with diluted *aqua regia* (100 c.c. of strong hydrochloric acid, 43 c.c. of strong nitric acid, and 143 c.c. of water), which dissolves the gold with moderate ease, but does not perceptibly attack the platinum. If there should be any silver left, the metal gets coated with silver chloride and the gold is prevented from dissolving; in that case, the liquid is poured off and the silver chloride removed by means of ammonia. The gold solution is heated with hydrochloric acid until the nitric acid is expelled, and the platinum then precipitated with excess of ammonium chloride.

If the alloy is composed of gold, silver, and platinum, each in large proportion, it must be fused with thrice its weight of zinc; after treating with sulphuric acid, the undissolved mass is treated as just directed.

L. DE K.

Method and Apparatus for Incinerating Vegetable and Animal Substances. By A. E. SHUTTLEWORTH and BERNHARD TOLLENS (*Chem. Centr.*, 1899, ii, 144; from *Jahrb. Landw.*, 47, 173).—Addition of calcium acetate prevents the sintering which so often forms an obstacle to complete incineration. The authors have devised a special platinum apparatus (not described) by the use of which the time necessary for incineration is much shortened, and volatilisation of chlorides is prevented.

M. J. S.

Tucker (this vol., ii, 52) has described a modified form of this apparatus.—EDITORS.

Application of the Kjeldahl Method of Destroying Organic Substances in the Detection of Metals. By OTTO GRAS and WILHELM GINTL, jun. (*Chem. Centr.*, 1899, ii, 145; from *Oesterr. Chem. Zeit.*, 2, 308).—Halenke's process (*Abstr.*, 1899, ii, 696) is especially suitable for the examination of coal-tar dyes. 10 grams of the substance is heated for 6—8 hours with 60—80 c.c. of sulphuric acid containing 10 per cent. of potassium sulphate, with final addition of some potassium nitrate. After diluting and warming, the solution is ready to be examined for metals.

M. J. S.

Estimation of Ferrocyanides in Spent Gas-purifying Material. By RUDOLF RIECHELMANN (*Chem. Centr.*, 1899, ii, 144; from *Zeit. öffentl. Chem.*, 5, 188).—The methods of Donath and Margosches (*Abstr.*, 1899, ii, 527) and that of Knublauch (*Abstr.*, 1890, 87) do not yield concordant results, since the former expresses as ferrocyanogen the iron soluble in other forms in the alkaline solution.

M. J. S.

Improvement in Trillat's Process for the Detection of Methyl Alcohol in Alcohols. By JULES WOLFF (*Chem. Centr.*, 1899, ii, 229—230; from *Ann. chim. anal. appl.*, 4, 183).—Pure ethyl

alcohol when treated by Trillat's process (Abstr., 1899, ii, 130) yields a condensation product which gives an identical reaction with that from methyl alcohol, but the former is not produced at atmospheric temperatures or below 60°. The following modification is therefore proposed: 100 c.c. of the alcohol is distilled; the first 10 c.c. are mixed with a solution of 15 grams of potassium dichromate in 130 c.c. of water and 70 c.c. of sulphuric acid (1:5); after 20 minutes, the mixture is distilled, the first 25 c.c. are rejected, and 50 c.c. from the following 100 c.c. are mixed with 1 c.c. of dimethylaniline and left at the ordinary temperature for 24 hours. After adding a little phenolphthalein, the liquid is accurately neutralised with soda and 30 c.c. distilled from it. To the residue there are added 25 c.c. of water and 1 c.c. of acetic acid, and the colour produced by lead peroxide is observed.

M. J. S.

Estimation of Alcohol in the Blood and Tissues. By NESTOR GRÉHANT (*Compt. rend.*, 1899, 129, 746—748).—See this vol., ii, 95.

Bromination of Phenols.—By WILHELM VAUBEL (*Zeit. angew. Chem.*, 1899, 1031—1032. Compare Abstr., 1893, i, 560; 1894, i, 19, 453; 1895, i, 55; 1896, i, 147, ii, 507).—A reply to Ditz and Cedivoda (this vol., ii, 54).—The author claims that good results are obtained by his method when a large excess of acid is present during the bromination and titration.

J. J. S.

Estimation of Carboic Acid and other Phenols. By E. RIEGLER (*Chem. Centr.*, 1899, ii, 322; from *Bull. soc. sci. Bucuresci*, 8, 51—53).—50 c.c. of the aqueous solution, containing not more than 0.1 gram of the phenol, are mixed with 10 c.c. of a 5 per cent. solution of sodium hydroxide and 20 c.c. of diazo-solution. The red solution is now gradually acidified with dilute sulphuric acid (1:5), which causes the precipitation of a yellow compound,

which is washed, dried at 100°, and weighed; it is practically insoluble in water, 100 c.c. only dissolving 0.0002 gram.

The diazo-solution is prepared by mixing 5 grams of *p*-nitraniline, 25 c.c. of water, and 6 c.c. of sulphuric acid; 100 c.c. of water and 3 grams of sodium nitrite dissolved in 25 c.c. of water are then added, and the whole diluted to 200 c.c. The reagent must be kept in a dark place.

L. DE K.

New Method for the Gravimetric Estimation of Sugars. By PH. CHAPELLE (*J. Pharm.*, 1899, [vi], 10, 395—398).—The sugar solution and 25 c.c. of Fehling's solution are placed in the tube of a centrifugal machine, diluted to 37.5 c.c., and heated in a calcium chloride bath at 110° for 6 minutes, in the case of dextrose solutions, and 10 minutes for lactose solutions. The whole is then whirled in the centrifuge for 3—4 minutes, and the liquid poured off from the precipitate, which adheres firmly to the sides of the tube. Boiling water is then added, and the whole again whirled. The water is then poured off, the tube and precipitate rapidly dried at 150—180° for 5 minutes and weighed. The method is rapid, and is applicable to the estimation of sugar in milk, urine, or gastric juice, from which

the proteids have been previously removed. The method is also applicable to the estimation of sugar by means of Sachsse's solution.

H. R. LE S.

Influence of Lead Acetate and Basic Acetate on the Estimation of Reducing Sugars in Wines and Lees. By HENRI PELLET (*Chem. Centr.*, 1899, ii, 573—574; from *Ann. chim. anal. appl.*, 4, 256—257).—Normal lead acetate is recommended in place of the basic salt in clarifying wines for polarisation, as the latter precipitates some of the sugar and so causes low results.

L. DE K.

Estimation of Sugar in Urine. By HENRI PELLET (*Chem. Centr.*, 1899, ii, 574; from *Ann. chim. anal. appl.*, 4, 256—257).—When preparing urine for polariscopic purposes, it is best to clarify with normal lead acetate or mercuric nitrate.

When using basic lead acetate, there is a danger that loss of sugar may occur, especially if the urine is neutral or alkaline.

L. DE K.

Estimation of Invert Sugar in the Presence of Sucrose. By H. JESSEN-HANSEN (*Chem. Centr.*, 1899, ii, 574; from *Compt. rend. trav. Lab. Carlsberg*, 1899, 103).—By operating as follows, the reduction of the alkaline copper solution by sucrose is reduced to a minimum: 10.4 grams of potassium sodium tartrate are dissolved in 15 c.c. of Kjeldahl's aqueous caustic soda, 15 c.c. of copper solution are added, and then the saccharine liquid; the whole is heated for 5 minutes on the boiling water-bath, a current of hydrogen being transmitted meanwhile.

L. DE K.

Estimation of Starch in Yeast. By GUSTAVE BRUYLANTS and H. DEUYTS (*Chem. Centr.*, 1899, ii, 154—155; from *Bull. assoc. Bely. Chim.*, 1899, 20).—The yeast is diffused in water, and the starch iodised by addition of a solution of iodine in potassium iodide. Its specific gravity is thereby increased and its tendency to ferment diminished. Any cell-residues are removed by passing the liquid through a silk sieve, and the mixture is allowed to deposit in a cylindrical glass vessel. As soon as the blue sediment becomes covered with a thin layer of yeast, the upper liquor is decanted and water added. The washing is continued until the microscope shows only traces of yeast. Hydrochloric acid is then added until the liquid contains 2 per cent. of acid, the mixture is heated until the starch dissolves and a small quantity of potassium sulphite added.

M. J. S.

Estimation of Glycogen. By ARMAND GAUTIER (*Compt. rend.*, 1899, 129, 701—705. Compare this vol., i, 81).

Detection of Acetic Acid in Urine. By V. ARNOLD (*Chem. Centr.*, 1899, ii, 146—147; from *Wien. Klin. Woch.*, 12, 541).—1 gram of *p*-aminoacetophenone is dissolved in 80—100 c.c. of water with addition of hydrochloric acid; a 1 per cent. solution of sodium nitrite is also required. 2 vols. of the former solution and 1 vol. of the latter are mixed, and 3 vols. of urine are added with 2—3 drops of strong ammonia. All urines give a more or less intense brownish-red coloration, which, on addition of 10—12 vols. of concentrated hydro-

chloric acid, passes into purple violet if acetic acid is present, but otherwise into yellow. Dark coloured urines are first decolorised by animal charcoal.

For the detection of bilirubin, an excess of aniline-*p*-sulphonic acid is added to 1 per cent. hydrochloric acid; then to 4 c.c. of this liquid, mixed with 0.5—1 c.c. of a 5 per cent. sodium nitrite solution and 50 c.c. of water, there is added $\frac{1}{2}$ —1 vol. of the urine. In presence of bile colouring matters, the mixture becomes orange-red, and on addition of a few drops of strong hydrochloric acid, violet. *p*-Diazobenzenesulphonic acid, which, as well as *p*-aminoacetophenone, can be employed for the detection of ethyl acetate in ether, does not give so marked a reaction with free acetic acid. M. J. S.

Estimation of the Insoluble Fatty Acids in Butter, and the Cause of Differences in the Results. By V. MAINSBRECK (*Chem. Centr.*, 1899, ii, 154; from *Rev. intern. falsific.*, 12, 87).—The want of agreement in the results obtained by different analysts in the estimation of the *Hehner* value appears to be due to differences in the time of heating and the amount of washing. From the author's experiments the loss amounts to 0.7 per cent. for each one and a half hours boiling. Litmus paper is not sufficiently sensitive for ascertaining the point of complete washing. In one experiment, 0.6 per cent. was removed by washing, and titration of the washings with *N*/10 alkali and phenolphthalein proved the continuous removal of soluble acids, after litmus ceased to show any acid reaction. It is therefore recommended that there should be a general agreement respecting the time of heating, and that the washing should be continued until 100 c.c. (with phenolphthalein) requires only 0.2 c.c. of *N*/10 alkali. M. J. S.

Estimation of Succinic Acid in Fermented Liquids. By J. LABORDE and L. MOREAU (*Ann. de l'Inst. Pasteur*, 1899, 13, 657—664).—When a solution containing succinic acid and glycerol is evaporated on the water-bath, a part of the succinic acid is converted into its glyceryl ester. This accounts for the low results obtained in the estimation of succinic acid in wines or other fermented liquids which invariably contain glycerol. This difficulty may be overcome thus: the succinic acid separated from the liquid is first titrated with decinormal alkali, and then the esters are hydrolysed by a known volume of decinormal alkali, and when the hydrolysis is complete the excess of alkali is titrated with decinormal acid. Only a small part of the succinic acid present in fermented liquids exists in the free state, the greater portion being present as a salt, from which the whole of the acid may be liberated by the addition of tartaric acid or potassium hydrogen sulphate. Tartaric acid is, however, slightly soluble in ether, and the amount dissolved by the ether must consequently be determined. This is done by converting the neutral tartrate into the acid tartrate by adding acetic acid and alcohol to the liquid which has been titrated, evaporating to dryness, and estimating the acid tartrate thus formed by titrating with decinormal alkali.

If the fermented liquid, in which succinic acid is to be estimated, contains more than 1 per cent. of sugar, it is evaporated to a syrup, 10 to 20 c.c. of alcohol are added, and the succinic acid separated by repeated extraction with ether. H. R. LE S.

Colour Reaction for Tartaric Acid and its Compounds. By JULES WOLFF (*Chem. Centr.*, 1899, ii, 569; from *Ann. chim. anal. appl.*, 4, 263).—Attention is called to a forgotten test for tartaric acid. A few centigrams of resorcinol are heated in a porcelain capsule with a little sulphuric acid until fumes are given off and the tartrate is added, when an intense dark red coloration is obtained. Neither oxalic nor citric acid gives the reaction. L. DE K.

Detection of Urochloralic Acid in Urine after Administration of Chloral Hydrate, especially in Cases of Poisoning. By DIOSCORIDE VITALI (*Chem. Centr.*, 1899, ii, 147; from *Boll. Chim. Farm.*, 1899, 38, 377).—The urine is concentrated to half its volume, and treated with a small excess of lead acetate and ammonia to feeble alkaline reaction. The precipitate of lead urochloralate is washed, then warmed with dilute sulphuric acid, and the filtrate cohobated for half an hour with zinc powder and sulphuric acid. The trichloroethyl alcohol resulting from the hydrolysis of urochloralic acid is thereby reduced to ethyl alcohol, which, after removal of the zinc by sodium carbonate, can be distilled over lime and recognised by odour, inflammability, conversion into iodoform, and into acetaldehyde (which may further be confirmed by Rimini's reaction), and by Vitali's reaction (treatment with carbon disulphide, potash, ammonium molybdate, and excess of dilute sulphuric acid, which produce the red colour of molybdenum xanthate). M. J. S.

Modified Soxhlet Apparatus for the Extraction of Fats from Liquids. By ALONZO ENGLEBERT TAYLOR (*Amer. J. Physiol.*, 1899, 3, 183—185).—The apparatus, which is figured and fully described, is stated to extract fat from solutions much more effectively than the Soxhlet apparatus, or the modifications of that instrument which have been hitherto devised. W. D. H.

Butter and Butter Substitutes. By W. G. INDEMANS (*Chem. Centr.*, 1899, ii, 495; from *Ned. Tijds. Pharm.*, 11, 219—226).—The chief points in butter analysis are, *A*, The number of molecules in a definite quantity of fat. *B*, The amount of olein. *C*, The solubility of the fatty acids in water.

The density, the electric resistance, the saponification number, the refractometer number, and the critical temperature of solution depend on *A*; the Hübl and Asboth's numbers depend on *B*; the melting and solidifying points depend on *A* and *B*, and the Reichert-Meissl and the Hehner-Angell numbers depend on *C*. As regards the number of molecules and the small amount of olein, butter-fat is surpassed by Ceylon oil, as it is also in density, electric resistance, and refractometer indication. The chief point of difference of butter from its surrogates, however, consists in the high percentage of fatty acids soluble in water and of the volatile acids; the latter vary with the season. L. DE K.

Rancidity in Butter-fat. By C. A. BROWNE, jun. (*J. Amer. Chem. Soc.*, 1899, 21, 975—994).—The so-called rancidity of fats is a much more complex phenomenon than hitherto believed.

As the rancidity of butter-fat increases, a decided increase in the acid, saponification, and Reichert numbers takes place; also a slight

increase in the ether number and a very marked decrease in the iodine absorption. Finally, an increase is noticed in the acetyl number and a decrease in the percentage of soluble acids and glycerol.

The physical constants of butter-fat, such as the specific gravity, refractive index, and heat of combustion, are also affected by rancidity.

L. DE K.

The Becchi Test. By ALPH. VAN ENGELN (*Chem. Centr.*, 1899, ii, 147—148; from *Rev. intern. falsific.*, 12, 90).—Several variations in the mode of applying this test are in use. The author shows that in applying it to the free fatty acids (Millieau's method) the presence of small quantities of free mineral acid is prejudicial; the fatty acids must therefore be thoroughly washed with hot water, and the form of the test in which the reagent is acidified with nitric acid should be abandoned. To ascertain whether cotton-seed oil could be detected in the butter of cows fed with cotton-seed cake, two reagents were employed. The first consisted of 1 gram of silver nitrate dissolved in the smallest quantity of water and mixed with 200 c.c. of absolute alcohol; the second, of a solution of 1 gram of silver nitrate, 250 c.c. of 98 per cent. alcohol, 40 c.c. of ether, and 0.2 c.c. of nitric acid. The fat was dissolved in an equal volume of amyl alcohol, mixed with 1 c.c. of the reagent, and heated in the water-bath for 15 minutes. With the first reagent, the butter gave a coffee-brown, with the second a lemon-yellow, coloration. These reactions, and others obtained with the fatty acids, are not regarded as decisive of the question.

M. J. S.

Becchi's Test for Cotton-seed Oil. By PAUL SOLTSIEN (*Chem. Centr.*, 1899, ii, 539; from *Zeit. öffentl. Chem.*, 5, 306—308).—The Becchi silver reduction reaction is chiefly due to the presence of sulphur, this occurring in decided amount in samples of cotton oil which have been extracted from the seed by means of light petroleum; oil obtained by pressure contains but a trace of sulphur, and it loses this on heating at 200°.

In the original Becchi test, it was recommended that some rape oil should be added to intensify the reaction; this must, however, previously be heated at 150° to desulphurise it.

L. DE K.

Baudouin's Reaction. By WILHELM KERP (*Chem. Centr.*, 1899, ii, 228—229; from *Zeit. Unters. Nahr.-Genussm.*, 2, 473).—Commercial furfuraldehyde requires to be purified by two distillations under reduced pressure; a dilute alcoholic solution keeps well in completely filled bottles in the dark. The production of a violet coloration with hydrochloric acid alone depends both on the strength of the furfuraldehyde solution and on the amount of acid added. When the solution is sufficiently dilute and the quantity of acid small enough, the violet colour is not produced immediately, whilst the sesamé oil reaction is both more rapid and more sensitive. The concentration of the acid is also of importance. Acid of sp. gr. 1.127 gives the Baudouin reaction, but produces no violet colour in the absence of sesamé oil; a stronger acid (1.16) may be used in doubtful cases. Heating must be avoided. The lower limit of the reaction is at a dilution of 0.2 per cent. of

sesamé oil : it follows that 2—2.5 grams of the oil can be detected in a kilogram of butter. The method cannot, however, be used as a quantitative colorimetric one. The behaviour of the red substance with various solvents is described, and some notes on its absorption spectrum are given. M. J. S.

Colour Tests for Sesamé Oil: Three New Characteristic Tests. By J. BELLIER (*Chem. Centr.*, 1899, ii, 453—454; from *Ann. chim. anal. appl.*, 4, 217—220).—The known tests are criticised. Behrens' reagent, a mixture of equal parts of sulphuric and nitric acids, is said to give better results if made of 100 c.c. of sulphuric acid, 10 c.c. of nitric acid, and 50 c.c. of water.

As new tests are proposed: *Ammonium vanadate*.—100 c.c. of sulphuric acid, 50 c.c. of water, and 2 grams of ammonium vanadate; this, on shaking with sesamé oil, gives a green colour, gradually becoming blackish. *Formaldehyde*.—100 c.c. of sulphuric acid, 50 c.c. of water, and 10 c.c. of 40 per cent. formaldehyde. Equal volumes of this reagent and sesamé oil gives, on shaking, a permanent bluish-black colour; an admixture of 1 per cent. of sesamé oil in olive oil may thus be detected. *Resorcinol*. 2 c.c. of the suspected oil is put into a test-tube, 2 c.c. of a saturated solution of resorcinol in benzene are added, and then 2 c.c. of nitric acid of sp. gr. 1.38 free from nitrogen oxides. In the presence of sesamé oil, an intense violet-blue or greenish-blue coloration is obtained. L. DE K.

Estimation of Formaldehyde in the Air. By M. WINTGEN (*Chem. Centr.*, 1899, ii, 454—455; from *Hygien. Rdsch.*, 9, 753—757).—A controversy with Peereboom on the subject of the estimation of formaldehyde in the air by Romijn's process (*Abstr.*, 1898, ii, 166). With care, this process gives satisfactory results. L. DE K.

Detection of Aldehydes in Alcohols. By CONSTANTIN I. ISTRATI (*Chem. Centr.*, 1899, ii, 148—149; from *Rev. intern. falsific.*, 12, 91).—Barbe and Janvier's method (*Ann. chim. anal. appl.*, 1, 325), as improved by the author, consists in mixing exactly 2 c.c. of the alcohol with 0.2 c.c. of a saturated alcoholic solution of the special reagent, and pouring 1 c.c. of sulphuric acid down the side of the test-tube. The colours produced are observed immediately, then half an hour later with gentle shaking, then after thorough mixing, and, finally, after addition of 10 c.c. of water. The colours produced by such reagents as pyrogallol, α - and β -naphthols, phenylhydrazine, quinol, guaiacol, &c., with various aldehydes are given. M. J. S.

Estimation of Carvone in Volatile Oils. III. By F. W. ALDEN and S. NOLTE (*Pharm. Archives*, 1899, 2, 81—91).—In a 500 c.c. flask, fitted with a reflux condenser, 10 grams of the oil, 25 c.c. of alcohol, 5 grams of hydroxylamine hydrochloride, and 6.5 grams of sodium hydrogen carbonate are boiled together for $\frac{1}{4}$ — $\frac{1}{2}$ hour on the water-bath, only a small surface of the flask being heated; 25 c.c. of water are then added, the alcohol and much of the limonene distilled off on the water-bath, and then steam is passed through, the distillate being collected in fractions of 5—10 c.c. in test-tubes until it is seen to contain crystalline carvoxime. The last fraction and the tube of the

condenser are rinsed back into the flask with hot water; when cold, the solid carboxime is filtered off and drained by aid of a filter pump, and finally dried in the air. Should any oxime separate from the previous fractions of the distillate during the next day or so, it is added to the main quantity. The whole is then heated for an hour in a tared glass dish on the water-bath over an opening 43 mm. in diameter, and weighed; 0.100 gram is added, to correct for loss by volatilisation during the heating, and the sum is multiplied by 0.909, to calculate the equivalent amount of carvone. The error of the method amounts to several units per cent.; the influence on it of various modifications of the conditions of the experiment was investigated. C. F. B.

Examination of Resins. X. Storax. By KARL DIETERICH *Chem. Centr.*, 1899, ii, 541; from *Pharm. Centr.-Halle*, 40, 423—428, 439—443. Compare *Abstr.*, 1898, ii, 58).—When testing storax, it is preferable to work on the crude sample instead of using the alcoholic extract.

To determine the acidity number, 1 gram of the sample is dissolved in 100 c.c. of cold 96 per cent. alcohol, and titrated with $N/2$ alcoholic potash, using phenolphthalein as indicator. The saponification number is found by dissolving 1 gram of the sample in 20 c.c. of $N/2$ alcoholic potash, and 50 c.c. of benzene, and, after 24 hours, titrating the excess of alkali with $N/2$ sulphuric acid. The following figures may be held to indicate the average composition of genuine storax: Water, not over 30 per cent.; ash, not over 1 per cent.; soluble in alcohol, not less than 60 per cent.; insoluble, not more than 3 per cent. Acidity number, 55—75; ether number, 35—75; saponification number, 100—140. L. DE K.

Testing Storax. By FERD. EVERS (*Chem. Centr.*, 1899, ii, 594; from *Pharm. Zeit.*, 44, 592—593).—The author objects to Dieterich's proposal of applying tests to the crude resin (see preceding abstract). L. DE K.

Examination of Resins. XI. Anime, Caranna, Dammar, Labdanum, Mastic, Sandarac, Tacamahaca, and Turpeth. By KARL DIETERICH (*Chem. Centr.*, 1899, ii, 541; from *Pharm. Centr.-Halle*, 40, 453—457).—A table giving the acidity, ether, and saponification numbers of the following resins: East and West Indian anime, caranna resin, several varieties of dammar, dammar adulterated with colophony, several varieties of mastic, labdanum, sandarac, tacamahaca resin, and turpeth resin. The acidity numbers of dammar and sandarac should be determined by dissolving 1 gram of the sample in 20 c.c. of $N/2$ alcoholic potash, adding 50 c.c. of benzene, and, after 24 hours, titrating the excess of alkali with $N/2$ sulphuric acid. L. DE K.

Examination of Resins. XII. Ammoniacum, Bdellium, Galbanum, Opoponax, and Sagapenum. By KARL DIETERICH (*Chem. Centr.*, 1899, ii, 542—543; from *Pharm. Centr.-Halle*, 40, 467—471).—A table showing the acidity, ether, and saponification

numbers of gum ammoniacum, bdellium, galbanum, opoponax, and sagapenum.

The acidity numbers of ammoniacum and galbanum are obtained by boiling 1 gram of the finely powdered sample with 50 grams of water and 100 grams of alcohol for 15 minutes in a reflux apparatus, 75 grams of the filtrate are then mixed with 10 c.c. of $N/2$ alcoholic potash, and after waiting for 5 minutes, the excess of alkali is titrated with $N/2$ sulphuric acid. The saponification number is found by using the author's cold benzene process.

The other resins are treated as follows: 1 gram of the sample is heated for 15 minutes with 30 c.c. of water, 50 c.c. of alcohol are added and the boiling continued for the same time; the liquid is then at once titrated with $N/2$ alcoholic potash. The saponification numbers are found by boiling 1 gram of the sample first with 30 c.c. of water and then adding 25 c.c. of $N/2$ alcoholic potash, the excess of which is afterwards titrated.

L. DE K.

Detection of "Saccharin" in Beer. By R. RÖSSING (*Chem. Centr.*, 1899, ii, 274; from *Zeit. öffentl. Chem.*, 5, 207—208).—The beer is acidified with phosphoric acid and shaken with an equal bulk of ether. The residue left on evaporating the ethereal extract is mixed with a little sand, dried in the water-oven, the powdered mass extracted with absolute ether, and an equal volume of benzene is added. The filtrate is then evaporated on a watch glass and the residue dried over sulphuric acid. The "saccharin" is thus obtained in white crystals of characteristic sweet taste.

L. DE K.

Colour Reaction for the Detection of Benzidine and Tolidine. By JULES WOLFF (*Chem. Centr.*, 1899, ii, 569; from *Ann. chim. anal. appl.*, 4, 263—264).—The substance is dissolved in a little glacial acetic acid, the liquid diluted with water, and lead dioxide suspended in water added; a splendid blue coloration is developed which is permanent in the cold. If other organic acids are used, the colour is not so intense. With a small amount of bromine, a blue coloration forms, but with excess a blue precipitate is obtained. Mineral acids prevent the reaction with either lead dioxide or bromine.

L. DE K.

Simple Alkalimetric Method for the Estimation of Salt-forming Alkaloids with the Aid of Phenolphthalein as Indicator. By HARRY M. GORDIN (*Pharm. Archives*, 1899, 2, 313—318, and *Ber.*, 1899, 32, 2871—2876).—The periodides (Abstr., 1899, i, 89) or mercuriodides (Prescott, Abstr., 1882, 664) of alkaloids, precipitated respectively by Wagner's and by Mayer's reagent, contain an indefinite amount of iodine or mercuric iodide, but apparently always a definite amount of hydrogen iodide, as represented by the formula, $m\text{Alk.}, \text{HI} + n\text{I}$, or $m\text{Alk.}, \text{HI} + n\text{HgI}_2$. This fact may be utilised for the estimation of alkaloids by titration. About 0.2 gram of anhydrous morphine is dissolved in 30 c.c. of standard hydrochloric acid (about $N/20$) in a 100 c.c. flask, Wagner's reagent (containing about 1 per cent. of free iodine and $1\frac{1}{2}$ of potassium iodide) added

gradually, the whole being shaken well after each addition, until further addition produces no further precipitate, when the contents are diluted to 100 c.c. and again shaken well. After the precipitate has settled thoroughly the liquid is filtered, 50 c.c. of the red filtrate decolorised by the gradual addition of 10 per cent. sodium thiosulphate solution, a few drops of phenolphthalein added, and the excess of acid titrated with *N*/20 potassium hydroxide. It is found that 1 c.c. of the acid is removed by 0.0137 gram of morphine; the equivalent quantities are, of hydrastine, 0.0184; strychnine, 0.0160; caffeine cryst., 0.0102; cocaine, 0.0146, and atropine 0.0139 gram. These alkaloids were then estimated in the same way, the factors just quoted being used in the calculation; the amounts found differed by about 1 per cent. only from those taken. Of Mayer's and Wagner's reagents that one is used which effects the more complete precipitation; if they are equal in this respect, Mayer's reagent is to be preferred, as the precipitate it produces settles more easily; when it is used, too, the subsequent addition of thiosulphate is unnecessary. Caffeine requires 50 c.c. of acid; colchicine cannot be estimated by this method, nor can berberine, which does not carry down any acid.

C. F. B.

Alkaloid resembling Aconitine found in a Corpse. By MECKE (*Chem. Centr.*, 1899, ii, 256—257; from *Zeit. öffentl. Chem.*, 5, 204—206. Compare Abstr., 1899, 311).—A ptomaine with properties very similar to those of aconitine has been found in a corpse. This alkaloid is extracted from alkaline solutions by ether, and gives the general reactions of the alkaloids, forming with phosphotungstic acid a white, with phosphomolybdic acid a yellow, and with a solution of iodine in potassium iodide a brownish precipitate. It gives a faint turbidity with mercuric chloride, and with concentrated sulphuric acid it forms, after a time, a reddish-violet coloration, which changes to a darker shade on warming. It remains colourless with dilute sulphuric or phosphoric acid, but becomes violet on evaporating. The yellowish solution in nitric acid, when evaporated, leaves a yellow residue which turns orange when moistened with potassium hydroxide solution. Even very small quantities instantly reduce potassium ferricyanide, and with Fröhde's reagent the alkaloid gives a greenish coloration, changing to yellowish-brown on warming. It is not precipitated by tannic acid, and after adding bromine water it is not attacked by concentrated sulphuric acid; potassium dichromate has also no action on it.

The violet coloration obtained by treating aconitine with phosphoric acid or concentrated or dilute sulphuric acid is only slowly formed, and differs from that of the corpse alkaloid both in shade and intensity. Delphinine, although stated by Otto to give a violet coloration with phosphoric acid, was found to produce only a brownish coloration, and its behaviour with sulphuric acid and bromine is not like that of the ptomaine.

The present methods of testing for aconitine are only to be trusted when considerable quantities are present and decomposed animal matter absent. Hilger and Tamba's reaction with phosphoric acid is

not available in presence of ptomaines, and, moreover, is scarcely characteristic of aconitine, for the different commercial varieties give different reactions. Urine which is several days old, when evaporated with phosphoric acid, also gives the same violet coloration as aconitine. The reactions with concentrated sulphuric acid, potassium ferricyanide (Brouardel-Boutmy's reaction), and Föhde's reagent are also untrustworthy. According to Jürgens, characteristic crystals of aconitine potassium iodide are obtained by dissolving the alkaloid in a drop of dilute acetic acid, evaporating with a grain of potassium iodide, and washing with water, but in many cases this test gave only amorphous precipitates or the tabular crystals of pseudoaconitine.

E. W. W.

Delicate Test for Caffeine. By ANDREA ARCHETTI (*Chem. Centr.*, 1899, ii, 453; from *Boll. Chim. Farm.*, 38, 340—341).—A solution of potassium ferricyanide is mixed with half its volume of nitric acid and heated to boiling. On adding an aqueous solution of caffeine a deposit of prussian blue will be noticed. The reaction is also given by other xanthine bases and uric acid, but only very feebly.

L. DE K.

Estimation of Cornutine. By FRANZ MUSSET (*Chem. Centr.*, 1899, ii, 323; from *Pharm. Centr.-Halle*, 40, 396).—The ethereal solution obtained according to Keller's directions contains, besides the cornutine, a resinous matter causing high result. By treating the weighed residue repeatedly with water containing 0.5 per cent. of hydrogen chloride, the cornutine dissolves and the insoluble resin may be weighed and allowed for.

L. DE K.

Recognition of Morphine and its Derivatives. By RUDOLF ROBERT (*Chem. Centr.*, 1899, ii, 149—150; from *Sonderabdruck aus Apoth.-Zeit.*, 14, No. 37).—The reagent proposed by the author's pupil Marquis is prepared by mixing 2—3 drops of formaldehyde solution with 3 c.c. of concentrated sulphuric acid. The pulverised alkaloid is added to this in a porcelain basin. *Morphine* gives at first a purple-red, passing through violet to almost pure blue; if partially protected from the air by placing in a test-tube, the blue colour remains for a long time. *Dionine* gives a deep blue, *codeine* a violet, *heroine* a reddish-violet turning to bluish-violet, *peronine*, a permanent reddish-violet, *methylphenomorpholine* an intense red. The absorption spectra of these coloured solutions show small differences.

M. J. S.

Estimation of Chloral Hydrate and Morphine in Organs. By RUSSWURM (*Chem. Centr.*, 1899, ii, 794; from *Pharm. Centr.-Halle*, 40, 543—544).—The united distillates from an acid and an alkaline distillation, containing therefore both chloral hydrate and chloroform, is diluted with alcohol to a definite bulk, and the chlorine estimated by boiling an aliquot part with alcoholic potash in a reflux apparatus, neutralising with nitric acid, and titrating with silver nitrate.

Morphine is estimated by first extracting the ammoniacal solution with hot amyl alcohol, which is, in turn, shaken with dilute hydrochloric acid. According to the author, the alkaloid may now be

obtained by supersaturating the liquid with ammonia and agitating with chloroform; this is then concentrated to a few c.c. in a small weighed beaker, and the morphine completely precipitated by adding 50 c.c. of light petroleum of low boiling point. L. DE K.

Estimation of Santonin in the Flower Buds of *Artemisia Maritima*. By KARL THAETER (*Arch. Pharm.*, 1899, 237, 626—632).—The author defends his method (Abstr., 1898, ii, 59) against Katz's criticisms (*Arch. Pharm.*, 1899, 237, 245). The extraction with ether must be continued for 12—18 hours. Before the magnesia is added, the solution should be evaporated to dryness, and the residue powdered; after mixture, the whole is moistened evenly with water and dried as rapidly as possible; there is then little fear that any of the santonin will be converted into magnesium salt. C. F. B.

Estimation of Urinary Indican. By EYVIN WANG (*Zeit. physiol. Chem.*, 1899, 28, 576—584. Compare Abstr., 1898, ii, 659; 1899, ii, 458).—The author defends his method against the criticisms of Bouma (Abstr., 1899, ii, 568). He holds that the method of purification described is necessary and correct, for the reddish-brown pigment removable by alcohol does not originate from indigo. W. D. H.

Volumetric Estimation of Sodium Cacodylate. By HENRI IMBERT and A. ASTRUC (*J. Pharm.*, 1899, [vi], 10, 392—395).—Cacodylic acid is neutral to methyl-orange, but behaves as a monobasic acid towards phenolphthalein, whereas pure sodium cacodylate is alkaline to methyl-orange and neutral to phenolphthalein. The commercial salt, however, is always acid to phenolphthalein, due to the presence of free acid. 1.6 grams of sodium cacodylate are dissolved in 100 c.c. water and to 10 c.c. of this solution carefully neutralised, using phenolphthalein as indicator, decinormal hydrochloric acid or sulphuric acid is then added until the liquid is neutral to methyl-orange. The number of c.c. of acid required multiplied by ten gives the percentage of pure sodium cacodylate. H. R. LE S.

Separation of Proteids from Flesh-bases by means of Chlorine and Bromine. By HARVEY W. WILEY (*Chem. Centr.*, 1899, ii, 586; from *Chem. News*, 80, 88—89).—The freshly powdered dry material, from which the fat has been removed by ether, is first extracted with cold and then with hot water and the extract filtered. The amount of proteids insoluble in water is calculated by multiplying the difference between the amount of nitrogen in the original material and that in the insoluble portion by 6.25. The filtrate, after acidifying with hydrochloric acid, is oxidised by repeatedly shaking with bromine. After remaining over night, the precipitated proteids are filtered and washed with water. The amount of flesh bases is obtained by multiplying the difference between the total amount of nitrogen and the sum of the amount of nitrogen in the soluble and in the insoluble proteids by 3.12. Liebig's extract was found by this method to contain 8.92 per cent. of proteids, previous determinations having given lower results. E. W. W.

Source of Error in Testing for Albumin in Urine. By E. DEBOISE and OUI (*Chem. Centr.*, 1899, ii, 570; from *Ann. chim. anal. appl.*, 4, 261—262).—Before being tested for albumin, the urine, if not quite clear, should be filtered; if, however, the turbidity is caused by micro-organisms, the ordinary filter fails and a so-called Kitasato filter must be employed.

It has been proposed to clarify the urine by means of calcined magnesia, but the authors find that this also precipitates most of the albumin.

L. DE K.

Microchemistry of Crystalline Hæmatin Compounds. Detection of Blood. By CASIMIR STRYZOWSKI (*Chem. Centr.*, 1899, ii, 140, 225; from *Oesterr. Chem. Zeit.*, 1899, 2, 305, 333—335).—Largely a repetition of earlier work. Ox-blood freed from salts, cholesterol, and fat was employed. None of Husson's results can be confirmed, except those relating to the formation of bromine and iodine compounds of hæmatin. Axenberg's mercury and manganese hæmatin compounds are non-existent. Buffalini's method (*Abstr.*, 1886, 184) must also be rejected, since the halogens (iodine, however, the least) destroy the colouring matter of blood. The results obtained by Bikfalvi (*Abstr.*, 1887, 165) by adding acetic acid and a haloid salt of an alkali metal to dialysed blood, appear to be perfectly correct. The so-called hæmidin crystals obtained by Dannenberg and others (*Abstr.*, 1887, 408) are nothing but sulphur. Teichmann's method simplified as follows will detect 0.000025 gram of blood. To the dried substance on a microscope slide with cover, acetic acid mixed with 1/50 vol. of hydriodic acid is added and the object is heated for a short time; well formed black crystals are obtained. Another very sensitive reagent is a mixture of 10 c.c. of glycerol of sp. gr. 1.26 with 2—3 drops of concentrated sulphuric acid. Blood, when heated with a very small quantity of this reagent on an object glass and examined with a magnifying power of 400 diameters, shows small, dark needles of hæmatin sulphate.

M. J. S.

Detection of Yolk of Egg in Margarine. By MECKE (*Chem. Centr.*, 1899, ii, 321—322; from *Zeit. öffentl. Chem.*, 5, 231—232).—Margarine melted at 45° is shaken with half its volume of a 1 per cent. solution of salt. The aqueous liquid is freed from fat by agitating with light petroleum and then cleared by alumina-cream. The filtrate is diluted with 5 times its bulk of water, when if yolk of egg is present in the sample, an abundant, flocculent precipitate of vitellin will be obtained. Or the margarine may be dissolved in light petroleum, the undissolved matter washed with ether, and then treated with salt solution.

L. DE K.

Detection of Albumoses in Urine. By LUDWIG VON ÁLDOR (*Chem. Centr.*, 1899, ii, 728—729; from *Berl. Klin. Woch.*, 36, 764—767, 785—787).—Any albumin is first removed by precipitation with trichloroacetic acid. 6—10 c.c. of the urine are acidified with 1—2 drops of hydrochloric acid and precipitated with slight excess of 5 per cent. solution of phosphotungstic acid. The precipitate is repeatedly whirled in a centrifugal apparatus with absolute alcohol

until all colouring matter is extracted and then suspended in water and mixed with aqueous sodium hydroxide. A blue coloration is noticed, which, however, fades on exposure to the air; the colourless liquid is then treated, as usual, with copper sulphate. L. DE K.

Analysis of Rubber Wares. By ROBERT HENRIQUES (*Zeit. angew. Chem.*, 1899, 802—804. Compare Abstr., 1893, ii, 399, and 1895, ii, 96, 191).—*Estimation of the total Sulphur and Metals.* The process does not materially differ from the former one, being carried out by oxidising with nitric acid, neutralising with excess of soda, and fusing the dry mass; the aqueous solution of this will contain the sulphur as sodium sulphate, whilst the metallic compounds remain as oxides or carbonates in the insoluble residue. For the detection and estimation of vermilion, which is often present in small quantities, the substance is digested with nitric acid, which gradually decomposes and dissolves the mercury sulphide; after expelling the bulk of the acid and diluting with water, the liquid is precipitated with hydrogen sulphide and the mercury looked for in the metallic sulphides so obtained.

Estimation of "Faktis" in Vulcanised Wares.—It is now recommended that the mass which has been exhausted with alkali shall be removed from the filter before drying to constant weight.

Estimation of Unsaponifiable Oils in Vulcanised Wares.—The mass, after being extracted with alkali, dried, and weighed, is again extracted with ether, the loss in weight representing the unsaponifiable matter, such as rosin-oil, paraffin, &c.

Estimation of "Faktis" in Non-vulcanised Wares.—The old process was not always satisfactory, and the following method has been substituted for it: 5 grams of the rasped sample is covered with 25 c.c. of benzene and heated on a boiling water-bath for an hour, the Erlenmeyer flask being attached to a reflux condenser; the whole is then left over night. The mass may now be successfully attacked by alcoholic soda.

Estimation of Unsaponifiable Oils in Non-vulcanised Wares.—Boiling acetone is substituted for ether and after evaporating the solvent, the residual unsaponifiable matter is weighed.

Estimation of Carbonic Anhydride.—Attention is called to the importance of estimating the carbonic anhydride present in combination with calcium, lead, zinc, &c. When dealing with non-vulcanised wares, the sample should first be repeatedly extracted with boiling nitrobenzene to remove the bulk of the rubber so as to facilitate the action of acids.

L. DE K.

General and Physical Chemistry.

Indices of Refraction of Metals. By EDMOND VAN AUBEL (*Zeit. physikal. Chem.*, 1899, 30, 565—566).—A comparison of the indices of refraction of metals obtained by calculation from the molecular refraction of salt solutions with those obtained directly by Drude (*Ann. Phys. Chem.*, 1890, [ii], 37, 537). The values show fair agreement in some cases, but in others are of a different order of magnitude, for example, silver, 2.37 and 0.203. Kundt's law, which states that the product of the index of refraction and electrical conductivity is constant, does not hold for either the direct or calculated values.

L. M. J.

Colour Changes of Illuminated Substances. By HEINRICH BILTZ (*Zeit. physikal. Chem.*, 1899, 30, 527—528).—Marchwald has given an account of these changes to which he has applied the term 'phototropy' (this vol., ii, 2). To the sensitive compounds there mentioned may be added the hydrazone of benzaldehyde and cuminal-osazone, anisilosazone, and piperilosazone. These compounds are yellow or greyish-yellow, but on exposure to light become red or orange in about an hour, returning again to the original colour in the dark. Benzilosazone, salicylosazone, and vanillylosazone are, however, not phototropic.

L. M. J.

Chemical Effects produced by Becquerel Rays. By P. CURIE and SKŁODOWSKA CURIE (*Compt. rend.*, 1899, 129, 823—825).—The radiations from highly radio-active barium salts convert atmospheric oxygen into ozone, and the latter is readily detected in the air of closed flasks containing the radio-active compounds. The compounds producing this result are all luminescent and highly radio-active, but their effect on oxygen seems to be connected with radio-activity rather than with luminescence.

The radiations also affect glass, and the vessels containing the salts gradually become deep violet and almost black, especially where the glass is in contact with the salt, even if the glass does not contain lead. The intensity of the coloration and the time required for its production depend on the intensity of the radio-activity.

Barium platincyanoide, under the influence of these radiations, becomes dark coloured and less fluorescent, but regains its original colour when exposed to sunlight, and at the same time becomes phosphorescent. Villard has obtained similar results with Röntgen rays (compare also Giesel, *Ann. Phys. Chem.*, 1899, [ii], 69, 91).

C. H. B.

Chemical Action of the X-Rays. By P. VILLARD (*Compt. rend.*, 1899, 129, 882—883. Compare preceding abstract).—The darkening of the wall of a Crookes' tube, which has been working for some time, is due to the reduction of the lead present in the glass to the metallic state by the cathode rays. If these are cut off by a thin

sheet of aluminium, which is transparent to the X-rays, the glass is coloured violet. This is due to the oxidising action of the X-rays, and the coloration is no doubt due to the manganese present in the glass.

H. R. LE S.

Phosphorescence Phenomena produced by the Radiations from Radium. By HENRI BECQUEREL (*Compt. rend.*, 1899, 129, 912—917).—The author finds that, in general, substances which phosphoresce when exposed to the action of ultra-violet rays, or of the X-rays, also become luminous under the influence of the radiation emitted by radio-active barium chloride; the order of the relative intensities of the luminous effects is, however, not the same in the two cases.

The phosphorescence excited by radium in certain minerals shows great persistence; fluorite, for example, remains luminous 24 hours after the influence of the radium has ceased.

When phosphorescent substances, which have been heated and thus rendered incapable of phosphorescence, are subjected to the action of an electric spark or to the prolonged action of the violet and ultra-violet rays, they are found to possess the property of exhibiting phosphorescence on heating. Fluorite, in these circumstances, emits a greenish-blue light, and the author finds that this mineral, after heating and exposing it to the radium radiation, gives out when heated a greenish-blue light which spectroscopic analysis shows to be identical with that produced by the electric spark.

T. H. P.

Influence of the Magnetic Field on the Rays Emitted by Radio-active Substances. By HENRI BECQUEREL (*Compt. rend.*, 1899, 129, 996—1001).—The radio-active substance used was barium chloride, and the influence of the magnetic field on the rays emitted by it was investigated by means of a fluorescent screen or a photographic plate. The author confirms the observations of Meyer and von Schweidler (*Physikalische Zeitschrift*, No. 10, 113—114) that some of the rays follow the direction of the magnetic field and are undeflected, whereas those in a plane at right angles to the magnetic field are deflected.

The results obtained point to a close relationship between cathodic rays and the rays emitted by radio-active substances. H. R. LE S.

Radiation of Radio-active Substances. By HENRI BECQUEREL (*Compt. rend.*, 1899, 129, 1205—1207). **Action of the Magnetic Field on Becquerel Rays: Deflected and Undeflected Rays.** By P. CURIE (*Compt. rend.*, 1900, 130, 73—76). **Penetration of Undeflected Becquerel Rays.** By SKŁODOWSKA CURIE (*Compt. rend.*, 1900, 130, 76—79).—The rays emitted by a very active specimen of Curie's polonium are not deflected in the magnetic field; the experiments were made about a month after the preparation of the substances, and the results are contrary to those obtained by Giesel with freshly prepared polonium compounds (this vol., ii, 19).

A portion of the rays emitted by radium are deflected by the electro-magnet; these behave like Röntgen rays, their velocity is of the same order, and their penetrating power increases with the thickness of the absorbent layer; the undeflected rays correspond with those from

polonium, and their penetrating power varies in the opposite sense to that of the deflected rays.
G. T. M.

Electromotive Behaviour of Chromium. By WILHELM HITTORF (*Zeit. physikal. Chem.*, 1899, 30, 481—507).—The peculiarities in the electromotive behaviour of chromium are further investigated (compare Abstr., 1898, ii, 363), and the author advances many arguments in support of the view that the inactive state cannot be due to the formation of a film of oxide. Owing to the existence of the different classes of chromium compounds, the metal may exhibit any potential between the two extreme values; the highest value corresponds with the active state in which chromium gives rise to the lower compounds. This active state is assumed when the metal is placed in sulphuric, oxalic, hydrofluosilicic, or the halogen acids, at temperatures which are lower the more concentrated the acid; it is also active in fused halogen salts or in their boiling solutions. The metal becomes inactive when immersed in solutions containing free chlorine or bromine, or in strong oxidising agents. The limiting values, however, last but a short time after removal from the liquids, the metal speedily assuming an intermediate state; the most stable active state is that produced by fused halogen salts. The activity is also lowered in all cases when the metal serves as an anode for a current produced either externally or internally, and, with sufficiently strong currents, chromic acid is produced, either by decomposition of water by anion and subsequent union of the metal and oxygen, or by the intermediate formation of a compound of the anion and chromium. When the metal is used as a cathode, it rapidly assumes the active state. The author points out that Berzelius and Wöhler had previously observed differences in chromium under different conditions.
L. M. J.

Influence of the Addition of a Salt with one similar Ion on Electromotive Force and Diffusion Velocity. By RICHARD ARREGG and EMIL BOSE (*Zeit. physikal. Chem.*, 1899, 30, 545—555).—A theoretical investigation of the above question. It is shown that if u and v are the cation and anion velocities, the addition of a salt with a similar cation or anion causes change of velocity of diffusion, tending to the values $V. (u + v)/2v$ or $V. (u + v)/2u$ respectively. In acids, the cation has a velocity about six times that of the anion, whilst in bases the velocity of the OH^- anion is about three times that of the cation. The velocity of diffusion of an acid or of a base hence is greatly increased by the addition of one of its neutral salts, and experiments are recorded in verification of this. Similarly, owing to the slight velocity of MnO_4^- and CrO_4^- ions, the diffusion of potassium permanganate or potassium chromate is decreased by the addition of potassium chloride. The increase of the catalytic action of an acid caused by the addition of its salts may be due to the increased mobility of the hydrogen ion.
L. M. J.

Molecular Susceptibility of the Salts of the Rare Earths. By H. DU BOIS and OTTO LIEBKNECHT (*Ber.*, 1899, 32, 3344—3348).—In determining the molecular susceptibility of a paramagnetic salt,

the substance is added to water until its paramagnetism just counterbalances the diamagnetism of the solvent; when this is the case, the meniscus of a portion of the solution contained in a capillary tube placed between the poles of an annular electromagnet remains stationary, whereas it moves backwards or forwards if the solution is either para- or dia-magnetic. The molecular susceptibility of the salt is then calculated from the equation $i_m = -m.M_w/M_s.x$ where m is the molecular weight of salt, M_w/M_s the ratio between the weights of water and salt in the non-magnetic solution, and x the specific susceptibility of water at 18° ; the exact value of this constant is not known, and the number 0.75×10^{-6} is employed as an approximation; the results, however, may be expressed in the form $-i_m/x$, and this expression is independent of the constant. The results obtained with the salts of eight of the rare earths are tabulated in the following manner:

	Salt, RCl_3 .	Atom. wt. ($O=16$).	Mol. wt. m .	$\frac{M_w}{M_s}$.	$-\frac{i_m}{x}$.	i_m .
1.	Yttrium chloride	89.0	195.35	1.41	276	0.00021
2.	{ Cerium "	140.0	246.35	13.197	3250	0.00243
	" bromide	"	379.88	8.4398	3210	0.00240
3.	Praseodymium chloride.	140.4	246.75	17.72	4370	0.00328
4.	{ Neodymium "	143.6	249.95	27.995	7000	0.00525
	" nitrate.....	"	329.72	20.98	6920	0.00519
5.	Samarium chloride	150	256.35	60.52	15510	0.01164
6.	Gadolinium "	156	262.35	130.24	34170	0.02563
7.	Erbium "	166	272.35	179.59	48910	0.03668
8.	Ytterbium "	173	279.35	33.95	9480	0.00711

These figures show that the salts investigated are derived from a well-defined group of paramagnetic elements, corresponding with the group chromium, manganese, iron, cobalt, nickel, and copper. In both cases, it is found that when the elements are arranged in the order of their atomic weights, the susceptibility is least for the salt of lowest atomic weight, also that it rises to a maximum, and then falls again. In the chromium-copper group, the maximum is reached at the third member (iron); cobalt is more paramagnetic than nickel, although recent atomic weight determinations place the latter nearer to iron. In the rare earth group, the maximum is reached only at the seventh stage (erbium), and then drops suddenly to ytterbium; in this group the increase and decrease of paramagnetism is strictly in accordance with the ascending order of the atomic weights.

G. T. M.

Change of Thermal Conductivity during Melting. By EDMOND VAN AUBEL (*Zeit. physikal. Chem.*, 1899, 30, 563—564).—The results of Lees (*Phil. Trans.*, 1898, 191, 428) have shown that fusion is not necessarily accompanied by a sudden change of conductivity. In the case of water, however, the conductivity at 0° is 0.072 and in the solid state between -21° and 0° about 0.30, so that, most probably, a sudden change occurs during the melting of ice.

L. M. J.

Influence of Pressure on the Critical Temperature of Complete Mixture. By N. J. VAN DER LEE (*Proc. K. Akad. Wetensch. Amsterdam*, 1898, 1, 158—165).—For two liquids, only partly soluble in each other, there exists a temperature above which mixture in all proportions is possible. The influence of pressure on this phenomenon has been investigated for mixtures of water and phenol, the critical temperature of complete mixture being in this case about 67° . The mixture to be investigated was contained in a thick glass tube of small bore, and subjected to pressures of 1—180 atmospheres; an electromagnetic stirring apparatus secured thorough mixing of the components in the tube. By means of a thermostat, in which ethyl alcohol boiled under varying pressures, the mixture could be kept at the desired temperature.

The temperature of complete mixture was in all cases found to rise slightly with increase of pressure; thus, in a case where 34 per cent. of phenol was present, the temperature of complete mixture was 67.6° under a pressure of 1 atmosphere, and 68.1° under a pressure of 130 atmospheres. The temperature of complete mixture was highest for the composition just referred to.

Theoretical considerations point to the curve $p=f(x)$, connecting the composition and pressure of the saturated vapour of the mixture, having a maximum or minimum when there is 34 per cent. of phenol present. The vapour pressures of numerous mixtures of water and phenol have accordingly been determined for the temperature range 71 — 90° . The composition of the mixture with maximum vapour pressure for any given temperature, cannot be exactly determined from the numbers obtained, but it is close to 34 per cent. of phenol.

J. C. P.

Hydrate of Sodium Dioxide and Preparation of Hydrogen Peroxide. By ROBERT DE FORCRAND (*Compt. rend.*, 1899, 129, 1246—1249).—The heat of dissolution of the hydrate $\text{Na}_2\text{O}_2 \cdot 8\text{H}_2\text{O}$ is -14.868 Cal.; its heat of formation from sodium dioxide and water is 34.081 Cal., and from the dioxide and ice, 22.641 Cals. These values indicate that the hydrate is possessed of considerable stability, and on this account it may be employed in the preparation of hydrogen peroxide; it furnishes a strong solution of this compound when dissolved in cold hydrochloric acid. The reaction Na_2O diss. + H_2O_2 diss. = Na_2O_2 diss. is accompanied by an evolution of 4.713 Cals. For the solid substances, the stable condition is Na_2O_2 , for 27.755 Cals. are evolved during the combination of oxygen with solid Na_2O ; in solution, the stable condition is $\text{Na}_2\text{O} + \text{O}$, for the addition of oxygen to dissolved Na_2O is attended by an absorption of heat equal to -16.987 Cals.

G. T. M.

Compound Metallic Radicles: Mercury Derivatives. By MARCELLIN P. E. BERTHELOT (*Compt. rend.*, 1899, 129, 918—920).—The following heats of combustion and formation have been determined:

	Combustion.		Formation.
	At const. vol.	At const. press.	
Mercurymethyl (liq.)	430·8 cal.	431·8 cal.	—36·2 cal.
Mercurydiethyl (liq.)	733·6 "	735·0 "	—12·8 "
Mercurydiphenyl (cryst.) ...	1563·8 "	1565·3 "	—88·5 "

T. H. P.

Compounds of Lithium Chloride with Ethylamine. By J. BONNEFOI (*Compt. rend.*, 1899, 129, 1257—1259).—The compound, $\text{LiCl}, \text{NH}_2\text{Et}$, produced when ethylamine is passed over lithium chloride heated above 70° , is a white, porous substance the heat of dissolution of which in water is 7·503 Cal.; its heat of formation determined experimentally is 13·834 Cal., the value calculated by Clapeyron's formula being 13·717 Cal. The substance closely resembles the corresponding methylamine and ammonia compounds the heats of formation of which are respectively 13·820 and 11·842 Cals. (Abstr., 1897, ii, 371; 1899, ii, 96). The compound $\text{LiCl}, 2\text{NH}_2\text{Et}$ is formed at temperatures between 58° and 70° ; the heat of dissolution is 9·43 Cal. and the heat of formation is 24·817 Cal. The heat evolved by the fixation of the second molecule of the amine calculated from the dissociation pressures of the substance by Clapeyron's formula is 11·09 Cal. The compound $\text{LiCl}, 3\text{NH}_2\text{Et}$ is obtained below 58° , and even when the liquid amine was employed no further combination took place; the heat of dissolution is 11·77 Cal. and the heat of formation 35·387 Cal. The heat evolved during the fixation of the third molecule of the amine is 10·57 Cal. determined calorimetrically, and 10·503 Cal. calculated by Clapeyron's formula from the dissociation pressures.

G. T. M.

Lactic Acid. By MARCELLIN P. E. BEETHELOT and MARCEL DELÉPINE (*Compt. rend.*, 1899, 129, 920—926).—Thermochemical data for silver and zinc lactates and for lactide are given in the following table:

	Heat of combustion			Heat of formation		solution.
	1 gram.	1 mol. at const. vol.	1 mol. at const. press.	from elements.		
$\text{C}_3\text{H}_5\text{O}_5\text{Ag}$	1609·7 cal.	316·6 Cal.	316·5 Cal.	138·9 Cal.		—2·05 Cal.
$(\text{C}_3\text{H}_5\text{O}_5)_2\text{Zn}$...	2592·1 "	640·15 "	640·15 "	355·45 "		+8·00 "
$\text{C}_3\text{H}_5\text{O}_5$	4542·8 "	327·1 "	327·1 "	93·8 "		+2·10 "

The heats of neutralisation of lactic acid are: with $\frac{1}{2}\text{Ag}_2\text{O}$, 4·1 Cal.; with $\frac{1}{2}\text{ZnO}$ (hydrated), +9·95 Cal.; and with $\frac{1}{2}\text{ZnO}$ (anhyd.) +9·3 Cal.

These numbers give, for the heat of formation of lactic acid from its elements, mean values of 163·2 Cal. for the pure liquid acid and 164·3 Cal. for the dissolved acid.

T. H. P.

Heats of Fractional Neutralisation of Carbonylhydroferrocyanic Acid compared with those of Hydroferrocyanic Acid. By JOSEPH A. MULLER (*Compt. rend.*, 1899, 129, 962—964).—Each addition of one-fourth of the equivalent quantity of potash to a

dilute solution of a gram-mol. of hydroferrocyanic acid gives a heat development of almost exactly 14 Cals., the total at 18°6' being 56·18 Cals. Sensibly the same number of Cals. (14) are liberated when carbonylhydroferrocyanic acid is neutralised by thirds in dilute solution, the mean total heat evolutions being, at 19·4° with potash, 41·91 Cals., and at about 18° with baryta, 42·29 Cals.

Thus, carbonylhydroferrocyanic acid is a strong acid, and the replacement of HCN in the molecule of hydroferrocyanic acid by the carbonyl group has no appreciable influence on the acidic properties of the remaining hydrogen atoms.

T. H. P.

Narceine. By ÉMILE LEROY (*Compt. rend.*, 1899, 129, 1259—1261).—The heat of hydration of narceine is 6 Cal. for the dihydrated form, and, in addition, 3 Cal. are evolved when this is converted into the trihydrate. The heat of combustion is 2790·9 cal. at constant volume, and 2792·2 cal. at constant pressure. The heat of formation of the anhydrous base is 302·2 Cal., that of the dihydrate being 308·24 Cal. The heat of neutralisation of the dihydrated form in excess of hydrochloric acid is - 4·62 Cal., whilst that of the anhydrous base is 1·58 Cal. The hydrochloride, $C_{23}H_{27}O_8N, HCl$, crystallises, with $3H_2O$, from a solution containing excess of acid; the heat of hydration of the salt is 6·76 Cal. with water, and 2·08 Cal. with ice, the heat of formation of the anhydrous salt being 21·52 Cal. The heat of formation of the potassium derivative, $C_{23}H_{26}O_8NK$, is 16·7 Cal., the heat evolved on adding potassium hydroxide solution to an aqueous solution of the alkaloid being 11·5 Cal.

Narceine is the least basic of the opium alkaloids, and, like narcotine, is neutral to litmus; the heat of formation of the potassium derivative indicates a distinctly acidic function, the substance being intermediate in stability between the acetates or benzoates and the phenoxides.

G. T. M.

Fractional Distillation under Reduced Pressure. By GIUSEPPI ODDO (*Gazzetta*, 1899, 29, ii, 355—357).—The apparatus described consists of a T-piece fitted to the end of the condenser by means of a piece of rubber tubing which is slightly greased so as to allow of the T-piece being rotated. To the two branches of the latter are fitted two receivers, one being an ordinary flask, and the other an Erlenmeyer flask which is also in connection with the pump used for exhaustion. After the first fraction has been collected in one of these receivers, the T-piece is turned round so that the second receiver comes into use. If more than two fractions are required, to each branch of the T-piece another T-piece is fitted by means of a piece of greased rubber tubing; in this way, four fractions are obtainable.

T. H. P.

Determination of Freezing Points in Dilute Solutions. By MEYER WILDERMANN (*Zeit. physikal. Chem.*, 1899, 30, 508—526).—A consideration of the errors which must exist in thermometric determinations of freezing points. The formation of ice caps and nets is probably due to the presence of variable quantities of air and organic compounds in the water; these impurities also, although not indicated by the conductivity, may occasion variations of the freezing point, to

the extent of a few thousandths of a degree. Changes of external and internal pressure may also cause errors, the variation of the observed freezing point with the author's $1/1000^{\circ}$ thermometer being about 0.0003° per mm. of mercury. For accurate work also, the thermometer should be always kept at a temperature approximately equal to zero and not at the ordinary temperature. The effect of variations in the external temperature is also considered, but a more subtle source of error lies in the existence in the thermometer of rough places and dead points, which the mercury is unable to pass when the actual temperature is sufficiently near. Errors are also introduced owing to inaccuracies of calibration, and accuracy is hence frequently expected beyond that possible; for example, if an accuracy of 0.0001° is required with a $1/100^{\circ}$ thermometer, then the calibration should be performed with a mercury thread of about 1 mm. in length. Other errors not due to causes inherent in the method are also considered, and the author replies briefly to criticisms on his work (compare Abstr., 1896, i, 352, 587).
L. M. J.

Freezing Points of Mixed Crystals of Two Compounds. By H. W. BAKHUIS ROOZEBOOM (*Zeit. physikal. Chem.*, 1899, 30, 385—412).—A theoretical consideration of the phenomena of solidification of mixed crystals under various conditions; the following types are considered. A. The liquid solidifies to a continuous series of mixed crystals; three different types of curves are obtained, namely, in the cases where (1) the freezing point for every mixture lies between those of the two constituents, (2) a maximum, and (3) a minimum occurs. Many examples of the first case have been examined; of the second, no case has been completely studied, but lead-thallium mixtures are probably an example, while the third type is exemplified by mixtures of mercuric bromide and iodide. The general law is deduced that in all cases the liquid phase is richer than the solid phase, in that constituent which, if added, causes a depression of the freezing point. B. When the mixed crystals form an interrupted series, two more types of curves result; (4) when the freezing point curve contains a transition point at which the two crystal mixtures occur together, whilst a maximum or minimum may also be present—an example of this type has been found in mixtures of sodium and silver nitrates; (5) an eutectic point occurs in the freezing point curve; examples are mixtures of thallium and lead nitrates (Van Eijk, next page), and also of naphthalene and monochloroacetic acid (Cady, Abstr., 1899, ii, 405). When two different classes of crystals result, new types of curves are obtained closely resembling 4 and 5, and the author discusses the means of determining the type of curve indicated by experimental determinations of the freezing point. The accounts of the experimental realisation of the various types mentioned in the paper are deferred.
L. M. J.

Transition Points in Mixed Crystals. By H. W. BAKHUIS ROOZEBOOM (*Zeit. physikal. Chem.*, 1899, 30, 412—429).—The possible types of curves for the transition of one set of mixed crystals to another are considered; the following types occur:—(1) A continuous series of mixed crystals, α , change to a continuous series, β ; the

forms of curve are analogous to types 1, 2, 3 in the preceding abstract, a complication being, however, introduced when only one component undergoes a transition; an example is the transition of mixtures of mercuric bromide and iodide. (2) A continuous series, α , change to a discontinuous series, β ; the transition curves are here analogous to types 4 and 5 of the freezing point curve, an example is probably the mixture of azoxyanisole and azoxyphenetole (Abstr., 1898, ii, 286); in this case also, transition of only one component may occur. (3) The mixed crystals form in the α state, and in the β state a continuous series; examples are the systems potassium and sodium nitrates, and sodium and silver nitrates. (4) The mixed crystals form discontinuous series in both states, an example being potassium and thallium nitrates (following abstract). (5) Isodimorphous mixed crystals change into a continuous or (6) an interrupted series of mixed crystals. Further types may occur in which the isodimorphous crystals are discontinuous, but these are not considered. L. M. J.

Formation and Transition of Mixed Crystals of Potassium and Thallium Nitrates. By C. VAN EIJK (*Zeit. physikal. Chem.*, 1899, 30, 430—459).—The melting point and transition curves were completely examined in the case of mixed crystals of the above compounds. The melting points of the pure compounds are: potassium nitrate 339° , thallium nitrate 206° , and an eutectic point occurs at 182° , the mixture containing 31 per cent. of potassium nitrate; the law stated by Roozeboom (preceding abstracts) regarding the composition of the solid and liquid phases was verified. During the solidification of the mass, the composition of the liquid phase changes continuously and the temperature falls; if the freezing is sufficiently slow, it is probable that the composition of the solid would also change, *pari passu*, until the whole mass solidifies at a final temperature corresponding with that at which the solid of the given composition is in equilibrium with a liquid phase. In the experiments, however, the solid phase was not found to change sufficiently rapidly, so that the final temperature is always lower than that deduced, as above, from the curves. As products of the freezing, a continuous series of rhombohedra were obtained to 20 per cent., and a second continuous series from 50 to 100 per cent. of potassium nitrate; for intermediate values, a conglomerate of the mixed crystals is obtained. The transition temperatures were obtained by both thermometric and dilatometric methods, as well as by the microscopical examination of the crystals. It was found that change to rhombic crystals occurs at 129° for potassium nitrate, and at 144° for thallium nitrate. For the mixed crystals, continuous transition curves are obtained from 144° to 133° on the thallium side, and from 129° to 108.5° on the potassium side. The conglomerate has, however, two transition temperatures, the first at 133° , at which temperature it changes to a mixture of rhombohedra and rhombic crystals, and the second at 108.5° , where the remaining rhombohedra change to the rhombic form. Although no transition in the conglomerate occurs above 133° , the composition of the two sets of mixed crystals changes with the temperature, the percentage of potassium nitrate being 20 and 50 per cent. at 182° , 20 and

69 per cent. at 133°, and 35 and 84 per cent. at 108.5°. This system thus forms a complete example of the type 4 of transition curve deduced by Roozeboom (preceding abstracts). L. M. J.

Cryoscopic Researches on the Constitution of Acid Amides. By KARL AUWERS [with MAX DOERN] (*Zeit. physikal. Chem.*, 1899, 30, 529—544).—It has been shown that amides in naphthalene solution are generally cryoscopically abnormal (compare Abstr., 1897, ii, 476). The constitution may be either $R \cdot NH \cdot CO \cdot R'$ or $RN \cdot CR' \cdot OH$, and in the latter case the abnormality may be occasioned by the hydroxyl group and the behaviour of the thioamides should be similar to that of the thiophenols. The thiophenols examined, however, were found to be cryoscopically normal, and the thioamides to be abnormal, so that the constitution $R \cdot NH \cdot CS \cdot R'$ is most probable. As, however, the abnormality may be due to the increased acidity of the thio-compounds, the case was further examined. The author shows that in general a substituent causes a decrease of abnormality only when this substituent and the group causing abnormality are attached to neighbouring carbon atoms. In the case of substituted derivatives of benzanilide, it was found that the compounds from ortho-substituted aniline are normal, but the derivatives of the ortho-substituted benzoic acid remain abnormal, and hence the abnormality is caused by an $\cdot NH$ group, that is, the previous conclusions are confirmed. Basic amines are, however, normal, although piperidine is slightly abnormal, and it is found that the abnormality of urethane is greatly decreased by the entrance of a phenyl group. L. M. J.

Accurate Determination of the Molecular Weight of Gases from their Density. By JOHANNES D. VAN DER WAALS (*Proc. K. Akad. Wetensch. Amsterdam*, 1898, 1, 198—201).—The molecular weight of a gas is proportional to the normal density d_n , which is equal to $d_0/(1+a)(1-b)$, where d_0 is the density found at 0° under the pressure p_0 , and a and b are the constants of van der Waals' equation. If d'_0 be the density found at another temperature T , mathematical discussion leads to the equation $d_n/d'_0 = 1 - 0.001645 T_k/T \cdot (27 T_k/8 T - 1)$, where T_k is the critical temperature of the gas. For $T > 27 T_k/8$, the correction is negative, and d_n/d'_0 has a maximum for $T = 27 T_k/4$.

The condition for the observation under a pressure of $\Pi/76$, without the vapour being saturated, is that T must not fall below a certain limit. When this limit is put at $T_k/1.6$, the normal density is 1 per cent. smaller than the value given by experiment. J. C. P.

True Density of Chemical Compound and its Relation to Composition and Constitution. By INNOCENTIVS I. KANONNIKOFF (*Chem. Centr.*, 1899, ii, 858—861; from *J. Russ. Chem. Soc.*, 31, 573—640).—According to the theories of Clausius and Mosotti, the ratio $\mu^2 - 1/\mu^2 + 2$, where μ is the refractive index, is the ratio of the actual volume of the molecules to the total volume; the true density is hence $d(\mu^2 + 2/\mu^2 - 1) = D$, and the value of this constant is the same for liquid and gaseous states. The value being, however, dependent on that of the refractive index, is obviously a function of wave-length and temperature, and may, if required, be corrected for

an infinite wave-length and for zero temperature by the Cauchy dispersion formula and the expression $D^2 = D_0(1 + kt)$. The author, however, employs the values for sodium light and a temperature of from 10° to 20° . If the true density is multiplied by the molecular weight, the product, termed the "molecular density," but of which the physical interpretation does not appear evident, is found to be an additive function. In hydrocarbons, it is given by the expression $39.7n + (2n \pm m)H - 4H + a.9H - b.6H - b'.26H - c.4H$, where n is the number of carbon atoms, $2n \pm m$ that of the hydrogen atoms, and a , b , b' , and c the number of closed chains, ethylenic unions, naphthaleno-ethylenic unions, and acetylenic unions respectively in the molecule, the value for H being 0.967. It is stated that for a large number of compounds the values so calculated are in accord with the determinations. In many cases, the "molecular density" may be a useful criterion of constitution, as the various modes of union have very diverse values, and various examples are given. L. M. J.

Equation of Condition. By MAX REINGANUM (*Chem. Centr.*, 1889, ii, 955; from *Diss. Gottingen*).—Van der Waals' equation can be regarded only as an approximation, but any improvement suggested must still necessitate the law of corresponding states. The author suggests the equation $\{p + a/v^2\}/\{(v - b)^4/v^3\} = RT$; this contains no more constants than van der Waals' expression; the constants also are functions of the molecular weight, and apparent and actual molecular volumes. The author states that it gives results in good accord with previous determinations, notably, those of Young on isopentane, and the validity of the equation is proved by the coincidence of the isothermals, and by the comparison of the predicted and found vapour pressure, expansion of liquid and vapour, and latent heat of vaporisation. The equation predicts the constant ratio between the critical and actual molecular volumes and the constant ratio of the critical density to the theoretical density calculated for a perfect gas, whilst the deduced temperature coefficients of internal friction are also in agreement with the experimental results. L. M. J.

Equilibrium in the System, Water—Phenol—Aniline. By FRANS A. H. SCHREINEMAKERS (*Zeit. physikal. Chem.*, 4899, 30, 460—480).—The theoretical aspects of such an equilibrium system are fully considered; in it, two pairs of the components are capable of forming two liquid layers as in the system, water—alcohol—succinonitrile (*Abstr.*, 1898, ii, 564), but the case is now complicated by the existence of a compound of phenol and aniline. In such a case, by the addition of water to the compound, two liquid phases may result in which (1), with or without decomposition, the relative concentrations of the two components of the compound are unchanged, or (2) owing to decomposition, the relative concentrations vary. In the first case, only one temperature occurs at which the compound and the two liquid phases can exist together, but in the second a series of temperatures occur, that is, a "transition interval." This interesting case is observed in the system considered, the compound of phenol and aniline being in equilibrium with two liquid phases between the temperatures

16.9° and 17.2°. The various theoretical and determined equilibrium curves and isothermals are given in the paper (Abstr., 1899, ii, 739).

L. M. J.

False Equilibrium. By MAX BODENSTEIN (*Zeit. physikal. Chem.*, 1899, 30, 567—569).—A reply to Duhem's criticisms of the author's results (see Abstr., 1899, ii, 739).

L. M. J.

Condition of Substances Insoluble in Water formed in Gelatin. By CORNELIS A. LOBRY DE BRUYN (*Proc. K. Akad. Wetensch. Amsterdam*, 1898, 1, 39—42).—The exceptional phenomenon of certain substances, such as silicic acid, remaining unprecipitated in aqueous solution, is general in aqueous gelatin solution. An insoluble compound formed by double decomposition in aqueous solution generally remains unprecipitated when the same substances are brought together in gelatin solution, although there are grounds for believing that the double decomposition has actually taken place. Thus, Cohen has shown that when silver nitrate and potassium bromide are mixed in gelatin solution, the resulting conductivity is that due to the potassium nitrate, and not that due to the two electrolytes, silver nitrate and potassium bromide. Further, although the gelatin solution remains transparent, it takes the colour of the product formed by double decomposition, as in the cases of Prussian blue and lead iodide.

Although the visible precipitation of amorphous substances is prevented by gelatin, crystalline, insoluble substances separate as in aqueous solution: this is the case, for example, with calcium oxalate and ammonium magnesium phosphate.

Genesis of Dalton's Atomic Theory. By HEINRICH DEBUS (*Zeit. physikal. Chem.*, 1899, 30, 556—562).—A further controversial paper in reply to Kahlbaum (Abstr., 1899, ii, 740).

L. M. J.

Some Anomalies in Mendeléeff's System. By THEODOR H. BEHRENS (*Proc. K. Akad. Wetensch. Amsterdam*, 1898, 1, 148—151).—Isomorphism is not to be rashly used as a guide to the natural position of an element, for the evidence is often conflicting. Retgers, who denies isomorphism between tellurates and sulphates, assigns to tellurium a place in the eighth group between ruthenium and osmium, disregarding the analogy between hydrogen telluride and sulphide, and recognising the isomorphism of K_2TeO_6 with K_2OsO_6 and K_2IrCl_6 . But, on other grounds, tellurium might be put in the fourth group, for the compounds Cs_2TeCl_6 and Cs_2SnCl_6 are isomorphous, and tellurium dioxide dissolves in potassium hydrogen oxalate, forming crystals like those of potassium zirconium oxalate; further, if tellurium should be placed between ruthenium and osmium, seventeen new elements would have to be looked for in that group.

With manganese, there is a similar ambiguity. The isomorphism between $KMnO_4$ and $KClO_4$ agrees with the position of manganese in the seventh group, but, on the other hand, K_2MnO_4 and K_2SO_4 are isomorphous, and experiments made with manganese tetrachloride point to an analogy between manganese and tin.

J. C. P.

Relation of Physical Properties of Elements to their Atomic Weights. By W. SANDER (*Chem. Centr.*, 1899, ii, 955; from *Electr. Zeit.*, 6, 133).—Curves are given in the original paper from which the author deduces that the coefficients of linear expansion, migration velocities of ions, electrical conductivity, and electrolytic potential of metals are periodic functions of their atomic weights.

L. M. J.

Inorganic Chemistry.

Nitrosyl Chloride and its Compounds. By W. J. VAN HETEREN (*Zeit. anorg. Chem.*, 1899, 22, 277—278).—Nitrosyl chloride, when cooled in a mixture of solid carbon dioxide and alcohol, solidifies in blood-red crystals which melt at -65° . It mixes in all proportions with liquid chlorine, and a mixture in the proportions required by the formula NOCl_2 does not crystallise at -80° . The compound, $\text{SnCl}_4 \cdot 2\text{NOCl}$, prepared by treating stannic chloride with nitrosyl chloride and distilling off the excess, melts in a sealed tube at 150° . The compound $2\text{SbCl}_5 \cdot 5\text{NOCl}$ melts in a sealed tube at 180° , and the compound $\text{Fe}_2\text{Cl}_6 \cdot 2\text{NOCl}$ at 116° .

E. C. R.

The Lower Oxides of Phosphorus. By AUGUST MICHAELIS and M. PITTSCH (*Annalen*, 1899, 310, 45—74. Compare Abstr., 1899, ii, 285).—Phosphorus suboxide, P_4O , first obtained by Le Verrier, is precipitated on adding an acid to a solution of phosphorus in alcoholic potash diluted with water; it is also formed on withdrawing the elements of water from hypophosphorous acid by the action of acetic anhydride. It is an orange-red powder of sp. gr. 1.9123 at 26° , but the colour depends largely upon the state of division, being sometimes pale yellow. When thoroughly dried, it is almost odourless, but a trace of moisture imparts to it the odour of phosphine; in the former condition, also, it may be heated in air to a comparatively high temperature without becoming ignited, but when moist it burns readily after being heated at 90° during several hours. If dried and heated in an indifferent gas, phosphorus distils over, leaving phosphoric oxide. Chlorine converts the dried oxide into phosphorus oxychloride and phosphorus pentachloride, the damp substance being oxidised to phosphoric acid, which is also produced by the action of sodium hypochlorite and of warmed sulphuric acid, the latter becoming reduced to hydrogen sulphide. Concentrated nitric acid ignites the substance, which is indifferent towards hydrochloric acid. Many metals are precipitated by it from solutions of their salts either in metallic form, or as phosphorus compounds. A solution of sodium or potassium hydroxide in aqueous alcohol dissolves phosphorus suboxide, forming a deep red solution which transmits only light between the C and D lines of the spectrum; when warmed, or on standing at the ordinary temperature, this solution evolves hydrogen and phosphine, sodium hypophosphite

remaining [dissolved]. The oxide is coloured brown by ammonia, but the latter is removed on exposure to air, and the substance regains its orange-red hue.

The result of the authors' investigation is to show that phosphorus suboxide is the only lower oxide of phosphorus existing at present, those of Gautier, Besson, and Franke being merely Le Verrier's compound in an unpurified condition. An examination of these supposed oxides has been made, and is described in the paper, which gives details of the analytical methods employed [compare Chapman and Lidbury, *Trans.*, 1899, 75, 973]. M. O. F.

A General Property of Phosphorous Acid. By LUDWIG VANINO (*Chem. Centr.*, 1899, ii, 930; from *Pharm. Centr.-H.*, 40, 637—668).—When sodium hydroxide solution is added to a mixture of 10 grams of a 10 per cent. solution of copper sulphate with several grams of phosphorous acid, only a faint turbidity is produced, and this disappears on further addition of the alkali. Under similar conditions, salts of the alkaline earths, cobalt, nickel, and iron (ferrous or ferric) also form clear, alkaline solutions. This property, however, is limited to those metals which form hydroxides, precipitates being formed in the case of salts of such metals as silver or mercury (mercurous or mercuric). These alkaline solutions do not usually form precipitates with sodium carbonate, but often give remarkable reactions with hydrogen sulphide or ammonium sulphide. The alkaline solution of a manganese salt is not at first attacked by hydrogen sulphide, and a similar solution of a ferric salt also resists the action of ammonium sulphide. The copper sulphate solution is not acted on by sodium carbonate or ammonium thiocyanate, but is reduced by a trace of dextrose. Although satisfactory results have not been obtained by analysis, it is probable that in this case, as in the case of arsenious acid, salts such as CuHPO_3 are formed, and that these then combine with sodium phosphate to form double salts. E. W. W.

Fluorohyperborates. By PETR G. MELIKOFF and S. LORD-KIPANIDZE (*Ber.*, 1899, 32, 3349—3354. Compare *Abstr.*, 1898, ii, 219 and 292).—*Potassium fluorohyperborate*, $\text{K}_4\text{B}_4\text{F}_{11}\text{O}_{11} + \text{H}_2\text{O}$, produced by treating an aqueous solution of potassium fluoroborate, $2\text{KF} \cdot \text{B}_2\text{O}_3$, with a slightly alkaline solution of hydrogen peroxide, separates on the addition of alcohol as a viscous mass which becomes crystalline on stirring; the substance is redissolved in water and the process repeated, the salt being finally obtained in rhombic prisms. The following constitution, $\text{OK} \cdot \text{BF} \cdot \text{O} \cdot \text{O} \cdot \text{BF} \cdot \text{O} \cdot \text{OK}, \text{OK} \cdot \text{O} \cdot \text{BF} \cdot \text{O} \cdot \text{O} \cdot \text{BF} \cdot \text{O} \cdot \text{OK}, \text{H}_2\text{O}$, is assigned to the compound. The aqueous solution has an alkaline reaction and slowly evolves oxygen at the ordinary temperature, this decomposition being accelerated by warming; the silver salt is produced as a yellow precipitate by adding silver nitrate to the solution; it is unstable, and blackens owing to the separation of metallic silver, oxygen being simultaneously evolved. The dry potassium salt is moderately stable; dilute sulphuric acid liberates hydrogen peroxide, whilst the concentrated acid evolves ozonised oxygen. This salt may also be obtained by the action of hydrogen peroxide on potassium orthofluoroborate, $\text{BF}(\text{OK})_2$. G. T. M.

Fluorohyperborates. By PETR G. MELIKOFF and S. LORD-KIPANIDZE (*Ber.*, 1899, 32, 3510—3512. Compare preceding abstract).—The potassium salt, $K_2B_2F_5O_6 + H_2O$, to which the structure

is assigned, is precipitated by alcohol from hydrogen peroxide solution as a crystalline powder. The ammonium salt, $Am_2B_2F_5O_6 + 3H_2O$, prepared by adding hydrogen peroxide, ammonia, and alcohol to a solution of boric acid and ammonium fluoride, is a white, crystalline powder, and is moderately stable; the aqueous solution decomposes gradually at ordinary temperatures, and rapidly on warming.

T. M. L.

Explosion of Potassium Chlorate. By MARCELLIN P. E. BERTHELOT (*Compt. rend.*, 1899, 129, 926—929).—Although the decomposition of potassium chlorate into the chloride and oxygen is an exothermic reaction, it is not regarded as an explosive, since it does not detonate when gradually heated. If, however, the melted chlorate be allowed to fall drop by drop into a glass tube heated to redness, a sharp and rather prolonged explosion occurs as each drop comes into contact with the hot tube, a white smoke of potassium chloride being simultaneously formed.

T. H. P.

Acid Iodates Containing Fluorine, and Cesium Fluoroperiodate. By RUDOLPH F. WEINLAND and O. KÖPPEN (*Zeit. anorg. Chem.*, 1899, 22, 256—265).—Cesium hydrogen tetrafluoriodate,

is obtained by dissolving cesium hydrogen iodate, cesium dihydrogen iodate, or cesium dihydrogen iodate with 2 mols. iodic acid in 20—60 per cent. hydrofluoric acid, and also in smaller quantities from a solution of cesium iodate in hydrofluoric acid. It crystallises from 40—60 per cent. hydrofluoric acid in thick, six-sided plates, or aggregates of thin plates, effloresces rapidly on exposure to the air, and dissolves slowly in water, yielding a strongly hydrofluoric acid solution.

Rubidium hydrogen tetrafluoriodate, with $2H_2O$, is obtained by dissolving rubidium fluoride (1 mol.) and iodic acid (2 mols.) in hydrofluoric acid of at least 40 per cent. It crystallises in plates, and is very easily converted into rubidium difluoriodate.

Cesium fluoroperiodate, $2CsIO_4 \cdot 3HF + H_2O$, obtained by dissolving cesium periodate in warm 60 per cent. hydrofluoric acid, crystallises in colourless, lustrous prisms, effloresces slowly on exposure to the air, and is decomposed by water.

E. C. R.

Reversible Reaction between Hydrogen Chloride and Silver. By JOURNALUX (*Compt. rend.*, 1899, 129, 883—886. Compare Abstr., 1879, 589).—The amount of hydrogen chloride formed when silver chloride and hydrogen are heated together increases with the time of heating, and reaches a limit which is dependent on the temperature to which the reacting substances are heated. At a temperature of 350° , equilibrium is established when the residual gas contains 75.85 per cent. of hydrogen chloride, and is attained after heating for 5 weeks, whilst at 600° the limit is reached after heating for 1 hour, and the residual gas contains 92.80 per cent. of hydrogen chloride. The action of hydrogen chloride on silver is also limited and

varies with the temperature. At 490° , 530° , and 600° , equilibrium is established when the residual gas contains 94.10, 92.95, and 92.80 per cent. of hydrogen chloride respectively. The limit at which equilibrium is established is practically independent of the amount of surface of silver chloride exposed, and for temperatures above the melting point of silver chloride this limit is quite independent of mass.

H. R. LE S.

Reciprocal Displacement of Metals. By ALBERT COLSON (*Compt. rend.*, 1899, 129, 825—827).—Experiments with silver and mercurous chloride, and silver and mercuric sulphide in sealed vacuum tubes between 150° and 300° , show that the direct displacement of silver by mercury is, under some conditions, a reversible reaction, limited by the pressure of the mercury vapour, just as heterogeneous dissociation is limited by a gaseous pressure.

Experiments with copper and cadmium sulphide or oxide gave similar, but less definite, results owing to the partial direct dissociation of the two cadmium compounds below 600° . Thin films of cadmium formed by condensation of the vapour in the cool parts of the tube were violet-blue by transmitted light.

C. H. B.

Preparation of Monocalcium Phosphate. By L. LÉON A. PRUNIER and ADOLPHE JOUVE (*J. Pharm.*, 1899, [vi], 10, 529—530).—If a mixture of dicalcium phosphate, $\text{Ca}_2\text{H}_2(\text{PO}_4)_2$, and orthophosphoric acid in the proportions to form monocalcium phosphate, $\text{CaH}_4(\text{PO}_4)_2$, is dissolved in an equal weight of water and the solution rapidly evaporated, a deposit of dicalcium phosphate, sometimes mixed with a little of the monocalcium salt, is obtained; whereas, if the liquid is subjected to prolonged boiling, only hydrated monocalcium phosphate is formed. From these results, it is concluded that the formation of the more stable hydrated monocalcium phosphate from the anhydrous salt is only slowly effected, and this is confirmed by the fact that the pure anhydrous salt only is precipitated when alcohol is added to the freshly prepared solution.

N. L.

Change of Volume during the Hardening of Hydraulic Cements. By HENRI LE CHATELIER (*Compt. rend.*, 1899, 129, 1232—1234).—The author's experiments indicate that the apparent expansion of mortars and cements during hydration is due to the relative displacement of the solid particles, and that in reality this action is accompanied by a considerable diminution in volume.

G. T. M.

Action of Hydrogen Fluoride and Fluorine on Glass. By HENRI MOISSAN (*Compt. rend.*, 1899, 129, 799—804).—Hydrogen fluoride, produced by heating carefully dried potassium hydrogen fluoride, acts at once on very carefully dried glass at the ordinary temperature. Gaseous fluorine obtained by electrolysis, and deprived as far as possible of hydrogen fluoride by passing it over sodium fluoride, acts on glass, but if hydrogen fluoride is completely removed by subjecting the fluorine to the temperature of boiling air, or by passing the gas over dry sodium fluoride cooled in a mixture of solid carbon dioxide and acetone, the fluorine no longer acts on glass, even at 100° , provided that it is dry and the surface is free from

organic matter. If these conditions are satisfied, liquid fluorine can be kept for a long time in sealed glass bulbs or tubes.

The author points out that glass may retain its polish even when acted on by hydrogen fluoride, and that phosphoric oxide cannot be used for drying hydrogen fluoride, owing to the formation of phosphorus oxyfluoride at the ordinary temperature. C. H. B.

Activity of Manganese in Promoting the Phosphorescence of Strontium Sulphide. By JOSÉ R. MOURÉLO (*Compt. rend.*, 1899, 129, 1236—1238. Compare *Abstr.*, 1899, ii, 97, 98, 366, 420, and 484).—The paper contains details of the preparation of phosphorescent strontium sulphide produced by the action of sulphur on strontium carbonate or sulphate at a red heat in the presence of small quantities of manganous sulphate, sodium chloride and sodium carbonate. The effect of the manganous sulphate on the strontium sulphide is similar to that of manganous carbonate or basic bismuth nitrate; the phosphorescence becomes more intense, lasts longer, and is attained after a shorter exposure to diffused daylight. When due to manganese, the phosphorescence has a yellowish-green colour, whilst that produced by bismuth is bluish-green. G. T. M.

Effect of various Solvents on the Allotropic Change of Mercuric Iodide. By J. H. KASTLE and MARY E. CLARK (*Amer. Chem. J.*, 1899, 22, 473—484).—The authors have studied the behaviour of mercuric iodide when dissolved in the following liquids at their boiling point: ethyl bromide, propyl chloride, acetone, ethylidene chloride, ethyl iodide, ethyl acetate, alcohol, isopropyl bromide, benzene, allyl alcohol, toluene, propionitrile, ethyl butyrate, isobutyrate and propionate, benzoic acid, phenol, benzonitrile, oil of winter green, propyl bromide, ψ -cumene, naphthalene and phenyl salicylate; with all these solvents, except isobutyl bromide and propyl chloride, yellow solutions were obtained, and in all cases, without exception, yellow crystals separated on cooling; the pink colour of the solutions obtained with isobutyl bromide and propyl chloride appears to be due, not to the red modification of mercuric iodide, but "to the formation of unstable alkyl iodides." The fact that only yellow solutions are obtained on dissolving the red iodide in the various solvents and that the yellow modification alone separates from these, appears to indicate that the transition temperature (128°) of mercuric iodide is lowered by the solvents dealt with, especially by those boiling at a low temperature. The question whether red mercuric iodide is insoluble in the solvents named, and only dissolves by being converted into the yellow modification, is discussed at some length. It is significant that the red modification is not obtained, but only crystals of the yellow variety, on adding a red crystal to the yellow solutions. W. A. D.

Transformation Temperature of the Quadratic and Orthorhombic Forms of Mercuric Iodide. By DÉSIRÉ GERNEZ (*Compt. rend.*, 1899, 129, 1234—1236).—Yellow mercuric iodide may be kept for a long time at the ordinary temperature, whilst the red variety persists at temperatures above that at which transformation is possible; the former state of the iodide is termed "crystalline superfusion,"

and the latter "crystalline superheating." On account of these retardations, it is difficult to determine the transformation temperature with exactness. When alternate layers of the two forms, placed in contact with each other, are maintained at the same temperature, it is found that at 127° the zones of yellow iodide slowly encroach on the red variety, whilst at 125° this modification gradually displaces the other. The transformation temperature is therefore 126° and is the same whether the crystals are heated under atmospheric pressure or in a vacuum.

G. T. M.

Dissociation by Water of Ammonium and Potassium Mercuriodides. By MAURICE FRANÇOIS (*Compt. rend.*, 1899, 129, 959—962. Compare Abstr., 1899, ii, 597).—In the presence of relatively large quantities of water, these salts suffer complete decomposition into the constituent iodides, part of the mercuric iodide being precipitated and the rest forming a saturated solution in the alkali iodide solution. By treatment of the mercuriodides with small quantities of water, as also by acting on excess of mercuric iodide with solutions of the alkali iodides, it is found that the decomposition is limited and reversible, and obeys the laws of dissociation of salts by water; when equilibrium is attained, the liquid contains a quantity of free ammonium or potassium iodide, which is constant for a given temperature.

T. H. P.

Preparation of Sulphur, Chlorine, and Bromine Compounds of the Cerite Metals. By WILHELM MUTHMANN and L. STÜTZEL (*Ber.*, 1899, 32, 3413—3419).—Didier's method of preparing cerium and lanthanum sulphides, by passing hydrogen sulphide over the heated oxides (Abstr., 1885, 955), does not give satisfactory results unless the oxide is very finely powdered; the pure sulphides can, however, be readily obtained if the anhydrous sulphates are used. The cerium sulphide is brownish-black to black, lanthanum sulphide is pure yellow, neodymium sulphide is olive-green, and praseodymium sulphide is chocolate-coloured. They are fairly stable in air at the ordinary temperature, but are slowly decomposed by boiling water with evolution of hydrogen sulphide (lanthanum sulphide the most readily), and dissolve readily in dilute acids; the four sulphides ignite readily below a red-heat and burn to a mixture of oxide and sulphate, and cerium sulphide when finely divided ignites spontaneously at the ordinary temperature. Mosander's greenish cerium oxysulphide and golden-yellow, crystalline sulphide could not be prepared. The densities are La_2S_3 , 4.9108; Ce_2S_3 , 5.020; Pr_2S_3 , 5.042; Nd_2S_3 , 5.179 at 11° , increasing with the atomic weight.

The chlorides are prepared by first passing hydrogen sulphide over the dry sulphates, then carbon dioxide and dry hydrogen chloride. Cerium and lanthanum chlorides are pure white, crystalline masses, neodymium chloride is rose-coloured, and praseodymium is green. They readily absorb moisture from the air, dissolve with hissing in water to a clear solution, dissolve in alcohol and are readily fusible, but only volatilise with great difficulty. For preparing large quantities of chloride containing a trace of oxide, the best method is by evaporation and ignition of the ammonium double chloride.

By passing hydrogen bromide over the sulphide, cerium bromide, CeBr_3 , was obtained as a snow-white, crystalline, soluble powder, which readily absorbed moisture from the air. T. M. L.

Specific Gravity of Yttrium, Zirconium, and Erbium. By STEFAN MEYER (*Monatsh.*, 1899, 20, 793—796).—Investigations of magnetic susceptibility have shown that the paramagnetic element yttrium occupies a position in the periodic system among a number of diamagnetic elements, and this peculiarity has led the author to determine some other characteristic constant. The specific gravity of yttrium powder was measured in a volumometer, the powder being contained in a small tube connected through a ground stopper with the rest of the apparatus. The specific gravity was found to be 3.80 at 15° ; with the atomic weight 89, the atomic volume is thus 23.6, a value corresponding with the position already assigned to yttrium in the periodic system. The abnormal magnetic behaviour of this element is therefore probably due to an admixture of some known or unknown element; if the presence of the new element victorium in yttrium should be confirmed, the former must be strongly paramagnetic.

The specific gravity of zirconium has been found to be 4.08, and that of erbium 4.77 at 15° . J. C. P.

Direct Combination of Aluminium and Nitrogen in the Electric Arc. By LEO ARONS (*Chem. Centr.*, 1899, ii, 643; from *Naturw. Rundsch.*, 14, 453—454).—When an electric arc is produced between electrodes of platinum, zinc, copper, tin, lead, iron, or cobalt in an atmosphere of nitrogen, the surface of the metal becomes coated with a film which probably consists of nitride. In the case of aluminium, considerable quantities of the greyish-black nitride are formed. This nitride is insoluble in water, and when treated with potassium hydroxide solution yields ammonia. When silver electrodes are used, the appearance of the silver changes, but there is apparently no formation of nitride. The analogy between the production of nitrides and that of acetylene by means of the arc, and the importance of utilising the nitrogen of the atmosphere are pointed out.

E. W. W.

Double Salts of Ferric and Aluminium Fluorides with Fluorides of Bivalent Metals. By RUDOLPH F. WEINLAND and O. KÖPPEN (*Zeit. anorg. Chem.*, 1899, 22, 266—276).—These salts are prepared by mixing a solution of aluminium or ferric hydroxide in dilute hydrofluoric acid with a solution of the carbonate or hydroxide of the bivalent metal in dilute hydrofluoric acid, and allowing the mixture to evaporate at the ordinary temperature over lime. An excess of one of the constituents and the amount of hydrofluoric acid present are immaterial. The salts can be recrystallised from dilute hydrofluoric acid.

Ferric ferrous fluoride, $\text{FeF}_3 \cdot \text{FeF}_2 + 7\text{H}_2\text{O}$, forms yellow, rhomboidal crystals and does not effloresce over sulphuric acid. *Ferric nickel fluoride*, $\text{FeF}_3 \cdot \text{NiF}_2 + 7\text{H}_2\text{O}$, separates in small, bright green crystals, *ferric cobalt fluoride* in rose-coloured crystals, and *ferric zinc fluoride* in very small, faintly red crystals.

Aluminium ferrous fluoride, $\text{AlF}_3 \cdot \text{FeF}_2 + 7\text{H}_2\text{O}$, forms small, greenish-white, rhomboidal crystals, does not oxidise on exposure to the air or effloresce when placed over sulphuric acid. The corresponding *nickel* salt separates in green crystals, the *cobalt* salt in reddish-white crystals, and the *zinc* salt in colourless crystals.

Aluminium fluoride combines with copper fluoride to form three double salts. The salt, $\text{AlF}_3 \cdot 2\text{CuF}_2 + 11\text{H}_2\text{O}$, obtained from solutions containing 1 mol. aluminium fluoride to 2 or more mols. copper fluoride, crystallises in spherical aggregates of blue leaflets and does not effloresce over sulphuric acid. The salt, $2\text{AlF}_3 \cdot 3\text{CuF}_2 + 18\text{H}_2\text{O}$, crystallises in deep blue prisms resembling feldspar from solutions containing 2 mols. aluminium fluoride to 3 mols. copper fluoride in the presence of only small quantities of hydrofluoric acid. If much acid is present, the salt, $\text{AlF}_3 \cdot \text{CuF}_2 \cdot \text{HF} + 8\text{H}_2\text{O}$, is formed; this crystallises in large, blue rhombohedra from solutions containing 1 mol. aluminium fluoride to 1 mol. or less of copper fluoride and an excess of hydrofluoric acid, and effloresces rapidly on exposure to the air with evolution of water and hydrofluoric acid.

E. C. R.

Action of Nitric Oxide on Chromyl Dichloride. By VICTOR THOMAS (*Compt. rend.*, 1899, 129, 828—831).—Nitric oxide acts violently on chromyl dichloride with abundant formation of higher nitrogen oxides. If the chromium compound is in the form of vapour, the solid product is at first white, but afterwards becomes brown; it is very slightly soluble in organic solvents, but dissolves readily in water with liberation of nitrogen oxides and production of a black solution containing chromic oxide, chromic acid, chlorine, and nitrogen oxides. This solid product has the composition $\text{Cr}_5\text{Cl}_5\text{O}_7 \cdot 2\text{NO}_2$; when heated, it yields chromic oxide, nitrogen oxides, and chlorine, and when treated with reducing agents the nitrogen is converted into ammonia. Chromium, like tin, bismuth, and iron, can evidently form compounds containing the NO_2 group, which are stable even in a vacuum at the ordinary temperature, but are readily decomposed by water.

C. H. B.

Molybdenum Disulphide. By MARCEL GUICHARD (*Compt. rend.*, 1899, 129, 1239—1242).—Crystalline molybdenum disulphide is readily prepared by heating a mixture of potassium carbonate, sulphur, and molybdenum dioxide or ammonium molybdate in the Perrot furnace. The amorphous sulphide is produced by heating a mixture of ammonium molybdate and sulphur in an earthenware crucible surrounded by lampblack, the operation being repeated to remove the last traces of oxygen from the product. The sulphide is not attacked by solutions of sulphur in alkaline hydrosulphides or sulphur chloride, and phosphorus is without action on it even at high temperatures. When heated in a current of hydrogen, it is directly reduced to the metal without forming a lower sulphide. Although native molybdenite loses the whole of its sulphur at the temperature of the electric arc, it is possible in the case of the artificial product to isolate an intermediate sesquisulphide.

G. T. M.

Molybdenum Silicide. By ÉMILE VIGOUROUX (*Compt. rend.*, 1899, 129, 1238—1239).—*Molybdenum silicide*, Mo_2Si_2 , resembles tungsten

silicide (Abstr., 1899, ii, 194), and is prepared in a similar manner by heating, in a carbon crucible in the electric furnace, a mixture of crystallised silicon and the molybdenum oxides obtained by calcining ammonium molybdate; the crystalline product is disintegrated by electrolysis in hydrochloric acid, and the mixture of crystalline silicides is treated successively with aqua regia, caustic potash, and hydrofluoric acid; the removal of carbon silicide is effected by means of cadmium tungstate solution, and the residue consists of molybdenum silicide mixed with more or less iron silicide. When heated in chlorine at 300° , molybdenum silicide becomes ignited, silicon tetrachloride and molybdenum perchloride being produced.

G. T. M.

Complex Inorganic Acids. VIII. Arsenoduodecitungstic Acid and Arsenoluteotungstic Acid. By FRIEDRICH KEHRMANN and E. RÜTTIMANN (*Zeit. anorg. Chem.*, 1899, 285—296).—Ammonium arsenoduodecitungstate, $3(\text{NH}_4)_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 24\text{WO}_3 + 12\text{H}_2\text{O}$, obtained by adding arsenic acid to a concentrated aqueous solution of sodium tungstate, then adding hydrochloric acid in excess and ammonium chloride, and heating to boiling, is a snow-white, crystalline powder resembling the analogous phosphorus compound. A solution of the acid is obtained by dissolving the salt in aqua regia, but decomposes on evaporation. When boiled with a 5 per cent. solution of ammonium carbonate, it is converted into the 22-acid and on adding barium chloride to the solution the barium salt, $7\text{BaO} \cdot \text{As}_2\text{O}_5 \cdot 22\text{WO}_3$, separates in small, lustrous octahedra.

Ammonium arsenoluteotungstate, $3(\text{NH}_4)_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 18\text{WO}_3 + 14\text{H}_2\text{O}$, obtained by heating sodium tungstate with a syrupy solution of arsenic acid and precipitating with solid ammonium chloride, crystallises in monoclinic, lemon-yellow prisms and is very soluble in cold water. When treated with ammonium carbonate, it is converted into the salt $5(\text{NH}_4)_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 17\text{WO}_3 + 8\text{H}_2\text{O}$, which crystallises in thick, white, semi-transparent crystals, and is decomposed by boiling with water with evolution of ammonia.

Potassium arsenoluteotungstate, when treated with potassium hydrogen carbonate, yields the salt $5\text{K}_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 17\text{WO}_3 + 22\text{H}_2\text{O}$, which crystallises in lustrous, white leaflets, and is not decomposed by boiling with water.

E. C. R.

Antimonic Acid and Antimonates. By A. E. DELACROIX (*Bull. Soc. Chim.*, 1899, [iii], 21, 1049—1054. Compare Abstr., 1898, ii, 340).—The two soluble antimonic acids, the existence of which in solution has previously been demonstrated, are more suitably termed tetra-antimonic and triantimonic acids instead of pyroantimonic and orthoantimonic acids respectively.

Tetra-antimonic acid is obtained, by freezing its aqueous solution, in the form of thin, optically active scales having the composition $\text{Sb}_2\text{O}_5 \cdot 4\text{H}_2\text{O}$, or, when dried over sulphuric acid, $\text{Sb}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$; a further H_2O is lost at 100° . It forms both monobasic and dibasic salts of the composition $\text{M}_2\text{O} \cdot 4\text{Sb}_2\text{O}_5$ and $\text{M}_2\text{O} \cdot 2\text{Sb}_2\text{O}_5$, respectively. The alkali salts are soluble in water, but not in solutions of other salts, and are prepared by adding to a solution of the acid the theoretical amount of alkali hydroxide or acetate, and freezing the liquid, when

the salts are obtained in the crystalline form; the dibasic alkali salts are precipitated in an amorphous state by adding alcohol to their solutions. The other tetra-antimonates are obtained by double decomposition from the metallic acetates, and are insoluble in water. The following salts have been prepared; some of them, the dibasic sodium salt, for instance, are decomposed by water, with the production of monobasic and dibasic triantimonates. $\text{Na}_2\text{O}, 2\text{Sb}_2\text{O}_5 + 9\text{H}_2\text{O}$; $\text{Na}_2\text{O}, 4\text{Sb}_2\text{O}_5$; the mixed salt, $\text{Na}_2\text{O}, 4\text{Sb}_2\text{O}_5, \text{Na}_2\text{O}, 2\text{Sb}_2\text{O}_5 + 20\text{H}_2\text{O}$; $\text{K}_2\text{O}, 2\text{Sb}_2\text{O}_5 + 9\text{H}_2\text{O}$; $\text{BaO}, 2\text{Sb}_2\text{O}_5 + 5\text{H}_2\text{O}$; $\text{BaO}, 4\text{Sb}_2\text{O}_5 + 15\text{H}_2\text{O}$; $\text{CuO}, 2\text{Sb}_2\text{O}_5 + 9\text{H}_2\text{O}$, a green salt which dissolves in ammonia to form a double salt crystallising in hexagonal prisms. Tetra-antimonates of silver, cadmium, mercury, nickel, and cobalt have also been obtained; the nickel and cobalt salts form respectively red and blue double salts with ammonia.

Triantimonic acid is obtained, by freezing its solution, in crystals of the composition $\text{Sb}_2\text{O}_5, 3\text{H}_2\text{O}$, which lose $1\text{H}_2\text{O}$ when dried over sulphuric acid. It forms salts of the types $\text{M}_2\text{O}, 3\text{Sb}_2\text{O}_5$, $2\text{M}_2\text{O}, 3\text{Sb}_2\text{O}_5$, and $3\text{M}_2\text{O}, 3\text{Sb}_2\text{O}_5$, besides other more complex derivatives, which are prepared by methods similar to those employed in the preparation of tetra-antimonates. The alkali salts only are soluble in water, those containing one equivalent of the base being also soluble in alcohol. The following triantimonates have been obtained: $2\text{Na}_2\text{O}, 3\text{Sb}_2\text{O}_5 + 10\text{H}_2\text{O}$; $\text{Na}_2\text{O}, 3\text{Sb}_2\text{O}_5 + 11\text{H}_2\text{O}$; $2\text{K}_2\text{O}, 3\text{Sb}_2\text{O}_5 + 10\text{H}_2\text{O}$; $\text{BaO}, \text{Sb}_2\text{O}_5 + 2\text{H}_2\text{O}$; $\text{BaO}, 3\text{Sb}_2\text{O}_5 + 5\text{H}_2\text{O}$; $9\text{BaO}, 10\text{Sb}_2\text{O}_5 + 18\text{H}_2\text{O}$; $2\text{CuO}, 3\text{Sb}_2\text{O}_5 + 10\text{H}_2\text{O}$; $\text{CuO}, 6\text{Sb}_2\text{O}_5 + 16\text{H}_2\text{O}$.

The antimonic acid described by Senderens (Abstr., 1899, ii, 557) is believed to be a mixture of tri- and tetra-antimonic acids. N. L.

Sesquichlorides of Rhodium and Iridium. By ÉMILE LEIDITZ (*Compt. rend.*, 1899, 129, 1249—1251).—Anhydrous rhodium sesquichloride is most conveniently prepared by dissolving in water the crude double salt, $\text{Rh}_2\text{Cl}_6, 6\text{NaCl}$, obtained by treating the metal with chlorine in the presence of sodium chloride, saturating the solution with hydrogen chloride, and after removing the precipitated sodium chloride, evaporating to dryness and heating the residue at $360\text{--}440^\circ$ in a stream of chlorine or hydrochloric acid. The anhydrous chloride forms a brown powder insoluble in water and acids; it dissolves in solutions of the alkalis, potassium cyanide, alkali tartrates, and oxalates. The double salts of iridium sesquichloride, $\text{Ir}_2\text{Cl}_6, 6\text{KCl} + 6\text{H}_2\text{O}$ and $\text{Ir}_2\text{Cl}_6, 6\text{NaCl} + 20\text{H}_2\text{O}$, are much more stable than the corresponding rhodium compounds, and are not completely decomposed even at 440° . The ammonium salt, $\text{Ir}_2\text{Cl}_6, 6\text{NH}_4\text{Cl} + 3\text{H}_2\text{O}$, like its rhodium analogue, undergoes a complex secondary reaction and cannot be employed in obtaining the sesquichloride. Iridium sesquichloride is best produced from the double salt, $\text{IrCl}_4, 2\text{NH}_4\text{Cl}$; it is a dark green substance insoluble in acids and alkalis. G. T. M.

Mineralogical Chemistry.

Composition of Naphtha from Grosny. By K. W. CHARITSCHKOFF (*Chem. Centr.*, 1899, ii, 920; from *J. Russ. Chem. Soc.*, 1899, 31, 655—658. Compare this vol, i, 74).—The naphtha of Grosny contains thiophen in the proportion of about 1 part in 10,000,000 of "benzine," and mercaptan and thio-esters are also present. The decrease in sp. gr. of the "benzine" fraction is also assumed to indicate the presence of large quantities of isoeptane (*loc. cit.*). The fractions boiling at 29—30° have a composition corresponding with that of a mixture of two isomeric pentanes. By the action of nitrosulphuric acid on the fraction boiling at 82—89°, dinitrobenzene is formed, this compound being derived from tetrahydrobenzene. The Grosny naphtha contains the same compounds as American naphtha, but in different proportions. E. W. W.

Texas Petroleum. By F. C. THIELE (*Amer. Chem. J.*, 1899, 22, 489—493).—Petroleum from Corsicana and from Sour Lake, Texas, was submitted to fractional distillation. The results obtained show that the Corsicana oil is closely related to Pennsylvania oils, especially that of the Washington district, but it contains a certain amount of asphaltum, and hence care is necessary in distilling it. The greater part of the Sour Lake oil, which is a "surface oil," consists of oils excellently suited for lubricating purposes, the last fraction having a viscosity of 19° (Engler apparatus); it contains 20 per cent. of asphaltum. W. A. D.

Analyses of Moravian Minerals. By FRANTIŠEK KOVÁŘ (*Jahrb. f. Min.*, 1900, i, Ref. 25; from *Zeit. Chem. Ind. Prag.*, 1898, 4 pp.).—Graphite from Klein-Tressny contains, according to two determinations on different samples, 39·60 and 42·35 per cent. of carbon; the remainder is ash with about 1·5 per cent. of water.

Pyrolusite from Stěpánovitz occurs as nodules in red clay, which fills cavities in limestone; analysis gives the formula

Analyses are also given of dolomitic limestone and of a fireproof clay. L. J. S.

Magnetite from near Rome. By FERRUCCIO ZAMBONINI (*Jahrb. f. Min.*, 1900, i, Ref. 9; from *Rivista min. crist. ital.*, 1898, 21, 21—35).—A description is given of the fine crystals of magnetite occurring in lava at the quarries of Acquacetosa and Tavolato, near Rome. Sp. gr. 5·04—5·11. Analyses gave I for grains and II for crystals.

	Fe ₂ O ₃	FeO.	TiO ₂	MgO.	Total.
I.	69·5	28·7	0·9	0·7	99·8
II.	70·2	28·9	0·6	0·7	100·4

L. J. S.

Auriferous Cobalt Ores in the Transvaal. By H. OEHMICHEN (*Chem. Centr.*, 1899, ii, 788; from *Zeit. prakt. Geol.*, 1899, 271—274).—Auriferous smaltite occurs as veins in diabase at Kruis River and Laatsch Drift. L. J. S.

Fluorine in Swedish Phosphorites. By J. G. ANDERSSON and N. SAHLBOM (*Bull. Geol. Inst. Univ. Upsala*, 1899, (1898), 4, 79—87).—Analyses of phosphorites from various Swedish localities are given; some show the presence of fluorine in the proper proportion for fluorapatite. The phosphorites occur in fossiliferous strata and have been derived from organic remains. Analyses of fossil and recent brachiopod shells show them to consist largely of calcium phosphate with some fluorine.
L. J. S.

Analyses of Moravian Minerals. By FRANTIŠEK KOVÁŘ (*Jahrb. f. Min.*, 1900, i, Ref. 23; from *Chem. Blätter, Prag*, 1899, 4 pp.).—The minerals analysed are from Wür, near Bistritz. The primitive limestone gave I for the pure white, and II for the grey-white, variety.

	CaCO ₃	MgCO ₃	(Fe, Al) ₂ O ₃	Insol. in HCl.	H ₂ O.	Total.
I.	93·21	2·35	0·29	3·84	0·18	99·87
II.	92·08	3·16	0·70	3·98	0·24	100·16

A compact, white to bluish-grey substance resembling halloysite in appearance is shown by analysis III to be kaolinite.

Melinite [?] is compact, ochre-yellow and opaque; the fracture is earthy and the streak shining; analysis gave the results under IV, agreeing with the formula $H_4AlFeSi_2O_6$.

Sphene, as small honey-yellow crystals in the primitive limestone, gave V.

Analyses of Moravian Minerals. By FRANTIŠEK KOVÁŘ (*Jahrb. f. Min.*, 1900, i, Ref. 24; from *Rozpravy České Akad. [Memoirs Bohemian Acad.]*, 1898, 7, class II, No. IX, 8pp.).—Limonite as a botryoidal coating, from near Gross-Tressny, gave analysis I.

Gymnite occurs as small veins in limestone at Gross-Tressny; it is yellow and has a resinous lustre; analysis II gives the formula $Mg_3Si_2O_{10} + 5H_2O$.

Turgite encrusts bog-iron-ore at Rovečín near Öls; it is black and has a dark red streak; analysis III (also MnO, 0·96; SO₃ trace) gives the usual formula, $2Fe_2O_3 + H_2O$.

Vivianite occurs as dark blue aggregates of minute needles in cavities of the bog-iron-ore at Rovečín. Analysis IV (also insoluble 0·97), gives the formula $18FeO, 3Fe_2O_3, 8P_2O_5 + 56H_2O$.

Analyses of Moravian Minerals. By FRANTIŠEK KOVÁŘ (*Jahrb. f. Min.*, 1900, i, Ref. 24; from *Zeit. Chem. Ind. Prag*, 1898, 4 pp.).—Whitish-grey kaolinite ("Steinmark") from the graphite mines at Klein-Tressany gave I; formula $2R'''_2Si_3O_9 \cdot R''SiO_3 + 2H_2O$.

Straw-yellow saponite filling cavities in the kaolinite is a plastic substance which falls to powder when exposed to the air. Anal. II gives the formula $Al_2Si_2O_7 \cdot 9MgSiO_3 + 9H_2O$.

Dull-green celadonite occurs as veins in the kaolinite. Anal. III, formula $R'''_2Si_3O_9 \cdot 4R''SiO_3 + 5H_2O$.

Solidification of Fused Silicates under High and Normal Pressure. By C. F. W. A. OMTLING (*Zeit. Kryst. Min.*, 1899, 32, 179; from *Tech. Min. Mitth.*, 1897, 17, 331—373).—Since natural magmas must in most cases have solidified under high pressures, several comparative experiments were made to observe the effect of pressure on the crystallisation of silicate fusions.

In the experiments, the following crystallised minerals were formed: corundum, graphite, magnetite, spinel, pyroxene, plagioclase, and melilite.

L. J. S.

Olivine from Latium. By FERRUCCIO ZAMBONINI (*Zeit. Kryst. Min.*, 1899, 32, 152—156).—A crystallographic description is given of olivine from the lavas, &c., of Latium. An analysis gave:

SiO ₂	FeO.	Al ₂ O ₃	MgO.	NiO.	Total.	Sp. gr.
40.39	8.81	0.35	49.73	0.12	99.40	3.41

L. J. S.

Two New Hydrosilicates. By FERRUCCIO ZAMBONINI (*Zeit. Kryst. Min.*, 1899, 32, 157—163).—*Müllerite*. This occurs as a yellowish-green coating on iron and manganese oxides from Nontron, Dept.

Dordogne, France. It is soft, compact and opaque, and resembles nontronite ($\text{Fe}_2\text{O}_3, 3\text{SiO}_2 + 5\text{H}_2\text{O}$) in appearance, but differs from this in the blowpipe reactions and in containing less water. The mean (I) of three analyses gives the formula $\text{Fe}_2\text{O}_3, 3\text{SiO}_2 + 2\text{H}_2\text{O}$. Some previous analyses of nontronite and other varieties of chloropal show considerable variations in composition. [The name müllerite is already in use.]

Melite. This is from Sealfeld, Thuringia, and forms an aggregate of imperfect prismatic crystals and stalactitic masses. It is bluish-brown, opaque and brittle; $\text{H}=3$. Analysis gave the results under II. Encrusting this mineral are small, snow-white spheres, which are shown by analysis III to be schrötterite. [The name melite is likely to be confused with mellite.]

	SiO_2	Fe_2O_3	Al_2O_3	CaO	MgO	MnO	H_2O	Total	Sp.gr.

III.	12.56	0.81	43.77	0.95	—	—	41.56	99.65	2.18

L. J. S.

Analyses of Sandstone Concretions. By CHARLES C. MOORE (*Proc. Liverpool Geol. Soc.*, 1898, 8, 241—265).—Analyses are given of concretions in Bunter sandstone from West Cheshire. L. J. S.

Phyllades and Slates. By T. MELLARD READE and PHILIP HOLLAND (*Proc. Liverpool Geol. Soc.*, 1898, 8, 274—293).—The phyllades of the Ardennes are compared with the slates of North Wales; several analyses of these, and of slates from other localities, are given.

L. J. S.

Vanadium in Rocks. By J. H. L. VOGT (*Chem. Centr.*, 1899, ii, 783; from *Zeit. prakt. Geol.*, 1899, 274—277).—From Hillebrand's analyses (*Abstr.*, 1899, ii, 112), the average amount of vanadium in the earth's crust is calculated to be between 0.0025 and 0.005 per cent.

L. J. S.

Rocks from Sumatra. By LUDWIG MILCH (*Chem. Centr.*, 1899, ii, 789; from *Zeit. Deutsch. geol. Ges.*, 1899, 51, 62—74).—In a paper describing the recent volcanic rocks of the Battak table-land in Central Sumatra, the following analyses by W. Herz are given: I, liparite; II, dacite; III, quartz-trachyte-andesite; IV, trachyte-andesite.

	SiO_2	Al_2O_3	Fe_2O_3	FeO	CaO	MgO	K_2O	Na_2O	H_2O	Total
I.	71.25	14.21	0.85	0.43	2.72	0.89	6.74	3.11	0.48	100.68

L. J. S.

Meteoric Iron from Iredell, Texas. By WARREN M. FOOTE (*Amer. J. Sci.*, 1899, [iv], 8, 415—416).—This iron, originally weighing about three pounds, was found in 1898 near Iredell, Bosque Co., Texas. It differs from other Texas irons in the fine pitting and the absence of Widmanstätten figures on an etched sur-

face. Analysis by J. E. Whitfield of material partially freed from schreibersite gave :

Fa.	Ni.	Co.	P.	S.	Total
93.75	5.51	0.52	0.20	0.06	100.04

L. J. S.

Analyses of Glacial Deposits and Waters. By PHILIP HOLLAND and EDMUND DICKSON (*Proc. Liverpool Geol. Soc.*, 1898, 8, 130—150).—Analyses are given of mud and other glacial deposits and of glacial waters from the neighbourhood of the Varanger Fjord in Arctic Norway.

L. J. S.

Physiological Chemistry.

Influence of some Alcohols of Simple or Complex Function on the Digestion of Proteids by Pepsin or Trypsin. By E. LABORDE (*J. Pharm.*, 1899, [vi], 10, 484—488).—The influence on peptic and pancreatic digestion of the presence of 0.5 and 2 per cent. of alcohol and other substances was determined by digesting coagulated albumin with pepsin or trypsin for 3—4 hours at 40°, estimating the albumoses and peptones produced, and comparing the results with those obtained in blank experiments carried out under similar conditions. Peptic digestion appears to be favoured by small quantities of isobutyl alcohol, glycerol, and malic acid, and also, although very slightly, by methyl alcohol, whilst ethyl and propyl alcohols, lactic and tartaric acids, mannitol and dextrose distinctly retard digestion. Pancreatic digestion is aided by methyl and isobutyl alcohols, glycerol and dextrose, whilst a retarding action is exhibited by ethyl and propyl alcohols, lactic, malic, and tartaric acids, and mannitol.

N. L.

Proteid Metabolism. By A. ALBU (*Chem., Centr.*, 1899, ii, 395; from *Fortis. Med.*, 17, 505—508).—Caseon, the name given to a preparation of milk-proteid, is recommended in cases of malnutrition. Its absorption and utilisation compare favourably with those of other proteids. By giving a high percentage of proteid in the diet, a person can hold back proteid in the body, so that at the end of the research he is not in nitrogenous equilibrium, although the increase of body weight is not correspondingly high.

W. D. H.

Nitrogenous Metabolism in the Cat. By LAFAYETTE B. MENDEL and ERNEST W. BROWN (*Amer. J. Physiol.*, 1900, 3, 261—270).—Kynurenin acid is not excreted by the cat even during the increased proteid metabolism produced by the administration of phloridzin. The ingestion of thymus and pancreas causes a marked increase of the uric acid output as in man and dog. Excretion of allantoin is also observed after thymus and pancreas feeding or after uric acid

ingestion; it was not observed after administration of hydrazine sulphate. The ordinary daily uric acid output per kilo. of body weight in the cat is scarcely smaller than in man and dog. Creatinine is ordinarily present in cat's urine in noticeable quantity.

W. D. H.

Comparative Determinations of the Specific Gravity, Dry Residue, and Amount of Iron in Blood. By S. JELLINEK and FR. SCHIFFER (*Chem. Centr.*, 1899, ii, 721; from *Wien klin. Woch.*, 12, 802—805).—Ordinary healthy blood has a sp. gr. 1·060—1·065, leaves 22·26—23·94 per cent. of dry residue, and contains 0·0431—0·0527 per cent. of iron. The iron was estimated by the ferrometer. The blood of patients suffering from various diseases was also examined. The various constants of the blood of healthy beings were found to maintain a certain relationship, and in other cases the sp. gr. and percentage of dry residue seemed also to be connected.

E. W. W.

Cerebro-spinal Fluid. By THEODOR PANZER (*Chem. Centr.*, 1889, ii, 722; from *Wien klin. Woch.*, 12, 805—807. Compare Nawratzki, *Abstr.*, 1898, ii, 36).—The cerebro-spinal fluids of two children had sp. gr. 1·0086 and 1·00917 respectively, and were faintly alkaline; the latter contained a hexose. Both fluids contained cholesterol, neutral fat and soaps, but albumoses, peptones, enzymes, and urea were not present in either. The fluid of the lower sp. gr. was found to contain 15·97 grams of solid substances, 7·34 of organic compounds, 8·63 of mineral substances, 1·404 of nitrogen, 5·99 of proteid substances (total), 4·85 of albumin, and 1·14 of globulin per litre. Analyses of both fluids are given.

E. W. W.

Hydrocele Fluid. By VERTUN (*Chem. Centr.*, 1899, ii, 624; from *Centr. Med. Wiss.*, 37, 529—530).—A specimen of hydrocele fluid was slightly opalescent, faintly alkaline, and contained traces of sodium chloride and phosphates, and 0·04 per cent. of proteid, which was mainly albumin, with a trace of globulin. Proteoses and spermin were absent. By the addition of Florence's potassium iodide solution, no crystals were formed; choline, which gives Florence's reaction as well as spermin, was therefore absent.

W. D. H.

Iodine in the Thymus and Thyroid. By LAFAYETTE B. MENDEL (*Amer. J. Physiol.*, 1900, 3, 285—290).—The accessory thyroids in man may contain relatively and absolutely more iodine than the thyroid proper of the same individual. The observations that the thyroids of newly-born children contain no iodine are confirmed. There is no satisfactory evidence to show that the carefully isolated thymus of man or animals contains iodine; traces found by others may have been due to adherent thyroidal tissue. The favourable effect of thyroid feeding in disease, like the similar effect of thymus, appears to be due not so much to the iodine as to organic substances with which it is united.

W. D. H.

Normal Existence of Arsenic in Animals and its Localisation in Certain Organs. By ARMAND GAUTIER (*Compt. rend.*, 1899, 129, 929—936).—A number of organs of different animals have been

examined for the presence of arsenic, small quantities of which were found in all the normal thyroid glands analysed; smaller proportions of this element also exist in the thymus and brain, and traces only in the skin. 127 grams of human thyroid gland gave 0.95 mg. of arsenic.

On separating the nucleins from the peptones of the thyroid gland of a sheep, all the arsenic was found in the nucleins; this points to the existence of arsenical nucleins along with those containing phosphorus.

In the following organs, arsenic could not be detected by the method of analysis employed (see this vol., ii, 168): sheep's, dog's, calf's and pig's liver, dog's and ox's spleen, pig's kidney, dog's flesh, pig's blood, and the human testicle.

T. H. P.

Fat in Glands during Inanition. By R. NIKOLAIDES (*Chem. Centr.* 1899, ii, 485; from *Arch. Anat. Physiol.*, 1899, 518—523).—Considerable importance is attached to the presence of fat in gland cells. In glands like the dog's submaxillary gland, they are present only in the albuminous acini. They arise from protoplasm by metabolic action, and disappear during inanition.

W. D. H.

The Source of Milk Fat. By WILHELM CASPARI (*Chem. Centr.*, 1899, ii, 483; from *Arch. Anat. Phys.*, 1899, Suppl., 267—280).—Even if it is shown that abundant proteid food increases the fat in milk, it does not follow that the fat originates from the proteid of the food. An important part of it is believed to originate from the fat of the food. Certainly iodised fats in the food pass into the milk, even though the food is poor in fat and rich in carbohydrates.

W. D. H.

Formation of Acetone in the Body. By WALDVOGEL (*Chem. Centr.*, 1899, ii, 396; from *Centr. inn. Med.*, 20, 729—731).—The question is undecided whether acetone comes from the proteid of the food or of the body. Administration of thyroid increases the amount of acetone, but not of uric acid, in the urine. Carbohydrates lessen the formation of acetone, if given by the mouth, but not if given subcutaneously. Fat given by the mouth increases the acetone. Rabbits and dogs excrete quite different decomposition products of fat. Acetone, acetoacetic acid, and β -hydroxybutyric acid are considered to be the result of the oxidising power of the organism.

W. D. H.

The Decomposition and Formation of Uric Acid in the Body. By HUGO WIENER (*Chem. Centr.*, 1899, ii, 262; from *Arch. exp. Path. Pharm.*, 42, 374—398).—Uric acid in the body of the rabbit leads to an increase of glycochine; this might occur by oxidation and hydrolysis with formation of allantoin and hydantoin as intermediate substances; but the experiments on animals do not confirm this. Neither can uroxamic acid or alloxan, which are highly toxic to rabbits, be regarded as intermediate substances. Extracts of the liver of dog or pig, but not of the ox, destroy uric acid; extracts of the kidney of ox and horse, but not of the dog, do so also. As uric acid can be destroyed in the body, the amount excreted in the urine in disease can be no measure of the amount produced. Glycochine is formed when uric acid is destroyed by extracts of ox kidney, but not

in so large amount as to account for all the uric acid ; the muscles of the ox give the same result. The 'surviving' ox liver is able, not only to destroy, but also to form uric acid from xanthine derivatives.

W. D. H.

Fate of Proteids after their Introduction into the Circulation. By IMMANUEL MUNK and MAX LEWANDOWSKY (*Chem. Centr.*, 1899, ii, 484 ; from *Arch. Anat. Phys.*, 1899, Suppl., 73—88).—In contradiction of Neumeister's results, it was found that if caseinogen, dissolved in soda, is introduced into the blood of rabbits (2.4 grams per kilo. of body weight), all but a small fraction is kept within the body and utilised. Egg-albumin is similarly used, in rabbits to the extent of 54 and in dogs of 82 per cent. Acid albumin, alkali-albumin, and nucleo-proteid are utilisable in a corresponding way. Proteids which have been profoundly altered, for instance, casein, are not utilised.

W. D. H.

Fate of 8-Hydroxyquinoline ; Excretion of Ethereal Hydrogen Sulphates ; Composition of Quinosol. By E. ROST (*Chem. Centr.* 1899, ii, 396 ; from *Arch. Kais. Ges. A.*, 15, 288—301).—Experiments on dogs show that 8-hydroxyquinoline leaves the body as the sulphate, and probably also as quinoline. When the amount of hydrochloric acid in the stomach is lessened, intestinal putrefaction increases, and so the amount of ethereal hydrogen sulphates in the urine rises. In complete inanition, the amount falls, but never to zero. Quinosol appears to be a mixture of 8-hydroxyquinoline sulphate and potassium sulphate.

W. D. H.

Chemical Reaction of the Intestinal Contents. By BENJAMIN MOORE and T. J. BERGIN (*Amer. J. Physiol.*, 1900, 3, 316—325).—The acid reaction of the intestinal contents to phenolphthalein is probably due to an excess of dissolved carbon dioxide. The alkaline reaction to methyl-orange, lacmoid, and litmus shows the absence of hydrochloric acid, and of all stronger organic acids, such as acetic, lactic, or butyric, which would be formed by the bacterial decomposition of carbohydrates or fats. These results were obtained by experiments on dog, sheep, and calf.

Absorption of food-stuffs, at least, in the dog, can be practically completed in the small intestine. A proteolytic enzyme active in alkaline solution, and a diastatic enzyme, also active in an alkaline solution, are present in the dog's intestine at this level.

W. D. H.

Cryoscopy of Urine in Diagnosis and Prognosis. By H. CLAUDE and V. BALTHAZARD (*Compt. rend.*, 1899, 129, 847—850).—If the difference between the freezing point of urine and that of water is corrected for the reduction due to soluble chlorides, and also, if necessary, for that due to sugar and albumin, the value δ thus obtained is a measure of the number of molecules, per unit volume of urine, of other compounds elaborated by the organism, and if this value is multiplied by the volume, V , of urine excreted in 24 hours and divided by the weight, P , in kilograms of the fixed proteids of the individual, the expression $\delta V/P$ has a value which varies greatly in different cases, and may serve as a valuable indication of

the beginning or progress of disease, especially in the case of maladies which affect the kidneys.
C. H. B.

Origin of the Proteids in Albuminuria. By MAX CLOËTTA (*Chem. Centr.*, 1899, i, 267; from *Arch. exp. Path. Pharm.*, 42, 453—466).—The proportion of serum-albumin to serum-globulin in the urine in cases of albuminuria is very different from that in the blood. This is accounted for by the different permeability of membranes to the two proteids. Nucleo-proteid, which is stated to be absent from blood-serum, is considered to arise from the kidney tissue.
W. D. H.

Sugar Formation in Severe Cases of Diabetes. By EMIL ROSENQVIST (*Chem. Centr.*, 1899, ii, 450—451; from *Berlin klin. Woch.*, 36, 612—617).—Partly on experimental, and partly on theoretical, grounds, the views of Seegen and Rumpf (*ibid.*, 36, 155), that in severe cases of diabetes mellitus fat may be a source of the sugar, is regarded as a possibility.
W. D. H.

Hydroxybutyric Acid and its Relationship to Diabetic Coma. By ADOLF MAGNUS-LEVY (*Chem. Centr.*, 1899, ii, 63—64; from *Arch. exp. Path. Pharm.*, 42, 149—237).—The amount of hydroxybutyric acid in the urine of severe cases of diabetes without coma is from 0.5 to 1 per cent. In coma, 160 grams may be excreted daily, especially if sodium hydrogen carbonate is administered. Diabetic coma is regarded as acid poisoning, but probably the production of the acid is the result of toxin poisoning. In coma, as a rule, there is no rise of proteid katabolism, although doubtless the acid originates from proteid. In urines which contain acetone, but are not diabetic, as much as 7 grams of hydroxybutyric acid may be excreted daily.
W. D. H.

Excretion and Detection of Glycuronic Acid in the Urine. By PAUL MAYER (*Chem. Centr.*, 1899, ii, 450; from *Berlin klin. Woch.*, 36, 591—593, 617—619).—The urine of a morphine-maniac contained glycuronic acid in combination, but the compound was not isolated. The greater number of tests for glycuronic acid are also given by pentoses, but if the orcinol test for pentoses is negative, and the urine contains glycuronic acid, a reducing substance will be obtained after treatment with sulphuric acid. Combinations of glycuronic acid do not yield a phenylhydrazine compound, but after treatment with sulphuric acid they do; the compounds are probably numerous, varying in melting point from 135° to 205°.

Glycuronic acid also occurs in urine after the use of chloral hydrate, and in small quantities in normal urine.
W. D. H.

Excretion of Alloxuric Substances in Nephritis. By CHARLES F. MARTIN (*Chem. Centr.*, 1899, ii, 266; from *Centr. inn. Med.*, 20, 625—631).—From observations on seven cases of different forms of nephritis, it is found that the total alloxuric substances excreted in the day are diminished, but the relation of the alloxuric bases to uric acid is but little altered.
W. D. H.

Theory of Narcosis. I. By HANS MEYER (*Chem. Centr.*, 1899, ii, 64; from *Arch. exp. Path. Pharm.*, 42, 109—118). **II.** By FRITZ BAUM (*Chem. Centr.*, 1899, ii, 65, from *ibid.*, 119—137).—In reference to Dubois' work on the action of anæsthetics (*Compt. rend. Soc. Biol.*, 1884, 583), the theory is advanced that the relative strength of these substances is dependent on their mechanical affinity for fatty substances (like lecithin in protoplasm), on the one hand, and to other constituents of protoplasm, especially water, on the other. In support of this view, the second paper shows that the proportion between concentration in fat and concentration in water of a number of narcotics runs parallel with their anæsthetising activity.

W. D. H.

Physiological Action of Creatine and Creatinine and their Value in Nutrition. By JOHN W. MALLETT (*Chem. Centr.*, 1899, ii, 563; from *Bull. No. 66, U.S. Dept. Agric.*; and *Chem. News*, 80, 43—45, 54—56, 69—71, 77—78).—Almost the whole of the creatine and of the creatinine given to human beings is excreted as creatinine in the urine; the fæces contain none. These bases do not therefore serve for the building up of proteids. They are not, however, intermediate substances between proteid and urea, and it is not probable that these bases in muscle are changed even slowly into urea. This supports the view so often urged by physiologists that meat extracts have no nutritive value. The physiological action of creatine and creatinine is much weaker than commonly supposed.

W. D. H.

Rôle of Leucocytes in Poisoning by Compounds of Arsenic. By BESREDKA (*Ann. de l'Inst. Pasteur*, 1899, 13, 49—66, 209—224, 465—479).—The leucocytes are capable of engulfing toxic substances, among them various compounds of arsenic, arsenic trisulphide and arsenious acid being specially investigated. Leucocytosis is one result of the injection, but the healthy state, as well as the number of the leucocytes, is important. After traversing the leucocytes, the metal is ultimately eliminated by the urine. If positive chemiotaxis and leucocytosis do not occur, the animal dies; if they do, it is protected. The administration of previous small doses renders the animal immune to fatal doses. The *antiarsenin* present in the serum is probably not a compound of arsenic. The intermediate rôle of the leucocytic action is, however, essential in the antagonism.

W. D. H.

Action of the Tetanus Toxin on Nervous Substance. By JEAN DANYSE (*Ann. de l'Inst. Pasteur*, 1899, 13, 156—168).—The nervous tissues fix to some extent the tetanus toxin, but this is not permanent, for *in vitro*, and probably *in vivo*, the toxin is again liberated by suitable media like physiological saline solution. The insoluble materials of the nervous tissue possess this power to the greatest degree, and the toxin is thus in part neutralised, but a determination of how much is rendered impossible by the fact that the soluble constituents of the tissue increase the toxic action.

W. D. H.

Fungus Poisons which Decompose Blood. By RUDOLF KOBERT (*Chem. Centr.*, 1899, ii, 781; from *Sitzungsber. naturf. Ges. Rostock*, 1899, No. 5).—*Agaricus phalloides* contains at least two poisons, con-

sisting of an alkaloid and a toxalbumin. When the alkaloid, which is soluble in alcohol but insoluble in ether, is administered to rabbits or cats, neither decomposition of the blood nor fatty degeneration of the organs takes place. The toxalbumin *phallin* has a stronger action than helvellic acid, but resembles it in dissolving the red corpuscles of the blood, dissolved oxyhæmoglobin, glycerophosphoric acid, and fragments of stroma also taking part in the action. By the liberation of glycerophosphoric acid, the alkalescence of the blood is decreased, the soluble hæmoglobin partially converted into methæmoglobin, and cyanose formed. A solution of phallin in 100,000 parts of water is sufficient to show the dissolving action on the red blood-corpuscles. Sections obtained from animals which had been poisoned by phallin showed many exudations of blood into the various organs. In many cases, the blood and urine were found to contain methæmoglobin or bile-colouring matters, and in most cases the kidneys were greatly affected. Phallin could not be detected in mushrooms or other edible fungi.

E. W. W.

Chemistry of Vegetable Physiology and Agriculture.

Buchner's Yeast Extract. By AUGUSTIN WRÓBLEWSKI (*Chem. Centr.*, 1899, ii, 672—673; from *Centr. Physiol.*, 13, 284—297. Compare Abstr., 1899, ii, 170).—The extract from a pure culture of wine yeast resembles that of ordinary yeast, both in composition and properties and, like it, is capable of fermenting sugar. The fermenting power of the zymase of the extract obtained from a pure culture of beer yeast is destroyed by the presence of formalin; 0.07 per cent. of hydroxylamine hydrochloride also exerts a slight preventive action, and larger quantities completely inhibit fermentation. From the results of experiments with pure hydrochloric acid, it is evident that the hydroxylamine hydrochloride combines with certain constituents of the extract, liberating hydrochloric acid, which then attacks the zymase. The extract has a denitrifying action on sugar solutions containing nitrites, and liberates nitrogen, but not carbon dioxide. Since the yeast cells are killed by even small quantities of nitrites, denitrification cannot be attributed to their action. The reduction of nitrites in soil is a purely chemical process, depending on their action on compounds analogous to amino-compounds, the action of small organisms being only of secondary importance. Nitrates are neither affected by the yeast nor its extract, and, like sodium chloride and ammonium sulphate, only hinder fermentation when present in large quantities. The addition of small quantities of neutral salts appears to increase the fermenting action of the yeast or of its extract, but large quantities of alcohol hinder fermentation, probably by precipitating the proteids of the extract.

The invertin resembles the proteose and peptone-like constituents of the extract, for when the extract is saturated with ammonium sulphate only a portion of the invertin is carried down mechanically, the major portion remaining in the filtrate. Invertin may be purified by fractionally precipitating with acetic acid, and finally fractionally precipitating from the acetic acid solution by means of alcohol. The inverting action of the invertin is increased by dilute acetic acid, and even a 4 per cent. solution of the acid does not very seriously interfere with this action. A 0.28 per cent. solution of hydrochloric acid does not appreciably affect the inverting power of invertin, but the prolonged action of alcohol, or the presence of even dilute solutions of alkalis, destroys it.

The properties of the zymase do not resemble those of the enzymes contained in the extract, and the former substance is more allied to protoplasm than to the group of proteoses and peptones. Zymase, unlike the enzymes, is unable to pass through an earthenware cell, and ferments only in concentrated solutions, dilution of the extract causing a rapid decrease of fermentation. Fermentation is also promoted by the addition of 1.5 per cent. of neutral salts. The enzymes, on the other hand, work better in dilute solutions and without the addition of salts. The effect of dilution and of the addition of neutral salts on the fermenting action of zymase appears to depend on osmotic processes.

E. W. W.

[A Beer Disease.] By VAN LAER (*Compt. rend.*, 1900, 130, 53—56).—Beers termed by Belgian brewers "double face" or "*twesekinds*" are quite clear by transmitted light, but by reflected light are dull brown and opalescent. Viewed from above, they appear dirty white and opaque, with a yellow fluorescence. This malady is closely connected with viscous fermentation, and seems due to a special organism, *Bacillus viscosus bruxellensis*, which always makes beer works ropy; its development is promoted by the presence of nitrogenous compounds, but its effects are reduced if the liquid is thoroughly aerated. The bacillus converts carbohydrates into lactic, acetic, and butyric acids, either by consuming them directly, or by first converting them into gummy substances. Other conditions being equal, dextrose is first attacked and then saccharose, maltose, and lactose. No invert sugar is formed.

C. H. B.

Reactions to Stimuli in Unicellular Organisms. By HERBERT S. JENNINGS (*Amer. J. Physiol.*, 1900, 3, 229—260. Compare Abstr., 1899, ii, 440).—This is a continuation of previous work in which *Paramecium* was used. It has been extended to *Chilomonas* and other flagellates, and also to numerous ciliated infusorians. The main results confirm those previously reached. Some of the results are now rather differently interpreted in accordance with modern chemical doctrines of solutions.

W. D. H.

Effect of Ions on Flagellated Infusoria. By WALTER E. GARREY (*Amer. J. Physiol.*, 1900, 3, 291—315).—*Chilomonas* was the organism selected as the subject of the experiment. The effect of

chemicals is analogous to those of other stimuli like light or galvanism. Whilst inorganic acids have equal effects if the ion concentration is the same, organic acids behave differently and the effect is greater than would be expected.

W. D. H.

Bacteriological Enzymes as a Cause of Immunity and their Healing Action in Infective Diseases. By RUDOLF EMMERICH and OSKAR LÖW (*Chem. Centr.*, 1899, ii, 135; from *Zeit. Hyg.*, 31, 1—65).—The enzymes secreted by various bacteria unite with the proteids of blood or of organs; the compounds so formed are termed *immunoproteidins*; the proteid of the leucocytes which unites with the enzyme of the pathogenic bacteria is termed *proteid*. The so-called agglutination is nothing but the first stage of the effect of the enzyme. There are also bacterial enzymes which are not only bactericidal, but also destroy toxins; thus *pyocyanase*, the enzyme of *Bacillus pyocyaneus*, destroys the deadly effect of the diphtheria toxin.

W. D. H.

Changes in the Mineral Constituents of the Seed during Germination. By GUSTAVE ANDRÉ (*Compt. rend.*, 1899, 129, 1262—1265).—A preliminary communication dealing with observations made on the variation of the mineral constituents of the Spanish bean (*Phaseolus multiflorus*) from the commencement of germination to the period at which the dry weight of the seedling is again equal to that of the seed. The weight of mineral substances is trebled, but the constituents do not vary to the same extent. The quantity of phosphoric acid remains fairly constant, and there is a slight increase in the total nitrogen.

As long as the plant feeds on its reserve materials, the amount of potash remains constant, but when the chlorophyllous functions develop, the weight of this constituent increases. The amounts of silica and lime present at the end of the period under observation are respectively 400 times and 17 times as great as the original quantities. The analytical results are arranged in tabular form.

G. T. M.

Chlorophyllous Assimilation induced by Sunlight filtered through Leaves. By ED. GRIFFON (*Compt. rend.*, 1899, 129, 1276—1278).—Timiriazeff found that whitelight, after passing through a chlorophyll solution, loses its power of inducing chlorophyllous assimilation.

The author finds that sunlight, after traversing a single leaf still induces the decomposition of carbon dioxide, but the action is considerably diminished, and with diffused light is almost negligible. The effect produced by sunlight after passing through two leaves is so feeble that the assimilative action is masked by respiration.

These results are chiefly due to the absorption of luminous radiations by chlorophyll, but protoplasm and the colourless parts of leaves also diminish the action; the effect of light filtered through bleached or chlorotic leaves is approximately half that due to direct sunlight.

G. T. M.

Amount of Sulphur in Plants. By SERGEI M. BOGDANOFF (*Chem. Centr.*, 1899, ii, 489; from *J. Russ. Phys. Chem. Soc.*, 31, 471—477).—Estimation of sulphuric acid in vegetable ashes gives incorrect results, as considerable loss of sulphur may take place during incineration. Liebig's method is very satisfactory, and when small amounts of potassium nitrate are employed the results are very exact.

Plants contain much more sulphur than is indicated in Wolff's tables, and it is believed that the amount of sulphuric acid in soil is of practical importance. In some Russian soils, certain crops gave considerably higher yields after manuring with sulphates.

N. H. J. M.

Hydrocyanic Acid in Vicia Seeds. By F. F. BRUYNING, jun., and J. VAN HAARST (*Rec. Trav. Chim.*, 1899, 18, 468—471).—Flour from the following species and varieties of *Vicia* contains hydrocyanic acid: *V. sativa*, *V. sativa* v. *dura*, *V. sativa* v. *flore alb.*, *V. sativa* v. *Bernayer*, *V. sativa* v. *Britannica*, *V. canadensis*, *V. hirsuta*, and *V. angustifolia*; these hence contain amygdalin or analogous substances. No hydrocyanic acid was detected in: *V. narbonensis*, *V. cracca*, *V. agrigentina*, *V. biennis*, *V. disperma*, *V. pannonica*, and *V. casubica*.

500 grams of flour from *V. sativa* contained 0.004 gram of hydrocyanic acid, and after germination for three days, the quantity was 0.003 gram. In the case of *V. sativa Britannica* and *V. angustifolia*, the same weight of flour yielded 0.0008 and 0.027 gram of acid respectively.

T. H. P.

Presence of Mannocellulose in the Ligneous Tissues of Gymnosperms. By GABRIEL BERTRAND (*Compt. rend.*, 1899, 129, 1025—1028. Compare Abstr., 1879, 613).—The tissues of the gymnosperms contain practically no xylan, but mannocellulose is present in considerable amount. The yield of mannose (obtained from mannocellulose by hydrolysis) from conifers is from 10—15 per cent. of the wood taken. In the *Gnetaceæ*, a class intermediate between the gymnosperms and angiosperms, the amount of mannocellulose is very small, and in some cases *nil*.

H. R. LE S.

Presence of Formaldehyde in Plants. By GINO POLLACCI (*Chem. Centr.*, 1899, ii, 881—882; from *Boll. Chim. Farm.*, 38, 601—603).—When leaves which have been exposed to the light are macerated and distilled with water, the first portion of the distillate contains formaldehyde. This compound was detected by the violet coloration produced on adding a mixture of codeine and sulphuric acid. This mixture is extremely sensitive to formaldehyde and even more so to the polymeric formaldehyde which is formed when the aqueous solution is evaporated. Other aldehydes such as acetaldehyde, propaldehyde, butaldehyde, valeraldehyde, and benzaldehyde give a yellow, whilst vanillin and acetone form a green, coloration. The formation of a solid, white polymeride, by slowly evaporating the aqueous solution at the ordinary temperature, is also characteristic of formaldehyde. The presence of this aldehyde was also detected by

the following methods. (1) An aqueous solution of aniline gives a white precipitate with formaldehyde. (2) When the distillate containing formaldehyde is added to a dilute solution of benzophenol and a solution of 94 per cent. sulphuric acid then poured into the mixture, a red ring is formed at the surface of contact of the liquids. (3) When a twig with green leaves which has been exposed to light is placed in an aqueous carmine solution which has been decolorised by sulphurous acid, the leaves become violet after a time, whilst the solution itself remains colourless. Magenta decolorised by sulphurous acid gives a violet coloration with formaldehyde. (4) Ammoniacal silver nitrate solution is reduced. (5) Nessler's reagent test-paper is turned black; and (6) phenylmethylhydrazine gives a white precipitate with the distillate.

E. W. W.

The "Honey" of *Euonymus Japonica*. By LÉON MAQUENNE (*Bull. Soc. Chim.*, 1899, [iii], 21, 1082—1083).—The honey-like substance which is sometimes found in dry seasons at the extremities of the branches of *Euonymus Japonica* is an exudation of the cell contents due to the punctures of insects; it is at first of a syrupy consistence, but soon dries to a crystalline mass. It has a marked sweet taste and is very soluble in water. When concentrated by evaporation, the solution deposits crystals of dulcitol and leaves a brownish, syrupy residue in which dextrose and saccharic acid were detected.

N. L.

Lotus Corniculatus. By GIUSEPPE D'ANCONA (*Chem. Centr.*, 1899, ii, 590—591; from *Staz. sper. agrar. ital.*, 32, 274—287).—Analyses of two Italian specimens of *Lotus corniculatus* are given:

Water.	Crude proteid.	Crude fat.	Crude fibre.	N-free extract.	Digestible nitrogen.	Ash.
1. 80.285	3.429	0.723	6.563	7.582	0.256	1.418
2. 76.489	3.730	0.872	8.113	8.859	0.312	1.937

The dry substance contained (1) 10.757 and (2) 11.233 per cent. of pentosans. The pure ash had the following percentage composition:

K ₂ O.	Na ₂ O.	CaO.	MgO.	Fe ₂ O ₃ + Al ₂ O ₃ .	P ₂ O ₅ .	SO ₂ .	SiO ₂ .	Cl.
1. 21.954	7.405	24.969	5.082	3.637	10.026	4.915	20.781	0.884
2. 21.987	6.772	23.629	4.091	5.066	10.687	4.383	22.335	1.029

N. H. J. M.

Absorption of Soluble Salts by Plants. By EM. DEMOUSSY (*Ann. agron.*, 1899, 25, 497—548 and 561—607).—A detailed account of experiments already described (*Abstr.*, 1899, ii, 172 and 238), with an historical introduction.

With regard to nitrates, the nature of the base has no effect on absorption by plants when supplied singly, provided that the base is not toxic; lithium, barium, and strontium nitrates, for instance, are only taken up in very small quantities, and their injurious effect soon becomes evident.

The fact that although plants absorb non-toxic metals with equal readiness, the amounts of these metals found in plants vary very greatly is attributed partly to the composition of the media in which the plant lives, and partly to the selective powers of plants.

Calcium, unlike potassium, does not prevent absorption of sodium.

Plants growing in solutions containing the same amount of calcium as nitrate and as chloride respectively absorbed more calcium in the form of nitrate than as chloride, but the absorption of chlorine was greater than that of nitrogen, owing to its greater molecular weight ; 2 mols. of nitrogen were absorbed to 1 mol. of chlorine.

N. H. J. M.

Composition of the Branches of Pear Trees Removed by Regular Thinning. By NAPOLEONE PASSERINI (*Bied. Centr.*, 1899, 28, 780—781; from *Ricerche e. Esper. Istituto Agrar. Scandicci*, 1896—1897).—Branches (without leaves) cut from pear trees were found to have the following composition :

Water.	N.	CO ₂ in		Per cent. in pure ash.							
		Crude ash.	Digestible crude ash.	K ₂ O.	CaO.	MgO.	Fe ₂ O ₃ .	P ₂ O ₅ .	SO ₃ .	Na ₂ O, Cl.	SiO ₂ loss.
49.29	0.506	1.748	33.79	15.11	63.00	4.51	0.60	4.90	2.64	1.66	7.58

In the case of old pear trees, it was found (average of twelve experiments) that 1381 kilograms of wood are cut yearly. The loss per annum is therefore as follows : N, 6.99 ; K₂O, 2.40 ; CaO, 10.02 ; MgO, 0.72 ; P₂O₅, 0.78, and SO₃, 0.42 grams in each tree. The soil for pear trees should be comparatively rich in lime, and requires nitrogenous and potash manures.

N. H. J. M.

Which Meadows should be Manured with Potash as well as with Basic Slag and Superphosphate? By JULIUS NESSLER (*Bied. Centr.*, 1899, 28, 737—738; from *Woch. Landw. Ver. Baden*, 1899, No. 11, 139).—Level meadows, the soil of which is poor in potash but not too shallow, with much moss, &c., should receive, in autumn or winter, kainite (6—8) and basic slag (3—4 cwt.), and each subsequent year 2—3 and 3—4 cwt. respectively of basic slag and kainite. In the case of heavy soils, superphosphate is usually preferred to basic slag, and potassium chloride (40 per cent.) is employed instead of kainite.

Sloping meadows should have more potash applied to the higher than to the lower portions, which in some cases do not require direct potash manuring. Irrigation with water from granite or gneiss generally renders application of potash unnecessary.

The best chemical method of ascertaining whether potash is needed is to determine the amount of potash in the hay ; the grass must be cut at the beginning of the flowering period and carefully dried. Estimating the potash in the soil takes longer and gives more uncertain results.

N. H. J. M.

Composition of *Molinia caerulea* and *Carex Goodenoughii*. By HEINRICH IMMENDORFF (*Bied. Centr.*, 1899, 28, 772—774; from *Landw. Jahrb.*, 1898, 27, iv, 503).—The two plants are important constituents of the herbage of peat meadows which are insufficiently drained and manured, but are not much valued as cattle-food. The composition as hay (water = 15 per cent.) is as follows :

	Crude protein.	Digestible protein.	Amides.	Fat.	N-free extract.	Crude fibre.	Ash.
1. <i>Molinia caerulea</i>	6.75	4.26	0.88	2.44	41.28	30.96	3.47
2. <i>Carex Goodenoughii</i>	9.00	4.69	0.60	2.51	42.14	27.40	3.94

Whilst *Molinia* hay is of very poor quality, the results obtained with *Carex* are more satisfactory, but the yield is very small. The dry substance of the two plants contained: Ash, (1) 4.196, (2) 4.64; K_2O , (1) 1.21, (2) 1.49; CaO , (1) 0.25, (2) 0.39; and P_2O_5 , (1) 0.29, (2) 0.43 per cent. N. H. J. M.

Hops and Hop Soils. By JOSEPH HANAMANN and LEOPOLD KOURINSKY (*Bied. Centr.*, 1899, 28, 778; from *Zeit. Landw. Versuchs-wesen. Oesterr.*, 1898, 1, 411).—During the early periods of growth, hop plants require plenty of potash, phosphoric acid, and nitrogen; subsequently, the plants contain nearly as much lime as potash.

The leaves and tendrils are rich in lime, and in the assimilating organs 50 per cent. of the ash consists of lime, indicating considerable production of organic acids in the sap, which have to be neutralised with lime. The leaves contain much more potash, lime, magnesia, and phosphoric acid than the tendrils and stems, whilst the umbels contain the most potash and phosphoric acid.

In the original paper, analyses of the soil and of the ashes of hops at different periods of growth are given. N. H. J. M.

Influence of Potash on the Development of Sugar Beet. By JULIUS STOKLASA (*Chem. Centr.*, 1899, ii, 490; from *Zeit. Zucker-Ind. Böhm.*, 23, 493—501).—Results of field experiments showed that potassium sulphate considerably increased the yield of roots and the percentage of sugar. Potassium chloride, in conjunction with superphosphate and nitrate, also increased the yield of roots without injuriously affecting the percentage of sugar. N. H. J. M.

Assimilation by Sugar Beet and Estimation of Available Nutritive Matter in Arable Soil. By H. WILFARTH (*Chem. Centr.*, 1899, ii, 536—537; from *Zeit. Ver. Rübensucker-Ind.*, 1899, 645—652).—Whilst sugar beet grows normally when manured with nitrate, ammonium salts and blood-meal gave decidedly unsatisfactory results.

Amides were determined in the roots as an indication of the degree of unripeness.

When calcium nitrate is employed as manure, the lime is eliminated from the root, whilst with potassium nitrate the potash is retained. Deficiency of nitrogen gives rise to yellow leaves, whilst a deficiency of potash produces brown and white spots on the leaves. In absence of sufficient phosphoric acid, the leaves do not become yellow as stated by Stoklasa, but their growth is checked, and they have a dark green colour with black edges and spots.

The results of pot experiments showed that with insufficient potash the roots contained only 4 parts of K_2O to 1000 parts of sugar, the amounts under normal conditions being 6—8 parts; with six times the necessary amount of potash, the roots were found to contain 37 parts of K_2O per 1000 of sugar. The roots are more liable to injury by nematodes in absence of potash than when a small amount of potash is applied.

It is proposed to estimate available plant constituents in soils by growing sugar beet, carrots or celery, and analysing the plants.

N. H. J. M.

Influence of the Amounts of Water and of Nutritive Substances in Soil on the Activity and Development of Potatoes. By JOHANN WILMS (*Chem. Centr.*, 1899, ii, 628; from *J. Landw.*, 47, 251—292).—The occasional injurious effect of Stassfurt salts on potatoes is attributed to the presence of potassium chloride. Nitrogenous substances are favourable to the development of the plants and to starch production. Potash also seems favourable to starch production. Increased amounts of moisture in the soil always diminish the percentage of starch in the tubers; and proportions of chlorides, which are otherwise harmless, become injurious when the amount of water is large. Transpiration is increased when the percentage of water in the soil increases, and there may be an increase, although less marked, in the actual amount of starch produced.

N. H. J. M.

How much Phosphoric Acid should good Arable Soil Contain? By AIMÉ PAGNOUL (*Ann. Agron.*, 1899, 25, 549—557).—The results of pot experiments, in which incarnate clover was grown in soils containing very little, and a good deal, of phosphoric acid respectively, with and without addition of superphosphate, indicated that 0.1 per cent., which is generally considered to be a normal amount for good soil, is too low, and that 0.15 to 0.2 per cent. is more probably the limit, at any rate for incarnate clover, beyond which manuring with phosphates becomes unnecessary.

N. H. J. M.

Alinit. By W. KRÜGER and W. SCHNEIDEWIND (*Chem. Centr.*, 1899, ii, 628; from *Landw. Jahrb.*, 28, 579—591).—Experiments were made on the behaviour of alinit towards free atmospheric nitrogen in nutritive solutions containing nitrogenous matters, and also towards nitrates. It is concluded that the preparation is without practical value. The microbe does not nitrify, but there was production of nitrite.

N. H. J. M.

Composition of Green Manure grown on Peaty and on Sandy Soils. By HEINRICH IMMENDORFF (*Bied. Centr.*, 1899, 28, 726—733; from *Landw. Jahrb.*, 1898, 27, 503).—The composition as regards dry matter and nitrogen of the crops grown for green manure on peat land (yellow, blue, and white lupins, serradella, grey peas, beans, rape, and white mustard) scarcely differs from that of the same plants grown in ordinary soil. In absence, however, of inoculation, the percentage of nitrogen in the dry matter is liable to be very low. In the case of blue lupins, for instance, the nitrogen in the dry matter was (1, inoculated) 3.26 and (2, not inoculated) 1.98 per cent.

In light, sandy soils, the most suitable crops for green manuring are lupins and serradella (white mustard is quite unsuitable), and the composition of the plants is normal. Application of burnt lime (3,000 kilograms per hectare) was very beneficial, even in the case of lupins. The soil did not require inoculation.

Pot and field experiments were made to ascertain the amounts of organic matter and nitrogen in the above-ground growth and roots of serradella and lupins grown in peaty soil fully manured with minerals. Normal percentages of nitrogen, both in roots and in the growth

above-ground, were only obtained after inoculation. Lupins yield (in the roots) more organic matter than serradella, but the latter is more nitrogenous.

Crops of serradella and lupins the above-ground growth of which contain 100 and 140 kilograms of nitrogen per hectare, yield in the roots about 15 and 20 kilograms of nitrogen respectively; these amounts may undoubtedly be increased by deepening the soil.

N. H. J. M.

Testing Soils for Application of Commercial Fertilisers. By H. A. WEBER (*J. Amer. Chem. Soc.*, 1899, 21, 1095—1099).—Five carefully selected portions of the soil are put into Wagner pots, and to four of these are added various descriptions of manure to ascertain which will answer best.

The seeds of the crops required to be raised are then introduced with the usual precautions and allowed to germinate; it is not necessary to bring the plants to maturity; observations made during 5 or 6 weeks will give sufficient information.

L. DE K.

Analytical Chemistry.

Estimation of Chlorine in Bleaching Powder. By C. WOŁOWSKI (*Zeit. anal. Chem.*, 1899, 38, 711—713).—The hypochlorite solution is added from a burette to potassium iodide acidified with sulphuric acid. A number of mixtures are made in which the amount of iodide is the same, and by shaking each mixture with chloroform the point is ascertained at which enough chlorine has been added to convert all the iodine into trichloride, which of course does not colour the chloroform. The author prefers to work with only 5 milligrams of potassium iodide, and measures the hypochlorite solution by counting the drops.

M. J. S.

Separation of Chlorine and Iodine. By LUDWIG VANINO and O. HAUSER (*Ber.*, 1899, 32, 3615—3617. Compare Abstr., 1898, ii, 545; and 1899, ii, 249).—Silver iodide, when heated at 90° with formaldehyde dissolved in 50 per cent. potassium hydroxide solution, is scarcely affected, whereas silver bromide under these conditions is almost wholly reduced, a considerable amount of reduction taking place even at the ordinary temperature; silver chloride is completely decomposed, even in the cold. When a mixture of silver chloride and iodide is heated at 40° with an alkaline formaldehyde solution of the above strength, the chloride is completely reduced, whilst the iodide remains unchanged; the precipitate is treated with nitric acid, the silver derived from the chloride dissolves, and is reconverted into the haloid salt. In this way, a quantitative separation of iodine and chlorine may be rapidly effected.

G. T. M.

Titration of Potassium Iodide. By E. VINCENT (*J. Pharm.*, 1899, [vi], 10, 481—483).—The valuation of potassium iodide may be rapidly and accurately effected by the following process, which avoids the errors incidental to some of the methods usually employed. A suitable quantity of the solution obtained by dissolving 1 gram of the sample in a litre of water is mixed with an equal volume of a 0.2 per cent. solution of iodic acid, and the liquid added from a burette to 5 or 10 c.c. of *N*/10 thiosulphate solution until a permanent yellow tint is produced. 0.2 per cent. of potassium hydrogen carbonate is added to the thiosulphate solution in order to prevent oxidation of the latter by the excess of iodic acid. N. L.

Estimation of [Dissolved] Oxygen in Water. By F. ZETSCHE (*Chem. Centr.*, 1899, ii, 727; from *Zeit. Unters. Nahr-Genussm.*, 2, 696—697).—A glass-stoppered bottle of 250—300 c.c. capacity is filled completely with the water; 1 c.c. of a saturated solution of manganous sulphate is introduced at the bottom of the liquid by means of a pipette, followed by 2 c.c. of a solution containing 48 grams of sodium hydroxide and 15 grams of potassium iodide per 100 c.c. The whole is now thoroughly shaken, and when the manganous-manganic hydroxide has subsided, the stopper is removed, 5 c.c. of hydrochloric acid are introduced, the stopper is replaced, and the whole shaken until a clear solution is obtained. The liquid is then emptied into a beaker, and the liberated iodine titrated with *N*/100 solution of sodium thiosulphate. When calculating the result, 3 c.c. only must be deducted for the reagents added; the volume of the hydrochloric acid added does not affect the calculations. L. DE K.

Estimation of Sulphuric Acid in the Presence of Iron. By GRÉGOIRE N. WYROUBOFF (*Bull. Soc. Chim.*, 1899, [iii], 21, 1046—1049. Compare Abstr., 1899, ii, 329 and 611).—A criticism of the methods described by Küster and Thiel (Abstr., 1899, ii, 247). N. L.

Estimation of Nitrogen in Fertilisers containing Nitrates. By F. P. VEITCH (*J. Amer. Chem. Soc.*, 1899, ii, 1094—1095).—Fields' process is recommended with only a slight modification. To the nitrate, 35—40 c.c. of sulphuric acid containing 34 grams of salicylic acid per litre, and after it has dissolved, 6—7 grams of crushed potassium sulphide, are added. After first heating over a low flame for 15 minutes, the contents are boiled for $1\frac{1}{2}$ hours, then cooled and distilled as usual with excess of soda. L. DE K.

Direct Estimation of Available Phosphoric Acid. By F. P. VEITCH (*J. Amer. Chem. Soc.*, 1899, 21, 1090—1094).—The sample is first extracted with water and the solution filtered into a 500 c.c. measure containing 5—10 c.c. of nitric acid. The insoluble residue is then treated with the ordinary ammonium citrate solution and the two liquids are united. The phosphoric acid is now precipitated in an aliquot part of the solution by means of the ordinary molybdate solution, the precipitation being probably complete in two hours at 65°. It does not seem necessary to destroy the citric acid, or any other organic matter present in the manure. L. DE K.

[**Estimation of the Available Phosphoric Acid in Soil.**] By AIMÉ PAGNOUL (*Ann. Agron.*, 1899, 25, 554—557).—After determining the dry matter and calcium carbonate, an amount of soil containing 10 grams of dry matter is digested for 2 hours with a solution containing 120 grams of glacial acetic acid in 1 litre (10 c.c. *plus* the amount required to dissolve the calcium carbonate) diluted with water to 50 c.c., the whole being shaken twelve times during digestion. The phosphoric acid is then determined in 25 c.c. of the filtered extract, by means of the colour reaction produced by potassium ferrocyanide in very dilute phosphomolybdate solution. The solutions required are (1) ordinary ammonia, 100 c.c., diluted to 1 litre; (2) sulphuric acid, 70 or 80 c.c., diluted to 1 litre; (3) potassium ferrocyanide, 10 per cent.; and (4) a standard phosphomolybdate solution containing exactly 4 milligrams of phosphoric acid per litre. This is prepared by precipitating a solution of sodium or ammonium phosphate, containing 4 mg. of phosphoric acid, as phosphomolybdate in the usual manner, decanting over a small filter, and washing with nitric acid until the filtrate gives no coloration with ferrocyanide. The whole is then dissolved in the dilute ammonia (solution 1) and made up to 1 litre with the same dilute ammonia.

The phosphoric acid in 25 c.c. of extract (corresponding with 5 grams of soil) is determined by precipitating as phosphomolybdate, filtering, and redissolving the precipitate in the dilute ammonia. The volume of the solution (V) will be from 10—50 c.c., according to the amount of precipitate. 5 c.c. of the standard phosphomolybdate solution (containing $P_2O_5 = 0.02$ milligram) is next put into a tube 2 cm. wide and divided into c.c., 5 c.c. of the solution to be examined being put into a similar tube. After adding ferrocyanide solution (2 c.c.) to both tubes, dilute sulphuric acid (solution 2) is added drop by drop until a permanent brown tint is obtained. A few drops of water are added to the tube containing the standard solution to make the volume up to 10 c.c., whilst the liquid in the second tube is diluted until the tints of both are alike, and the volume (V') read off. The phosphoric acid, in mg. per cent., in the soil will be $0.4 \times \frac{V_1}{10} \times \frac{V}{5}$. If the colour

produced by 5 c.c. of solution is too dark, 1 or 2 c.c. may be employed, but the solution must then be diluted with the ammonia solution to 5 c.c. before adding the ferrocyanide. A number of determinations may be made simultaneously with advantage. N. H. J. M.

Detection of Fraudulent Additions to Bone Superphosphate. By HENRI LASNE (*Chem. Centr.*, 1899, ii, 973—974; from *Ann. chim. anal. app.*, 4, 235—331).—A microscopical examination will indicate the origin of added mineral phosphates, foreign minerals, &c.

To facilitate the microscopic research, the sample may be first freed from true bone phosphate by successive treatment with dilute (3 per cent.) acetic acid and a concentrated solution of ammonium citrate.

L. DE K.

Valuation of Basic Slags. By FRANZ W. DAFERT (*Chem. Centr.*, 1899, ii, 727; from *Zeit. Landw. Vers.-Wes. Oesterr.*, 2, 467—476).—The author states that the valuation of basic slags by their citrate

solubility cannot be considered a scientific method, as it depends too much on the personal equation of the operator. L. DE K.

Detection and Estimation of very small Quantities of Arsenic in the Organs. By ARMAND GAUTIER (*Compt. rend.*, 1899, 129, 936—938).—The method, details of which are given, consists essentially in destroying the organic matter by successive treatment with nitric acid, sulphuric acid, and, finally, nitric acid again; the arsenic is precipitated, together with an excess of sulphur, by hydrogen sulphide, the precipitate digested with ammonia to dissolve the arsenious sulphide, which is then oxidised by a mixture of nitric and sulphuric acids, and finally treated by Marsh's method for detecting arsenic. T. H. P

Estimation of Graphitic Carbon in Cast Iron and Pig Iron. By ALLEN P. FORD and IVAN M. BREGOWSKY (*J. Amer. Chem. Soc.*, 1899, 21, 1113—1115).—1 gram of the sample is dissolved in nitric acid of sp. gr. 1.2; a few drops of hydrofluoric acid are then added and the liquid boiled for a short time to dissolve the silicon. After diluting with four times the bulk of water, the insoluble matter is collected on a Gooch's crucible, the asbestos of which has been selected with care and purified by digestion in hydrochloric acid. After drying for fully an hour at 120°, the crucible is weighed, the graphite burnt off, and the crucible re-weighed, the difference representing the graphite. L. DE K.

Report of the [American] Committee on Coal Analysis. By WILLIAM A. NOYES, WILLIAM F. HILLEBRAND and CHARLES B. DUDLEY (*J. Amer. Chem. Soc.*, 1899, 21, 1116—1132. Compare Abstr., 1898, ii, 488).—Final instructions are given as to the analysis of coal so as to ensure uniform results. When estimating the sulphur, it is recommended to avoid the use of coal gas. If an ultimate analysis is thought desirable, the sample should be burnt with lead chromate so as to retain the sulphur; it is unnecessary to employ a spiral of copper. When calculating the percentage of oxygen, it is recommended to deduct from 100 the sum of the carbon, hydrogen, nitrogen, ash, and five-eighths of the sulphur. In the preliminary report, it was recommended to give the heating effect on the basis of the coal burned to "vapour of water at 100°;" this is now altered to "liquid water at the ordinary temperature." L. DE K.

Estimation of Volatile Combustible Matter in Coke and Anthracite Coal. By RICHARD K. MEADE and JAMES C. ATTIX (*J. Amer. Chem. Soc.*, 1899, 21, 1137—1145).—In order to completely expel the last portions of volatile matter from coke or anthracite, it is necessary to finally employ the blast, but this causes some of the carbon to burn; the oxidation may be practically prevented by heating in a current of nitrogen.

If after heating a sample over a blast, say, for 7 minutes and weighing, the ignition is continued for another 7 minutes under exactly the same conditions, the second loss in weight should

represent with fair accuracy the amount of carbon oxidised during the first heating. The results obtained by this correction are satisfactory.

L. DE K.

Apparatus for the Analysis of Illuminating and Fuel Gases. By GEORGE E. THOMAS (*J. Amer. Chem. Soc.*, 1899, 21, 1108—1112).—This is a compact apparatus for technical work. It consists essentially of a burette and levelling tube joined by rubber and capillary glass tubes to a series of absorbing bottles, filled with aqueous caustic potash, bromine water, and phosphorus covered with water, another bottle is filled with water only, as it is only used for storing gas.

There is also the usual arrangement for exploding mixtures of gas and air. The water in the burette is acidified with sulphuric acid so as to diminish the solubility of carbon dioxide.

L. DE K.

Chemical Detection of Carbonic Oxide in Blood. By KARL IPSEN (*Chem. Centr.*, 1899, ii, 889; from *Vierteljahrschr. gericht. Med. öffentl. Sanitätswes.*, [iii], 18, 46—65).—4—10 c.c. of the suspected blood is put into a small test-tube, a drop of caustic alkali is added, and then a small amount of dextrose. After closing the tube with cotton wool and sealing it with paraffin wax, it is well shaken and kept for some length of time in a cool place. A blank experiment should be made with pure blood at the same time.

Blood containing carbonic oxide turns a light cherry-red colour, whilst ordinary blood becomes almost black.

L. DE K.

Chemical Detection of Carbonic Oxide in Blood. By LEO WACHHOLZ (*Chem. Centr.*, 1899, ii, 889; from *Vierteljahrschr. gericht. Med. öffentl. Sanitätswes.*, [iii], 18, 255—257. Compare preceding abstract).—The dextrose test may lead to erroneous results. The best process at present in use for detecting carbonic oxide in blood is the tannic acid process, proposed by Kunkel and modified by Schulz.

L. DE K.

Apparatus for the Estimation of Carbon Dioxide in Mineral Waters. By ALFRED HELD (*Bull. Soc. Chim.*, 1899, [iii], 21, 983—986).—The essential feature of the apparatus lies in the fact that the precipitation of the carbon dioxide by milk of lime and calcium chloride, the collection and washing of the precipitate, and the decomposition of the latter by dilute acid, are carried out in one and the same vessel, in an atmosphere free from carbon dioxide. For this purpose, the flask, in which the precipitation has been effected in the usual manner, is fitted with a cork bored with three holes, through which are passed: (1) A delivery tube, serving both for the admission of air free from carbon dioxide, and, subsequently, for the passage to the absorption apparatus of the gas liberated from the precipitated carbonate; (2) a tap-funnel for the inlet of water or acid; (3) a syphon tube, one limb of which reaches nearly to the bottom of the flask, and is connected by a cork to a small test-tube, pierced with several holes, and covered with a cap of filter paper. By means of this syphon, the liquid and washings are removed from the flask, leaving the precipitate to be treated with acid in the usual way.

N. L.

Estimation of Carbon Dioxide in Ammoniacal Gas-Liquor.

By F. CHEVALET (*Chem. Centr.*, 1899, ii, 847; from *Ann. chim. anal. appl.*, 4, 295—296).—The sample is allowed to run into an acid solution of cuprous chloride; the apparatus employed, which is a slight modification of the one introduced by Geissler, is weighed before and after the operation, and the carbon dioxide found by difference. The object of the copper solution is to retain hydrogen sulphide.

L. DE K.

Stutzer and Hartleb's Process for the Estimation of Combined Carbon Dioxide (Calcium Carbonate) in Soils.

By RUDOLF WOY (*Chem. Centr.*, 1889, ii, 847; from *Zeit. öffentl. Chem.*, 5, 400—401. Compare Abstr., 1899, ii, 521).—The author objects to the process, as decided quantities of ammonia are given off on boiling by the dissociation of the added ammonium chloride.

L. DE K.

Estimation of Silver on Plated Copper Utensils.

By JULIEN GIRARD (*Chem. Centr.*, 1899, ii, 975; from *Ann. chim. anal. appl.*, 4, 342—343).—The object is thoroughly cleansed and immersed in a liquid composed of 9 volumes of sulphuric and 1 volume of nitric acid; this rapidly dissolves the silver without acting appreciably on the copper. The silver may be ascertained from the loss in weight, or be estimated in the solution as chloride.

L. DE K.

Estimation of Small Quantities of Zinc in Organic Substances, especially in Apple Chips.

By KARL B. LEHMANN (*Zeit. anal. Chem.*, 1899, 38, 723; from *Arch. Hygiene*, 28, 291).—The substance is mixed with nitric acid and either incinerated until perfectly white, or after charring is mixed with sodium carbonate and potassium nitrate and fused in a porcelain basin. The ash is dissolved in nitric acid, copper precipitated by hydrogen sulphide, and the zinc then separated from iron, aluminium, and silica by repeated precipitation with ammonia. A small excess of acetic acid is added to the ammoniacal filtrate and the zinc thrown down by hydrogen sulphide. The zinc sulphide is then dissolved in hydrochloric acid and the zinc titrated by Fahlberg's ferrocyanide method (this Journ., 1875, 665) using a ferrocyanide solution of which 1 c.c. precipitates 0.1 milligram of zinc. The zinc solution must be only feebly acid; the presence of ammonium salts is harmless. For quantities of less than 1 milligram, a correction (about -0.15 mg.) must be applied.

M. J. S.

Titrimetric Estimation of Cerium.

By PHILIP E. BROWNING [with WM. D. CUTLER, G. A. HANFORD, LEO. A. LYNCH, and F. J. MALL] (*Zeit. anorg. Chim.*, 1899, 22, 297—307).—Accurate results are obtained with the following modification of Bunsen's method. The cerium dioxide is mixed in a stoppered flask with potassium iodide and a few drops of water, the air is then driven out by a current of carbon dioxide, pure hydrochloric acid added, and the flask stoppered and heated with steam for 1 hour, or until the dioxide is completely dissolved. The contents of the flask are then diluted, and the liberated iodine titrated with thiosulphate. The liberated iodine was also estimated by titration with arsenious acid after the contents of the

flask connected with an absorption apparatus were neutralised with potassium hydrogen carbonate, but in this case a loss of about 2 per cent. of the iodine occurred.

Cerium dioxide is only partially reduced by arsenious acid and cannot therefore be estimated by this reagent.

Stolba's method (Abstr., 1880, 749) by titrating the oxalate with permanganate, gives good results. A measured quantity of cerium chloride solution is precipitated with a known excess of ammonium oxalate and the precipitate separated by filtration and washed. The cerium oxalate is then dissolved in sulphuric acid and the oxalic acid titrated with permanganate. The excess of ammonium oxalate in the filtrate and wash-water is also titrated, the result giving a control to the titration of the cerium oxalate.

E. C. R.

Preliminary Tests for Clays. By WERNER CRONQUIST (*Chem. Centr.*, 1899, ii, 974; from *Oesterr. Zeit. Berg-Hütt.*, 47, 522—525).—Clays intended for the manufacture of crucibles should contain at most 47—72 per cent. of sand. This may be estimated with sufficient accuracy by first boiling the clay with hydrochloric acid, and then boiling the undissolved matter with a strong solution of sodium carbonate.

L. DE K.

Rapid Solution of Ignited Ferric Oxide in Hydrochloric Acid. By HUGO BORNTRÄGER (*Zeit. anal. Chem.*, 1899, 38, 774).—By adding to the hydrochloric acid a little iron-free manganese dioxide, even strongly ignited ferric oxide can be dissolved with great facility. This effect seems to be due to the chlorine evolved, since all the halogens facilitate the solution of ferric oxide in hydrochloric acid.

M. J. S.

Use of Hydrogen Peroxide in Quantitative Analysis. By CARL FRIEDHEIM and ERNST BRÜHL (*Zeit. anal. Chem.*, 1899, 38, 681—710).—After a review of the various proposals that have been made for the use of hydrogen peroxide in qualitative and quantitative reactions, the greater part of the paper is devoted to a study of the methods advocated by Jannasch and his pupils; separation of manganese from copper, zinc, and nickel, and of chromium from iron, aluminium, and manganese, by means of alkaline solutions of the peroxide (Abstr., 1895, ii, 331; 1896, ii, 220, 222, 546, 548). It is shown that the apparently satisfactory results obtained by Jannasch are largely due to compensating errors, none of the above separations being at all complete. The accuracy of the method of estimating manganese, in the absence of other metals, by precipitation with ammonia and hydrogen peroxide (Rosenthal, Abstr., 1887, ii, 923) is fully confirmed, but only in the absence of any considerable amount of ammoniacal salts. With increase in the proportion of ammonium salts, the amount of unprecipitated manganese increases, but at the same time the precipitate becomes more highly oxidised, so that apparently correct results may in some cases be obtained if the precipitate is regarded as Mn_2O_4 . Although alkaline solutions of

chromic oxide are oxidised by hydrogen peroxide, the oxidation is under no circumstances complete. This probably is the reason why chromium cannot by this method be separated from metals whose hydroxides are insoluble in alkalis. M. J. S.

Estimation of Thallium as Chromate. By PHILIP E. BROWNING and GEORGE P. HUTCHINS (*Amer. J. Sci.*, 1899, [iv], 3, 460—462).—Crookes having shown that thallous chromate is practically insoluble in water, the authors have applied this principle to the gravimetric estimation of thallium. The liquid containing the thallium is rendered distinctly alkaline by adding a solution of potassium carbonate, then heated to 80°, and precipitated with excess of potassium dichromate. The thallous chromate is collected on a Gooch's asbestos filter, washed, dried over a low flame, and weighed. Twelve test experiments prove the accuracy of the method. If precipitated in the cold, the precipitate is liable to run through the filter; this may be largely prevented by adding ammonium nitrate.

Moderately accurate results may be obtained by adding a known amount of potassium dichromate and titrating the excess with arsenious acid as described by Browning (*Abstr.*, 1899, ii, 73). L. DE K.

Ultimate Analysis of Organic Compounds. By MARCELLIN P. E. BERTHELOT (*Compt. rend.*, 1899, 129, 1002—1005).—For the estimation of the elements in an organic compound, the method employed by the author for the analysis of organic compounds and determination of their heat of combustion by burning the substance in a calorimetric bomb, is recommended as being simpler and more rapid than the methods in general use. For the estimation of sulphur, phosphorus, halogens, or metals in compounds poor in carbon, it is necessary to first mix the substance with camphor or naphthalene, so as to ensure easy combustion, and in the determination of the halogens, the presence of a small amount of sodium arsenite or sulphite solution in the calorimetric bomb ensures the conversion of the whole of the halogen into the corresponding hydrogen haloid.

H. R. L. S.

Estimation of Halogens in Organic Compounds. By AMAND VALEUR (*Compt. rend.*, 1899, 129, 1265—1267).—The calorimetric bomb may be employed in the estimation of the halogens in organic compounds (Berthelot, preceding abstract). When a compound containing chlorine is burnt in compressed oxygen in the presence of ammonium hydrate, the whole of the halogen is obtained as ammonium chloride, and may be estimated by the ordinary volumetric or gravimetric methods. Bromine is estimated in a similar manner. The combustion of an organic substance containing iodine is carried out in the presence of a concentrated solution of caustic potash; the latter, which contains the whole of the halogen, is decomposed with sulphuric acid and potassium dichromate, and distilled in order to recover the iodine, which is collected in potassium iodide solution and estimated volumetrically.

G. T. M.

Estimation of Benzene Vapour in Illuminating Gas. By OTTO PFEIFFER (*Chem. Centr.*, 1899, ii, 976; from *Journ. Gasbel.*, 42, 697—701).—Harbeck and Lunge's process of conversion into nitrobenzene is recommended (*Abstr.*, 1898, ii, 193). L. DE K.

Analysis of Ethereal Oils, especially the Citrus Oils. By ARTURO SOLDAINI and E. BERTÉ (*Chem. Centr.*, 1899, ii, 849—850; from *Boll. Chim. Farm.*, 38, 537—544).—These oils should conform to the following standards: *Oil of Lemon*.—Sp. gr. 0.854—0.860 at 15°. Rotatory power in 100 mm. tube +56° to +66° at 20°. Amount of citral above 6.5 per cent. On fractional distillation, the half which comes over first should show the same rotation as the original. Boiling point 171—172° under 760 mm., or 85—87° under 30—40 mm. pressure. In the absence of oil of bitter orange, the sample should not turn yellow on adding a solution of bromine in chloroform or sodium hydrogen sulphite.

Oil of Bergamot.—Sp. gr. 0.882—0.886 at 15°. Rotation at 20° +8° to +20°, generally +12° to +18°. Linanyl acetate, 34—42 per cent. Boiling point, 69° under 20—30 mm. pressure. Residue on evaporation, 5—6 per cent. Soluble in half its volume, or more, of 90 per cent. alcohol. No reaction with Schiff's test.

Oil of Bitter Orange.—Sp. gr. 0.847—0.853 at 15°. Rotation at 20°, +96° to +98°. Boiling point 173—174° under 760 mm., or 79—81° under 20—30 mm. pressure. On distillation, the rotation of the first (half) fraction is always 1° or 3° higher than the original, and it should not give a coloration with Schiff's reagent. L. DE K.

Valuation of Lemon-Oil. By J. WALTHER (*Chem. Centr.*, 1899, ii, 942—943, from *Pharm. Centr.-H.*, 40, 621—625).—The amount of citral and citronellal contained in lemon-oil is determined by converting them into oximes by means of hydroxylamine hydrochloride and then titrating the excess of this compound. A 20 per cent. solution of hydroxylamine hydrochloride in 80 per cent. alcohol is titrated first using methyl-orange and then phenolphthalein as indicator. An equal volume of the same solution is boiled with about 10 grams of lemon-oil and 0.5—1.0 gram of sodium hydrogen carbonate for 45 minutes. Hydroxylamine hydrochloride may be heated with the carbonate in presence of an indifferent liquid such as alcohol or turpentine without loss. The cooled solution is made up to 250 c.c. and 25 c.c. titrated with hydrochloric acid using methyl-orange, then back again with decinormal sodium hydroxide solution and finally again with alkali in presence of phenolphthalein. The percentages of citral c or of citronellal c' may be calculated from the formulæ $c = \frac{1.52a}{g}$ and $c' = \frac{1.54a}{g}$ in which a = c.c. of decinormal sodium hydroxide solution used, and g = weight of oil taken. By this method, lemon-oil was found to contain only 5 per cent. of citral, whereas according to Schimmel & Co., 7—8 per cent. is the usual amount. In order to avoid a large excess of hydrochloric acid, as little sodium hydrogen carbonate as possible should be used in the titration of hydroxylamine; the oximes are hydrolysed by an excess of acid,

forming ammonium citronellate and geraniate respectively, and these salts interfere with the titration.

The results were controlled by the following method. After forming the oximes, the product is made up to a certain volume, the oil separated, and the aqueous solution filtered. To 25 c.c. of the filtrate, after treating with 1 gram of sodium hydrogen carbonate, decinormal iodine solution was added, and the excess finally titrated with thio-sulphate solution. 1 c.c. of iodine solution corresponds with half a molecule of hydroxylamine.

E. W. W.

Lemon Flavouring Extract and its Substitutes. By A. S. MITCHELL (*J. Amer. Chem. Soc.*, 1132—1137).—10—20 c.c. of the extract is introduced into a kind of Babcock milk bottle of 80 c.c. capacity furnished with two necks. The larger tube, used for filling should enter at the side and pass almost to the bottom of the flask. The smaller tube, used for measuring the separated oil, should have an internal diameter of about 3 mm., and a length of about 12 cm.; the tube contains 1 c.c. between its extreme graduations, and is divided to fiftieths of a c.c., each division representing 0.2 per cent. of oil when 10 c.c. of the sample have been taken.

10 drops of hydrochloric acid and 30 c.c. of water are added and the flask placed in water at 70° until the oil separates; it is then filled with warm water and whirled in the centrifuge, when the oil collects in the neck. The separation is the more complete the richer the sample is in oil, but if only 5 per cent. or less is found, an allowance of 1.2 per cent. extra should be made. The oil may now be removed with a pipette and examined in the polariscope or the Zeiss butter refractometer. The rotation of oil of lemon in a 200 mm. tube, using a Schmidt and Haensch polariscope, is 63—64°, and its refraction at 30° varies from 67—72. Lemon substitutes give widely differing figures, which are recorded in a table. The rotations of alcoholic solutions of 5 and 1 per cent. strength of oil of lemon and its substitutes are also given.

To estimate the alcohol, 25 c.c. are pipetted into a 100—110 c.c. flask; 2 c.c. each of a saturated solution of aluminium chloride and sodium hydrogen phosphate are added, the mixture diluted to 110 and well shaken. 100 c.c. of the filtrate are diluted with 25 c.c. of water and then distilled until 100 c.c. have passed over, when the sp. gr. is taken.

L. DE K.

Estimation of Mercuric Oyanide. By E. VINCENT (*J. Pharm.*, 1899, [vi], 10, 537—539).—The mercury and the nitrogen in mercuric cyanide are simultaneously estimated by heating the salt with soda-lime, the mercury being collected and weighed in the metallic state, whilst the ammonia evolved is received in standard sulphuric acid. The method, which is both rapid and accurate, is also applicable to mercuric cyanate. Commercial specimens of the latter salt are usually very impure, and largely consist of mercuric cyanide mixed with more or less oxide.

N. L.

Detection of Nitroprussides in Cases of Poisoning. By GIUSEPPE VENTUROLI (*Zeit. anal. Chem.*, 1899, 38, 743—744; from *Bull. chim. farm.*, March, 1897).—Nitroprussides are highly poison-

ous; 12 milligrams of sodium nitroprusside killed a dog when injected under the skin. Nitroprusside could not be detected in the urine, it having been completely decomposed into nitrite and thiocyanate. It is therefore recommended that a suspected liquid should be boiled with ammonium sulphide and filtered, the filtrate, mixed with potassium hydroxide, evaporated to dryness, the residue treated with absolute alcohol, and the alcoholic extract examined for nitrite and thiocyanate by the usual tests. M. J. S.

Action of Strong Aqueous Soda on Methyl Acetate in the Presence of Methyl Alcohol and Acetone. By L. CUNIASSE (*Chem. Centr.*, 1899, ii, 975; from *Ann. chim. anal. appl.*, 4, 346—347).—Methyl acetate is but imperfectly decomposed by aqueous sodium hydroxide of sp. gr. 1.3, but its solution in methyl alcohol is completely decomposed by this alkali. Acetone dissolved in methyl alcohol is insoluble in ley of the above sp. gr., and separates. If methyl acetate is present, it is then not attacked by the alkali, and is found unaltered in the layer of acetone. L. DE K.

Estimation of Fusel Oil in Alcoholic Liquids. By ERNST BECKMANN [with H. BRÜGGEMANN] (*Chem. Centr.*, 1899, ii, 731—732; from *Zeit. Unters. Nahr. Genussm.*, 2, 709—714).—The process is briefly as follows: To the spirit some dry calcium chloride is added, and the fusel oil is then extracted by repeatedly shaking with carbon tetrachloride. This extract is shaken with water to remove any ethyl alcohol, and the amyl alcohol is then converted into amyl nitrite by passing through its solution a current of dry nitrous anhydride, the flask containing it being attached to a reflux condenser. The mixture is then boiled for a short time while transmitting a current of dry carbon dioxide, and, when cold, the nitric oxide generated by bringing it in contact with ferrous sulphate is liberated and measured in a Schulze-Tiemann's apparatus, and calculated into its equivalent of amyl alcohol. The presence of ethereal compounds in commercial spirits does not interfere with the process. L. DE K.

Estimation of Geraniol in Oil of Citronella. By SCHIMMEL & Co. (*Chem. Centr.*, 1899 ii, 880; from *Geschäftsber.*, Oct., 1899).—In the ordinary method of estimating the amount of geraniol in citronella oil by forming the acetyl derivatives and hydrolysing them, geraniol and citronellal are estimated together, the latter forming isopulegol acetate. In order to estimate geraniol separately, 2 grams of the oil are warmed on the water-bath for 2 hours with 2 grams of phthalic anhydride and 2 grams of benzene. The cooled product is shaken for 10 minutes with 60 c.c. of seminormal potassium hydroxide solution, the anhydride is converted into potassium phthalate, and the acid geraniol ester into the corresponding potassium salt. The excess of alkali is titrated with seminormal sulphuric acid. By subtracting the amount of potassium hydroxide used from the amount which corresponds with the quantity of phthalic anhydride added, the alkali equivalent to the phthalic acid combined with the geraniol is obtained,

and from this the percentage of geraniol may be easily calculated. The oil of citronella was found to contain 33 per cent. E. W. W.

Wood-Tar Creosote. By LYMAN F. KEBLER (*Chem. Centr.*, 1899, ii, 827; from *Amer. J. Pharm.*, 71, 409—413).—The amount of guaiacol contained in creosote is of importance in regard to its medicinal use, and may be determined as follows: 5 c.c. of creosote are mixed with 50 c.c. of a 20 per cent. alcoholic solution of potassium hydroxide. The crystalline mass, which separates in 10—30 minutes, consists of a compound of guaiacol and creosol with potassium. The dried crystals are heated for a moment with 5 c.c. of a 10 per cent. solution of sulphuric acid, the liquid is diluted, and the mixture of guaiacol and creosol, which separates as a heavy oil, removed. By treating this oil with 4 c.c. of a concentrated solution of ammonia, the guaiacol ammonium compound is formed as a crystalline mass which separates before the less crystalline creosol compound. The latter is removed by means of benzene, and the guaiacol ammonium compound decomposed by a 10 per cent. solution of sulphuric acid. The liberated guaiacol is dissolved by shaking with benzene and finally weighed after evaporating the solvent.

The amount of creosote and phenols contained in the tar may be estimated from the diminutive of volume of the tar after extracting with an aqueous solution of glycerol. E. W. W.

Estimation of Sugar in Diabetic Urine. By GUSTAVE PATRIN and E. DUFAU (*Bull. Soc. Chim.*, 1899, [iii], 21, 1028—1033. Compare Abstr., 1899, ii, 375).—The author has repeated the experiments of Pellet, who suggests the use of normal lead acetate instead of the basic salt for the precipitation of the proteids before estimating sugar in urine, and finds that, although more accurate results are thus obtained, certain proteid substances, especially peptones, escape precipitation, both by normal and basic lead acetate, the polarimetric results being thus rendered inaccurate. If, however, the proteids are precipitated by an acid solution of mercuric nitrate, accurate and concordant results are obtained both by Fehling's solution and by the polarimeter. The existence of laevorotatory sugars in diabetic urine is exceedingly doubtful; according to Béhal's experiments, the substance which interferes with the polarimetric estimation of sugar in urine is a laevorotatory proteid, which is precipitated by heat and by nitric acid, mercuric nitrate, and alcohol, but not by acetic acid, lead acetate, or magnesium sulphate. N. L.

Rapid Estimation of Sugar in Fatty Substances. By GIOVANNI POSSETTO (*Chem. Centr.*, 1899, ii, 977; from *Giorn. Farm. Chim.*, 49, 433—435).—The sugar is extracted by treatment with a definite volume of hot water, and estimated in an aliquot part of the clear filtrate by the usual methods. L. DE K.

Rapid Process for the Estimation of Starch: Estimation of Starch in Yeast. By D. CRISPO (*Chem. Centr.*, 1899, ii, 851—852; from *Ann. chim. anal. appl.*, 4, 289—290, 290—291).—3.391 grams of the sample of starch are rubbed with water and transferred to a 200 c.c. flask; 50 c.c. of a 6 per cent. solution of potassium

hydroxide are added, the whole diluted to about 150 c.c., and heated for an hour on a boiling water-bath, with frequent shaking. When cold, the solution is diluted to the mark, filtered repeatedly, and polarised in a 200 mm. tube. If a German polariscope is used, the number of degrees of rotation multiplied by six equals the percentage of anhydrous starch.

The process may be applied to the estimation of starch in commercial yeast. The starch is first removed from the yeast by lixiviation, and finally dissolved in potash. The results are, however, somewhat below the truth.
L. DE K.

Chemical Detection of Vegetable Fibres. By EDMOND JANDRIER (*J. Amer. Chem. Soc.*, 1899, 21, 1175—1176).—The sample to be examined for cotton, for instance, a piece of woollen goods, is, after careful washing, treated with sulphuric acid of sp. gr. 1.162 and heated for half an hour over the water-bath to convert the cellulose into soluble carbohydrates. The solution is diluted and a few c.c. are put into a test-tube containing about 0.01 gram of a phenol such as resorcinol. A little strong sulphuric acid is then gently poured down the side of the tube, when an orange colour will develop at the place of contact. *a*-Naphthol gives a purple, gallic acid a green gradually becoming violet, quinol and pyrogallol a brown, morphine and codeine a lavender, and thymol and menthol a pink colour.
L. DE K.

Separation of Lactic, Butyric, and Valeric Acids. By SCHNEIDER (*Zeit. anal. Chem.*, 1899, 38, 775—776; from *Zeit. angew. Mikroskopie*, 1897, 45).—The mixture is distilled with superheated steam, when butyric and valeric acids pass over, whilst lactic acid remains in the residue. The distillate is evaporated to dryness with calcium carbonate, and extracted with alcohol, when calcium acetate and formate remain undissolved. From the solution, zinc nitrate precipitates zinc valerate in thin plates, and from the concentrated filtrate copper nitrate throws down copper butyrate. To identify the lactic acid, the contents of the retort are evaporated with zinc oxide and filtered while hot; zinc lactate crystallises on cooling. A few centigrams of the zinc lactate are mixed with phosphoric acid and extracted with ether. The ethereal solution is evaporated, and a little cobalt acetate and lead acetate added. A precipitate is obtained of cobalt lead lactate in the form of colourless, hexagonal plates which are feebly levorotatory.
M. J. S.

Volatile Acids in Beer; Detection of Neutralising Agents in Beer. By EDUARD SPAETH (*Zeit. anal. Chem.*, 1899, 38, 745—769).—The acid reaction of normal beers is chiefly due to the presence of primary phosphates, with comparatively small quantities of volatile and non-volatile organic acids. In beer brewed with due regard to cleanliness and purity of yeast, a further development of acidity is extremely slow, and is mainly due to the production of volatile acid (acetic). In many small breweries, however, these precautions are not observed, and the conditions are often highly favourable to the access of the lactic acid bacterium. It is accordingly found that home-brewed beers, which have turned sour owe their increased acidity principally to the

development of lactic acid, whilst the amount of acetic acid is often scarcely greater than in normal beers. The proposal of Ott to recognise the fact of a sour beer having been neutralised with an alkali by estimating the volatile acids obtained by steam distillation before and after the addition of phosphoric acid, fails therefore to attain its object.

An estimation of the alkalinity of the ash of the beer will often indicate that the beer has been neutralised. The ash of 100 c.c. of normal beer rarely requires more than 0.3 c.c. of normal acid; a higher alkalinity is a qualitative indication, but for quantitative purposes the author has not been able to simplify his earlier process (Abstr., 1898, ii, 407). Prior's method (Abstr., 1893, ii, 53) seems also to be a trustworthy one.

M. J. S.

Detection of Glycuronic Acid in Urine. By PAUL MAYER (*Chem. Centr.*, 1899, ii, 450; from *Berlin klin. Woch.*, 36, 591—593).—See this vol., ii, 155.

Determination of the Bromine Absorption of Oils. By PARKER C. McILHINEY (*J. Amer. Chem. Soc.*, 1899, 21, 1084—1089. Compare Abstr., 1894, ii, 370).—The author has slightly modified his process. The oil is dissolved in carbon tetrachloride and a solution of bromine of known strength in the same solvent is added. The action of the bromine is complete in a few minutes; the bottle is placed in ice and solution of potassium iodide is introduced by the ordinary device. The excess of bromine liberates iodine, which is then titrated with *N*/10 solution of sodium thiosulphate.

If rosin or rosin oil is present, hydrogen bromide will be also formed; this is estimated by adding to the bleached liquid a solution of potassium iodate. This, in the presence of potassium iodide and the acid, liberates iodine, which is then again titrated and calculated into hydrogen bromide.

L. DE K.

Detection of Sesamé Oil. By A. BÖMER [with K. WINTER] (*Chem. Centr.*, 1899, ii, 729—730; from *Zeit. Unters. Nahr.-Genussm.*, 2, 705—709).—The author has investigated the properties of sesamin, one of the unsaponifiable constituents of sesamé oil, in which it occurs to the extent of 0.2—0.5 per cent. It is very soluble in chloroform but only slightly so in ether or light petroleum; by means of ether, it may be readily separated from phytosterol. The unsaponifiable portion of sesamé oil is first crystallised from alcohol and the crystals are then washed with small quantities of ether until the undissolved mass is free from phytosterol crystals. Sesamin is colourless, crystallises in large needles, or forms irregularly shaped, round crystals, and melts at 120—122°; when contaminated with phytosterol, the melting point may be as low as 110—112°. A mixture of equal parts of acetic anhydride and sulphuric acid added to sesamin causes a brownish-green, then bluish-green, finally dark cherry-red, or reddish-blue coloration. Sulphuric acid added to the chloroform solution turns cherry-red or blue, leaving the chloroform colourless; water does not discharge the colour. Its alcoholic solution turns violet on adding

sulphuric acid. Solutions of sesamin show a right-handed polarisation. It seems incapable of esterification.

Sesamé oil contains a small quantity of an active principle to which the Baudouin reaction, so characteristic of this oil, is due. This substance may be removed from the mother liquor of the crude phytosterol or even from sesamé oil itself by treatment with animal charcoal. From the charcoal, it may be recovered by treatment with ether; it then forms a pure brown or reddish-brown, resinous mass which still gives the Baudouin reaction in a dilution of 1:500,000. As this substance is affected by heat, care must be taken to avoid over-heating when testing margarine for sesamé oil.

L. DE K.

Milk Analyses: New Process for the Simultaneous Estimation of Residue, Fat, and Ash. By H. TIMPE (*Chem. Centr.*, 1999, ii, 977; from *Zeit. öffentl. Chem.*, 5, 413—416).—5 c.c. of milk are introduced into a weighed Gooch's crucible filled with asbestos and the residue is obtained by drying for 4—5 hours in an air-bath at 100—102°.

The fat is extracted with ether, the crucible being placed in a Soxhlet's apparatus, and the ash found by incineration.

L. DE K.

Determination of the Melting Point of Fats. By FERDINAND JEAN (*Chem. Centr.*, 1899, ii, 973; from *Ann. chim. anal. appl.*, 4, 331—334).—A platinum wire, such as is used for making borax beads, is dipped into the liquid fat and the bead allowed to cool for 4 hours. It is then attached to the bulb of a thermometer and suspended in a beaker containing water; heat is applied and the temperature is noticed first when the edges of the fat become translucent and then when the whole globule is transparent, the mean of the two observations being taken as the melting point. If the fat does not melt to a clear liquid, the wire is first bent like an 8, dipped into the fat, and when cold it is pulled straight. The temperature at which the fat detaches itself from the wire and floats on the water is taken as the melting point.

L. DE K.

Detection of Acetaldehyde in Ether. By HERMANN BLASER (*Chem. Centr.*, 1899, ii, 848; from *Pharm. Centr.-Halle*, 40, 607).—Instead of using a solution of magenta decolorised with sulphurous acid, the author takes a very weak solution of magenta (1:100,000) and bleaches this completely by exposure to sunlight. This solution gives very sharp reactions with aldehyde.

L. DE K.

[Detection of] Acraldehyde and certain other Aldehydes. By LOUIS LEWIN (*Ber.*, 1899, 32, 3388—3389).—Acraldehyde gives a gentian-blue coloration with a mixture of piperidine and a solution of sodium nitroprusside; very dilute solutions give a greenish-blue colour, but the reaction can be observed at a dilution of 1:3000; the blue colour becomes violet on adding ammonia, rose-violet to rusty-brown with sodium hydroxide, and brown with mineral acids, the blue colour returning on adding water. Dimethylamine can be used in place of piperidine, but is much less sensitive.

Acetaldehyde gives a similar blue coloration even at a dilution of 1:10,000, paraldehyde and propaldehyde at 1:1000, and cinnamaldehyde in alcohol solution a green to blue colour. Formaldehyde, trichloroaldehyde, isobutaldehyde, benzaldehyde, salicylaldehyde, phenylacetaldehyde, cinnamaldehyde and furfuraldehyde give no coloration with this reagent.

T. M. L.

Detection of Acetone in Urine and other Animal Secretions. By CARL OPPENHEIMER (*Chem. Centr.*, 1899, ii, 888—889; from *Berl. klin. Woch.*, 36, 38).—Denigé's process (*Abstr.*, 1899, i, 22; ii, 256) with mercuric sulphate containing excess of sulphuric acid is recommended. When applying the process quantitatively, the factor 0.055 should be substituted for 0.06 when calculating the weight of the mercurial acetone compound to acetone.

L. DE K.

New Methods in Indigo Assay. By ROBERT CLAUSER (*Chem. Centr.*, 1899, ii, 978—979; from *Oesterr. Chem. Zeit.*, 2, 521—523).—After pointing out the defects of the present methods, the author states that the best results are obtained by means of a slight modification of Schneider's naphthalene process.

0.3—0.5 gram of the powdered sample is mixed with quartz sand and extracted by means of 30—40 grams of boiling naphthalene. The naphthalene cake, which contains all the indigo, is then extracted in a specially constructed apparatus with 200 c.c. of boiling ether, and the indigo which is left undissolved is collected on asbestos and weighed.

L. DE K.

A New Alkaloidal Reagent. Detection of Opium. By MECKE (*Chem. Centr.*, 1899, ii, 683—686; from *Zeit. öffentl. Chem.*, 5, 351—354).—The reagent is made by dissolving 0.5 gram of selenous acid in 100 grams of sulphuric acid. A complete table and a lengthy description are given showing the action of the acid on the alkaloids in the cold and on warming.

By means of the intense bluish-green coloration given by the new reagent, it is possible to detect with certainty the presence of the rarer opium alkaloids in suspected cases of poisoning with that drug.

L. DE K.

48

General and Physical Chemistry.

Method for the Exhibition of the Properties of Polarised Light. By NICOLAI A. UMOFF (*Zeit. physikal. Chem.*, 1899, 30, 711—715).—The paper contains an account of a number of interesting lecture experiments. If a beam of plane polarised light is projected on to a glass cone with a vertical angle of about 68° , to the base of which is attached a paper screen, a circular disc of light is formed on the screen, by reflection from the glass, with two dark minima 180° apart, these showing the plane of polarisation. Various colour effects are obtainable by interposing plates of quartz, &c. By downward reflection of the beam into a glass jar of water, to which has been added a little alcoholic solution of resin, two dark lines down the opalescent liquid mark the plane of polarisation and one of the most interesting suggestions is the replacing of the water by a solution of sugar, &c., when spiral dark bands are obtained, illustrating the rotation of the plane of polarisation. L. M. J.

Spectrum of Silicon. By SIR NORMAN LOCKYER (*Proc. Roy. Soc.*, 1899, 65, 449—452).—A double line previously found in the spectra of gases distilled from the mineral eliasite was probably due to the fusion of the glass, and in reality belongs to silicon, of which element several other lines have now been detected. The silicon lines may be divided into three sets, no two of which behave alike under varying electrical conditions. It is found that the three sets of lines respectively attain a maximum intensity at the levels of stellar temperature represented by β , γ , and ζ Orionis. A line, however, at λ 3905.8, occurring in both arc and spark spectra, is not represented in the spectra of any of these stars. J. C. P.

New Lines in the Ultra-red of the Argon Spectrum. By RAFFAELE NASINI, FRANCESCO ANDERLINI, and ROBERTO SALVADORI (*Real. Accad. Lincei*, 1899, [v], 8, ii, 269—271).—By photographing the ultra-red portion of the spectra of various natural gases, including gas from a fumarole on Vesuvius and that of the Grotta del Cane, new argon lines of the following wave-lengths are detected : 798.0, 803.0, 814.0, 832.0, 845.0, and 857.5. T. H. P.

Reversible Photochemical Processes. By ROBERT LUTHER (*Zeit. physikal. Chem.*, 1899, 30, 628—680).—The changes investigated were the blackening of silver chloride and silver bromide ; this being attended with the liberation of halogen, it is probable that for any particular light intensity the products are in equilibrium when the pressure of the halogen reaches a certain value. In order to determine the relation between the light intensity and the halogen pressure, observations were made of the intensity necessary to cause blackening of glass plates coated with deposits of silver chloride and bromide, the deposits being in contact with halogen solutions of

varying strength, details of the method adopted being given. Curves are obtained for log. concentration against log. light intensity. The question is also investigated theoretically, and the author deduces an equation for the variation of the equilibrium constant with illumination, namely, $RT \cdot \{\log K_{\text{bright}} - \log K_{\text{dark}}\} = C/3 \sum a_x v_x (l_x - 1)$, where C represents the concentration of the light rays, and a_x , v_x , and l_x are the molecular coefficients, molecular volume, and the capacity function for radiations of the several substances entering into the reaction. Hence the equilibrium constant is unaffected by light only when this expression is zero; in general, the form is $\log K = AI + C$, where I is the light intensity and A and C are constants, but the experimental results are not in accord with these deductions. The E.M.F.'s of platinum electrodes in various illuminated halogen solutions, that is, the oxidation potentials of the solutions, were also determined, and the comparison of these values with the light intensity again shows no accord with the theories of either the author or of Luggin. No evidence could be obtained of a reverse process, that is, no light phenomena are obtainable by the chlorination of the darkened products. The values 1.44 and 1.14 volts were obtained for the E.M.F.'s of respectively bright and dark silver chloride electrodes in $N/10$ chloride solution. By determinations of the E.M.F. of a platinum electrode in a solution containing silver powder with varying quantities of chlorine or bromine, evidence was obtained of the existence of the compounds Ag_3OI and Ag_3Br , but no other compounds are indicated. Further work on the same question is promised by the author.

L. M. J.

Absorption of Röntgen's Rays by Aqueous Solutions of Metallic Salts. By LORD BLYTHSWOOD and E. W. MARCHANT (*Proc. Roy. Soc.*, 1899, 65, 413—428).—The absorption of normal solutions of salts with the same acid radicle increases with the atomic weight of the metal, although the increase in some cases, for example, calcium, strontium, and barium, is not very marked. Bromides and iodides are all highly absorbent, and of other salts nitrates, chlorides, and sulphates are placed in the order of increasing absorptive power. The absorption in a given thickness of salt solution is not proportional to the concentration, but follows approximately a logarithmic law. The amount of absorption varies logarithmically with the thickness of the solution traversed by the rays. The results are largely confirmatory of those obtained by Gladstone and Hibbert (*Abstr.*, 1897, ii, 131; *Chem. News*, 1898, 78, 199).

J. C. P.

Radiations from Radium. By HENRI BECQUEREL (*Compt. rend.*, 1900, 130, 206—211. Compare this vol., ii, 81, 125, 126).—The rays emitted by the chloride and carbonate of radium are equally deviated by the electro-magnet, the radiation from different specimens varying in intensity, but not in kind. The deviation produced by a given magnetic field remains constant, whether the experiments are made in air or in a vacuum. The remainder of the paper contains an account of physical experiments not suitable for abstraction.

G. T. M.

Dispersion of the Radiation of Radium in a Magnetic Field. By HENRI BECQUEREL (*Compt. rend.*, 1900, 130, 372—376. Compare this vol., ii, 126).—The author continues his researches on this subject, and describes various experimental improvements which enable him to obtain more definite results. N. L.

Electromotive Force and Chemical Equilibrium. By VICTOR ROTHMUND (*Zeit. physikal. Chem.*, 1899, 31, 69—78).—When k is the equilibrium constant of a chemical process which in a galvanic element originates the electromotive force E , then $E = RT \log_e k$: application of this general equation to the system:—metal | oxide | KOH | oxygen at atmospheric pressure | platinum, leads to the equation

$$\Pi = (L_m/c_m)^{1/n} \cdot (L_0/c_0)^4,$$

where Π is the dissociation pressure of the metallic oxide, n the valency of the metal, L_m and L_0 the electrolytic solution pressures of the metal and oxygen, c_m and c_0 the concentrations of the metal and hydroxyl ions respectively. When the solution is saturated with oxide, the product $c_m^{1/n} \cdot c_0 = \text{const.}$, so that the dissociation pressure of an oxide depends, not only on the electrolytic solution pressure of the metal, but also on a constant peculiar to the oxide. In general, however, the order of affinity of metals for oxygen will be determined by their electrolytic solution pressures.

The E.M.F. of the combination Pt | O₂ | NaOH | HgO | Hg is 0.159 volt; from this value, with the equation $E = RT \log_e \Pi$, the dissociation pressure Π of mercuric oxide is calculated to be $10^{-8.08}$ mm. of mercury at ordinary temperatures; this does not agree with the value calculated from Pélabon's numbers (*Abstr.*, 1899, ii, 423) and the heat of formation of mercuric oxide.

A theoretical connection is established between the dissociation constant of a gas and the electrolytic solution pressures of its components; thus it is shown that the dissociation of hydrogen iodide can be calculated from the electrolytic dissociation of aqueous hydriodic acid, Henry's partition coefficients, and the electrolytic solution pressures of hydrogen and iodine. The author urges investigation of the relation between various equilibrium constants, and advocates the use of ergo-chemical equations. J. C. P.

A New Kind of Transition Element. By ERNST COHEN (*Proc. K. Akad. Wetensch. Amsterdam*, 1899, 2, 153—158; *Zeit. physikal. Chem.*, 1899, 30, 623—627).—Although below 20° the grey modification of tin is the stable one, yet the white modification may be supercooled, and an element may accordingly be constructed of the form:—Electrode of grey tin | Solution of a tin salt | Electrode of white tin. The E.M.F. will be $0.0001983 \frac{T}{n} \log_{10} \frac{P_g}{P_w}$ volt for this element where n is the valency of the tin, P_g and P_w the electrolytic solution pressures of the grey and white modifications respectively. Actual measurement of the E.M.F. showed that the ratio P_w/P_g was 1 at 20°, the transition temperature, and >1 at temperatures below 20°. Thus the white modification has the greater electrolytic solution pressure, and will precipitate grey tin from solutions of tin salts below 20°, a conclusion confirmed by experiment. This explains why a

solution of a tin salt is highly favourable to the conversion of the white into the grey modification.

When E_1 is the difference of potential between the grey tin and the tin solution in which it is immersed, i_1 the heat of ionisation of the grey tin, and $e_0 = 96540$ coulombs, then $E_1 = i_1/ne_0 + T.dE_1/dT$: a corresponding relation holds for the other electrode. Combining these with the equation $T.dD/dT = r_1/(V_w - V_g)$, where D is the external pressure, r_1 the heat evolved when 1 kilogram of white tin is converted into grey tin, V_w and V_g the volume in cubic metres occupied by 1 kilogram of the white and grey modifications, the author deduces the equation $dT/dD = 0.00105 A(V_w - V_g)/n(dE_1/dT - dE_2/dT)$, A being the atomic weight of the metal forming the electrode. J. C. P.

Theory of the Transition Cell of the Third Kind. By ERNST COHEN (*Proc. K. Akad. Wetensch. Amsterdam*, 1899, 2, 334—342. Compare Abstr., 1898, ii, 276).—The general type of this transition element consists of two cells coupled in opposition—(a) electrode reversible with respect to the anion | saturated solution of a salt S in contact with the stable solid phase of the salt | electrode reversible with respect to the cation, and, (b) electrode reversible with respect to the anion | saturated solution of the salt S in contact with the metastable solid phase of the salt | electrode reversible with respect to the cation; S, for example, may be zinc sulphate, the transition temperature of the hydrates $ZnSO_4 \cdot 7H_2O$ and $ZnSO_4 \cdot 6H_2O$ being 39° . The temperature coefficient of this transition element at 39° is calculated in the following way. Differentiation of the equation $E = q(P - T)/P$, leads to $dE/dT = -q/P$, where E is the E.M.F. of the element, q the heat effect of the change involved, and P the absolute transition temperature of the change; q is calculated by extrapolation from Thomsen's figures, and also determined experimentally, leading to dE/dT at $39^\circ = -0.51$ millivolts. From Jaeger's values (compare Abstr., 1898, ii, 202) for the E.M.F. of Clark cells containing solid $ZnSO_4 \cdot 7H_2O$ or $ZnSO_4 \cdot 6H_2O$, it may be shown that dE/dT at $39^\circ = -0.55$ millivolts, agreeing well with the calculated coefficient.

The solubilities of both hydrates of zinc sulphate have been determined at temperatures between -5° and 39° , and results obtained agreeing closely with those of Callendar and Barnes (Abstr., 1898, ii, 276). J. C. P.

Alleged Identity of Red and Yellow Mercuric Oxides. I. By ERNST COHEN (*Proc. K. Akad. Wetensch. Amsterdam*, 1899, 2, 273—281).—The E.M.F. of the system mercury | red mercuric oxide in caustic potash | yellow mercuric oxide in caustic potash | mercury has been very carefully determined by comparison with a standard cell at 25° . To begin with, the E.M.F. was 0.585 millivolt, but it increased to a maximum of 1.237 millivolts in about 24 hours, falling thereafter, and reaching a constant value, 0.685 millivolt, after 170 hours. When the oxides were previously shaken with water to remove soluble matter, and left in contact with the aqueous caustic potash before being put in the cell, the E.M.F. was constant from the first, and equal to 0.685 millivolt. It thus appears that red and yellow mercuric oxides are isomeric, contrary to Ostwald's view (*Zeit. physikal.*

Chem., 1895, 18, 159). The author's results are also at variance with those of Glazebrook and Skinner, according to whom a difference of 7 millivolt exists at 12° between the E.M.F. of Gouy standard cells made with the two oxides (*Phil. Trans.*, 1892, 183, 367). J. C. P.

Metallic Crystallisation by Electrical Transport of Certain Metals in Distilled Water. By THOMAS TOMMASINA (*Compt. rend.*, 1900, 130, 325—327).—When an electric current of less than 1 milli-ampère is sent through flat zinc electrodes placed in distilled water, the electrodes being very close to each other, well defined crystals of metallic zinc are deposited. At first, no gas is evolved, but after the action has been going on for some time, there is an evolution of gas from the cathode, the electrodes become oxidised, and the deposition of the metal ceases. If the anode is removed, cleaned, and then replaced, the action begins again. With a copper plate as cathode, and a zinc anode, crystals of zinc are deposited on the copper. Similar results were obtained with silver and cadmium. If the two electrodes are too widely separated, then a kind of haze appears between them; this contains very small, metallic crystals, which are arranged in a chain-like form. H. R. LÆ S.

Polarisation Phenomena observed in Quantitative Electrolytic Determinations. By HUGH MARSHALL (*Proc. Roy. Soc. Edin.*, 1899, 22, 532—538).—Attempts have been made to determine the time necessary for the complete electrolytic deposition of nickel, with varying current strengths, and different quantities of metal. With a cathode current density of 0.6—0.7 ampère per sq. decim., the time required for the deposition of 0.1—0.5 gram nickel was found to be 4 hours; the volume of the solution was 135 c.c., and it contained 5 grams each of ammonium sulphate and ammonia. In certain cases, the voltmeter showed a rise of 0.5 volt towards the end of the operation, and precisely in these cases was the deposition of the nickel complete. This rise of potential may, in fact, be taken as an indication that all the nickel has been deposited, as is shown by a number of test experiments.

The removal of the last traces of nickel from the solution is thus accompanied by an increased resistance between the electrodes. Experiment shows that, when the potential begins to rise, only 2—3 mg. of nickel remain in solution. When small quantities of nickel have to be estimated, it is advisable to use a small volume of solution and a small vessel, in which case the rise of potential above referred to is more marked and rapid. It remains to be seen whether this polarisation effect, probably due to a film on the cathode, can be trusted to appear in all cases. J. C. P.

Electrolytic Reduction of Potassium Chlorate. By ADOLPH L. VOOGH (*J. Physical Chem.*, 1899, 3, 577—601).—The investigations were made with the object of collecting data to serve as basis for a theory of electrolytic reduction. Electrolysis in acid and alkaline solutions showed that the percentage quantity of hydrogen used in the reduction is greater in the former than in the latter, and is, moreover, a function of the current, decreasing with increasing current density.

In the further experimental work, solutions in dilute sulphuric acid were chiefly used. The reduction varies with the metal employed as electrode, and was greater for zinc than for platinum, being also dependent on the physical structure; in the case of cadmium, the reduction efficiency did not alter with varying current density, so that this metal is less efficient than zinc for weak currents, but more efficient for strong currents. The effect of the acid concentration was determined, and it was found that the maximum efficiency was obtained for acid about $3/4$ normal, the potassium chlorate being about $1/2$ concentrated at 64° . Rise of temperature causes an increase of efficiency, the reduction being increased from 52 to 90 per cent. by a rise of from 25.6° to 81.1° . Potassium chloride was usually found in the anode liquid, but this was due entirely to diffusion from the cathode liquid, and not to any anodic reduction. A greater reduction than that due to the electrolytic hydrogen is sometimes obtained, this being most probably caused by the secondary action of the zinc on the potassium hydroxide, produced at the cathode, with the consequent formation of potassium zinc-oxide and hydrogen. Copper was found to readily dissolve in the acid solution of potassium chlorate, with no evolution of hydrogen, but with a 98 per cent. yield of potassium chloride; the electrolytic reduction with copper electrodes, however, is not as great as in the case of zinc electrodes.

L. M. J.

The Dilution Law. By WILDER D. BANCROFT (*Zeit. physikal. Chem.*, 1899, 31, 188—196).—The empirical formula $K = C_i^n/C_u$ is suggested as a general expression of the dilution law, where C_i and C_u are the volume concentrations of the dissociated and undissociated portions respectively; K and n vary for different electrolytes. By using Kohlrausch's numbers for ten strongly dissociated salts, and plotting $\frac{1}{2}\log C_i$ along one axis, and $\frac{1}{2}\log C_u$ along the other, the author shows that the curve obtained for each electrolyte is a straight line, and that n may be calculated in each case from the pitch of the curve; K may then be calculated for each dilution, and from the mean of the values so found the degree of dissociation which satisfies the equation $K = C_i^n/C_u$ may be calculated and compared with the observed value. A remarkably good agreement is obtained, except in the case of the most concentrated solutions; n varies from 1.36 for potassium chloride to 1.55 for silver nitrate. It is suggested that the generalised dilution law may give more accurate values for the dissociation in concentrated solutions than can be obtained from conductivity determinations.

J. C. P.

Molecular Susceptibility of the Salts of the Rare Earths. By STEFAN MEYER (*Ber.*, 1900, 33, 320—321. Compare du Bois and Liebknecht, this vol., ii, 127).—The author's values for the molecular magnetism of the series praseodymium, neodymium, samarium, gadolinium, and erbium, derived from a study of their dry compounds, indicates that their susceptibility coefficients have the following relative values: Pr : Nd : Sa : Gd : Er = 2 : 5 : 10 : 23 : 40, whilst from the data furnished by du Bois and Liebknecht from their determinations of the atomic magnetism in solutions of the salts of the rare earths, the following ratio is obtained: Pr : Nd : Sa : Gd : Er =

3:5:12:26:37. The discrepancy in the two series is probably due to the variable quantities of impurities present in the substances under examination, the paramagnetism of yttrium and ytterbium, for example, being almost certainly due to the presence of other elements.

G. T. M.

Molecular Susceptibility of the Paramagnetic Salts of the Iron Group. By OTTO LIEBKNECHT and A. P. WILLS (*Ber.*, 1900, 33, 443—445. Compare this vol., ii, 127).—Determinations of the magnetic susceptibility of 36 salts of the metals chromium, manganese, iron, cobalt, nickel, and copper have been made, and the results are indicated in tabular form. The salts of cobalt are placed next to those of iron on account of the close relationship existing between the magnetic properties of these elements, whether free or combined. When the series is arranged in this order, the molecular susceptibility attains its maximum at iron and manganese and falls to its minimum at copper. The susceptibility of the complete series of halogen salts was determined in the case of bivalent manganese, cobalt, and nickel; it was found to increase from the fluoride to the chloride and then fall to a minimum value for the iodide.

G. T. M.

Electrolytic Dissociation of Certain Salts in Methyl and Ethyl Alcohols, as Measured by the Boiling Point Method. By HARRY C. JONES (*Zeit. physikal. Chem.*, 1899, 31, 114—141).—In the various forms of boiling point apparatus, there are two defects: (1) too little attention is paid to the effect of radiation, (2) the condensed solvent is returned directly into the boiling liquid. An apparatus, resembling in some respects that of Hite (*Abstr.*, 1895, ii, 479), has been devised and used by the author, in which a cylinder of platinum foil is placed between the thermometer and the walls of the boiling tube; this reduces the effect of radiation, and prevents the condensed solvent coming in contact with the thermometer before it is reheated. The boiling tube is surrounded by an asbestos jacket, and rests on a piece of wire gauze, which is directly heated by the flame.

With this comparatively simple apparatus, the author has studied the effect of various dissolved substances on the boiling points of methyl and ethyl alcohols. Determinations with acetanilide, acetamide, diphenylamine, and triphenylmethane gave a mean value of 8.4 for the boiling point constant of methyl alcohol. Experiments then made with dissociating inorganic compounds allowed the degree of dissociation to be determined. The bromides and iodides of potassium and ammonium are dissociated to the extent of about 50 per cent., whilst the dissociation of sodium bromide and iodide is greater. Potassium and sodium acetates are dissociated to about 37 per cent., calcium nitrate to about 14 per cent. Most of the solutions contained 1/100th—1/50th of the molecular weight per 100 grams of solvent.

Generally, similar results were obtained with ethyl alcohol as solvent. The following degrees of dissociation were determined: potassium iodide 25—27 per cent., sodium iodide 31—33 per cent., sodium bromide 26—27 per cent., ammonium bromide 20—21 per

cent., sodium and potassium acetates 13—15 per cent., calcium nitrate 4—5 per cent.

Comparison of the dissociation of various inorganic compounds in water, methyl alcohol, and ethyl alcohol leads to the conclusion that there is not a proportionality between the dielectric constants of these solvents and their dissociating power, although the dielectric property seems to be the chief factor concerned. Other solvents with high dielectric constants, such as formic acid, allyl alcohol, acetone, nitrobenzene, *o*-nitrotoluene, will have to be investigated in order to settle the point satisfactorily.

J. C. P.

Specific Heats of some Organic Substances. By GUSTAVE FLEURY (*Compt. rend.*, 1900, 130, 437).—The specific heats of some dry clothing materials were determined, with the following results: cellulose, 0.366; wool, 0.393; leather, 0.357. In the ordinary moist state, these substances contain 7, 11, and 16 per cent. of water respectively, and the specific heats are: cellulose, 0.41; wool, 0.459; leather, 0.45.

N. L.

Atomic Weights and Physical Properties. By THOMAS BAYLEY (*Chem. News*, 1899, 80, 282).—The product of melting point (absolute) and coefficient of linear expansion has a nearly constant value 0.02 for certain elements. The value of α in the equation (specific heat) \times (melting point) = α (atomic weight) is given for a number of elements.

J. C. P.

Change in the Transition Point of Ammonium Nitrate at 32° through addition of Potassium Nitrate. By WOLF MÜLLER (*Zeit. physikal. Chem.*, 1899, 31, 354—359).—If t_0 and t_1 are the transition temperatures of ammonium nitrate before and after addition of potassium nitrate, and c is the molecular concentration of potassium nitrate in 100 grams of ammonium nitrate, the molecular depression of the transition point is $(t_0 - t_1)/c$; this molecular depression diminishes as the concentration of potassium nitrate increases, and the change takes place according to Rothmund's equation $t_0 - t_1 = RT^2/q \cdot (c_2 - c_1)$, where T is the absolute transition temperature of pure ammonium nitrate, c_2 and c_1 the molecular concentrations of potassium nitrate in 100 grams of the two modifications of ammonium nitrate, and q the heat of transition (compare Abstr., 1898, ii, 158). The results obtained seem to show that the transition of ammonium nitrate at 32° consists in a change of quadruple into triple molecules.

J. C. P.

New Method of Determining Transition Temperatures. By ERNST COHEN (*Zeit. physikal. Chem.*, 1899, 31, 164—175).—Systems which pass into each other are equally soluble at their transition temperatures. By measuring at various temperatures the electrical resistance of saturated solutions of the stable and metastable modifications, two curves are obtained connecting temperature and resistance, and these curves cut each other at the temperature of transition. An apparatus is described in which the preparation of the saturated solution and the measurement of the resistance can be conveniently made. The application of the method to the systems $\text{ZnSO}_4 + 7\text{H}_2\text{O}$ and $\text{ZnSO}_4 + 6\text{H}_2\text{O}$ gave for the transition temperature 39°, in agreement with the values obtained by other methods (Abstr., 1898, ii, 276;

this vol., ii, 184). The metastable form below 39° , $\text{ZnSO}_4 + 6\text{H}_2\text{O}$, is obtained by covering a solution saturated about 60° with a layer of paraffin oil, and allowing it to cool very slowly in a large water-bath.

The method is also employed for determining the resistance of a saturated copper sulphate solution at various temperatures; the curve connecting temperature and resistance shows in this case a slight discontinuity at 56° . A Daniell cell, in which a saturated copper sulphate solution is combined with a 5 per cent. zinc sulphate solution, shows a discontinuity in the E.M.F. curve at the same temperature. The author criticises Preece's (*Proc. Roy. Soc.*, 1883, 35, 48) and Carhart's experiments on the internal resistance of the Daniell cell.

J. C. P.

Partial Association of Liquid Molecules. By J. J. VAN LAAR (*Zeit. physikal. Chem.*, 1899, 31, 1—16).—A thermodynamical treatment of the subject with a number of involved calculations. The equation $(\text{H}_2\text{O})_2 \rightleftharpoons 2\text{H}_2\text{O}$ represents the equilibrium between the simple and double water molecules, and the association is accompanied by the absorption of 1930 cal. per 18 grams at 0 – 60° . For ethyl alcohol, a similar equation holds, whilst methyl alcohol and acetic acid are to be regarded as consisting partly of triple molecules.

The change of 18 grams of simple water molecules into double molecules is accompanied by an expansion of 8.44 c.c., the corresponding expansion for 46 grams of ethyl alcohol being 2 c.c.; the contraction which occurs in mixing water and ethyl alcohol therefore points to a decrease in the number of associated molecules. It is further shown that the partial association of the molecules explains the irregular thermal expansion of water.

J. C. P.

[Negative Heat of Formation of Alloys of Zinc and Copper]. By ALEXANDER GALT (*Proc. Roy. Soc. Edin.*, 1899, 22, 137—149 and 619—621).—By determining the heat of solution in dilute nitric acid of a powdered alloy and of a mixture of the two component metals in the same proportion, the heat of formation of the alloy may be ascertained. Copper-silver alloys shows little or no heat of formation. Copper-zinc alloys containing more than 30 per cent. of copper have a considerable positive heat of formation, but if the percentage of copper is less than 30, the heat of formation is negative.

J. C. P.

[Thermochemistry of] the Uric Acid Series. By MARCELLIN P. E. BERTHELOT (*Compt. rend.*, 1900, 130, 366—372).—The following determinations were made with the object of ascertaining the thermal effect of oxidation and methylation in the uric acid series.

Substance.	Heat of combustion.		Heat of formation.
	At constant volume.	At constant pressure.	
1-Methylpurine	820.88 Cal.	820.60 Cal.	- 47.74 Cal.
7-Oxypurine	583.57 "	582.69 "	+ 26.86 "
2-Oxypurine	592.47 "	591.59 "	+ 17.96 "
1-Methyl-7-oxypurine	760.08 "	759.49 "	+ 18.37 "

A comparison of these figures with the results previously obtained for xanthine (Abstr., 1899, ii, 400) shows that the conversion of 7-oxypurine (hypoxanthine) into xanthine and uric acid by the successive fixation of oxygen develops 69.8 Cal. and 51.4 Cal. respectively; from the former figure, the heat of formation of purine itself is calculated as -44 Cal. The decreasing development of heat for successive additions of oxygen is in accord with the results obtained in the indole series (*loc. cit.*). The conversion of hypoxanthine into 1-methylhypoxanthine is accompanied by the absorption of 13.5 Cal., instead of by the development of 5-6 Cal. as is commonly the case with homologous compounds; the difference between the heats of combustion (176.8 Cal.) is also greater than the normal (157 Cal.). Methylation is therefore accompanied by an increase in the energy of the system, just as is the case with the three methylxanthines, and Matignon's observations as to the anomaly exhibited by compounds in which the methyl group is directly united to nitrogen are confirmed. By deducting from the heat of formation of methylpurine the difference between the corresponding figures for hypoxanthine and methylhypoxanthine, the heat of formation of purine is found to be -34.2 Cal. as against the value -44 Cal. deduced above from the oxidation phenomena. N. L.

Heat of Dissociation of Violuric Acid and of Water. By RICHARD ABEGG (*Ber.*, 1900, 33, 393-394).—Guinchard has shown (Abstr., 1899, i, 781) that the dissociation constant of violuric acid increases rapidly as the temperature rises; from his values, the heat of dissociation can be calculated by van't Hoff's formula, the mean value being about -3700 Cal. This is about 10 times as great as the values obtained with acetic and other weak acids, and confirms the view that the ionisation is accompanied by an (endothermic) isomeric change.

In a similar way, the high value of the heat of dissociation of hydrogen fluoride (-3550 Cal.), when compared with hydrogen chloride (-1080 Cal.) and hydrogen bromide (-1617 Cal.), is an indication that the ionisation is accompanied by the dissociation of H_2F_2 into $2HF$.

The heat of dissociation of water into the ions H^+ and OH^- is very large, amounting to -13000 Cal., and this is regarded as due in part to its high association factor, the complex molecules $(H_2O)_x$ being broken down into xH_2O in the ionisation. T. M. L.

Antimony Trichloride in Cryoscopy. By STANISLAW TOLLOCZKO (*Zeit. physikal. Chem.*, 1899, 30, 705-710).—According to the views of Brühl (Abstr., 1899, ii, 10), the dissociating power is due to incomplete saturation of the solvent, and if so, marked dissociation should be found for solutions in antimony trichloride, a compound which, owing also to its convenient freezing point, is well adapted for cryoscopy. The cryoscopic constant was found to be 184 by determinations of the depressions produced by xylene, anthracene, diphenylmethane, acetophenone, and benzophenone; this high constant, ten times that of water, indicates a latent heat of fusion of 12.9 cal. With potassium chloride and potassium bromide, indications of consider-

able dissociation were obtained, increasing with dilution, the value 0.69 being obtained for the bromide at a concentration of about 0.2 per cent. Brühl's views have hence, in this case, been confirmed (see, however, Kahlenberg and Lincoln, *Abstr.*, 1899, ii, 397). The author points out the suitability of the substance as a solvent for cryoscopic determinations of the molecular weight of organic compounds, which are for the most part soluble in it.

L. M. J.

Real and Apparent Freezing Points and Cryoscopic Methods. By MEYER WILDERMANN (*Zeit. physikal. Chem.*, 1899, 30, 577—585. Compare *Abstr.*, 1896, ii, 290).—The paper, much of which has been previously published, is essentially a recapitulation of the errors inherent in freezing point determinations. Even if the instruments are absolutely accurate, and if no accidental extraneous errors exist, the freezing point observed is not the true freezing point, but a temperature dependent on the velocity of precipitation or of melting of the ice, the rate of cooling, and the variation from the convergence temperature. Identity of results obtained under similar conditions is thus no indication that these yield the true temperatures desired, so that repetition of experiments leads to no final accuracy. As the errors are functions of the temperature, the observed depressions are also inaccurate, and it is only by determining the magnitude of each effect, and correcting for it, that really trustworthy determinations of freezing points and cryoscopic depressions can be obtained. Examples are given where neglect of this may lead to errors of 6 to 12 per cent. The same reasoning applies also to determinations of boiling points and other constants, but these are not further considered (compare this vol., ii, 131).

L. M. J.

Thermokinetic Properties of Solutions. By LADISLAUS NATANSON (*Zeit. physikal. Chem.*, 1899, 30, 681—704).—A purely mathematical paper, in which the author discusses, from a thermodynamical standpoint, a system consisting of a mixture separated from a pure substance, but in which the passage of one component in either direction is permitted. When the pure substance is one component of the mixture, the case reduces to one of a solvent separated from a solution by a semipermeable partition, and two values are deducible for the osmotic pressure, according to the component which is regarded as the solvent. In a solution, therefore, there are two osmotic pressures and it should not be impossible in certain cases, as for two miscible liquids, to experimentally verify this.

L. M. J.

Liquefaction of Gaseous Mixtures. By F. CAUBET (*Compt. rend.*, 130, 167—169).—Curves representing the tension of saturated vapour against temperature are given for methyl chloride, carbon dioxide, and ten different mixtures of these compounds, the determinations being carried to the critical temperature; the tangent to each curve at its critical point forms the critical line for these mixtures. Retrograde condensation is observed under those conditions represented by the portion of each curve to the right of the critical ordinate, the most favourable conditions for the observation of the

phenomenon being when this portion is greatest. In the mixtures examined, this is the case for those containing 32.2 and 40.4 per cent. of methyl chloride, where it occurs within temperature limits of 5°. Where comparable, the results are in good accord with those of Kuenen, as is seen by the comparison of the author's results for the mixture containing 59 per cent. methyl chloride with Kuenen's results for the mixture containing 61 per cent. of the same compound.

L. M. J.

Deviations from Boyle's Law of Mixtures of Hydrogen and Carbon Dioxide. By J. E. VERSCHAFFELT (*Zeit. physikal. Chem.*, 1899, 31, 97—102).—For mixtures of hydrogen and carbon dioxide, the author finds that the values of the coefficient m_1 in the equation: $pv = RT + m_1/v + m_2/v^2 +$, &c., can be calculated from the formula: $m_1 = 0.00074x^2 - 0.0012x(1-x) - 0.0063(1-x)^2$, where x represents the ratio of the number of hydrogen molecules to the total number of molecules of the mixture. The experimental numbers for m_1 show good agreement with the calculated values.

At 18°, mixtures of these gases obey to the second approximation the law: $pv = 1.067 + m_1/v = 1.067(1 + 1/v \cdot m_1/1.067)$; the expression within the brackets, which is equal to $1.00069x^2 + 1.9989x(1-x) + 0.9941(1-x)^2$, is greater than unity for hydrogen (that is, when $x=1$) less than unity for carbon dioxide ($x=0$), and equal to unity for the value $x=0.795$. So that for a mixture of composition represented by this value of x , Boyle's law is obeyed to the second approximation.

T. H. P.

Determination of Vapour Density under Arbitrary Pressure. II. By OTTO BLEIER and LEOPOLD KOHN (*Monatsh.*, 1899, 20, 909—925. Compare Abstr., 1899, ii, 643).—Several improvements in this method are announced. Instead of an air-pump, it is now recommended that a mercury pump should be used, so that the determination may be started under a pressure of only 2—3 mm. The bulb in which the vaporisation of the substance takes place should be of 400—500 c.c. capacity. Determinations can be carried out in which the increment of pressure is only about 5 mm. Such small increments of pressure are not conveniently measured by means of the manometer previously described (*loc. cit.*), which is replaced by the special form of differential manometer here figured. It is filled with paraffin oil instead of mercury, so that the "difference" on the manometer is about 17 times as great as

it would be were mercury used and can be easily read off by the unaided eye. The upper end of this manometer is attached to a large flask which is provided with two stopcocks and an ordinary manometer and acts as a "vacuum reservoir." Determinations are carried out as follows: The substance is first placed in the neck of the bulb, which is then

heated in the required bath. The apparatus, with the stopcock of the manometer open, is then exhausted by the pump till the required diminution of pressure is obtained. The stopcock of the manometer is then closed and that of the vacuum reservoir opened (this reservoir having been previously exhausted). The substance is allowed to fall into the bulb and the "increment" of pressure occasioned by its vaporisation is directly read off after an interval of not more than 4 minutes. The air is let into the apparatus again by means of a slit in the stopcock between the "reservoir" and the manometer, which in one position allows air to pass into the manometer, but not into the "reservoir."

This procedure further appears to afford a means of determining whether a substance undergoes dissociation, for in such cases the increment of pressure is only slowly, whilst in normal cases it is rapidly (1—4 min.), shown.

The results of the large number of determinations quoted, using baths of water, toluene, xylene, and aniline, all agreed with the theoretical value to within 2 per cent.

New Pyknometer for the Determination of the Specific Gravity of Light Liquids. By HEINRICH GÖCKEL (*Zeit. angew. Chem.*, 1899, 1194—1195).—This is a pyknometer bulb, sealed to a massive glass foot, which supports the instrument in an upright position when placed in water in order to acquire a definite temperature. L. DE K.

Molecular Volume of Camphor Derivatives. By ALBIN HALLER and PAUL TH. MÜLLER (*Compt. rend.*, 1900, 130, 221—224. Compare Abstr., 1899, i, 622, and this vol., i, 182).—The molecular volumes of a series of camphor derivatives dissolved to a $N/4$ solution in toluene were obtained by direct experiment and by the employment of the following expression: $V = \bar{M} + S/d - S/d'$, where \bar{M} , is the molecular weight of the compound, S the weight of solvent containing one molecular proportion of the dissolved substance, and d and d' the specific gravities of the solution and solvent respectively. These constants may also be calculated from Traube's formula, $V = \Sigma a - N - L + C$, where N is a coefficient depending on the number of hexamethylene rings in the molecule, L a coefficient proportional to the double linkings, C the co-volume, and Σa the sum of the atomic coefficients. It is found that the calculated values are always greater than those obtained by experiment, the difference being the sum of the decrements due to the closed chains other than hexamethylene rings present in the molecule.

In the case of methyl camphorate which contains one additional ring, the decrement is 17.6, whilst with camphor, borneol, methyl camphor-carbonate, benzylidenecamphor, benzylcamphor and their homologues, the mean value of the decrement due to two camphor nuclei is 23, the extremes being 20.6 and 25.4. Piperonylidenecamphor and piperonylcampmor contain, in addition to the camphor nuclei, an additional piperonylic ring; this increases the decrement by 6 units, the mean value of this coefficient being 29.

Bornyl succinate contains two camphor residues, and the decrement

is 33.2; this result indicates that the effect produced by four closed chains is not double that produced by two, and therefore the law of the addition of nuclear decrements is not absolutely general. G. T. M.

Surface Tension of Organic Liquids. By PAUL DUTOIT and LOUIS FRIDERICH (*Compt. rend.*, 1900, 130, 327—330. Compare Abstr., 1899, ii, 350).—The following values of k , the temperature coefficient of molecular surface energy, were determined by the method of Ramsay and Shields:

m-Xylene, 2.20; mesitylene, 2.15; durene, 2.14; pentamethylbenzene, 2.165; aniline, 1.60—2.05; methylaniline, 1.99—2.08; ethylaniline, 2.22; dimethylaniline, 2.39; diethylaniline, 2.34; *o*-toluidine, 2.05; *p*-toluidine, 1.72; dimethyl-*o*-toluidine, 2.53; diphenylamine, 2.57; acetonitrile, 1.50—1.56; propionitrile, 1.67—1.74; butyronitrile, 1.89; *p*-toluonitrile, 1.88—2.05; hexane, 2.11; diphenyl, 2.22; naphthalene, 2.29; acenaphthene, 2.31; diphenylmethane, 2.25; *s*-diphenylethane, 2.49; pyridine, 2.17; quinoline, 2.43; acetone, 1.83; methyl ethyl ketone, 1.85; acetophenone, 2.14; benzophenone, 2.63.

The following conclusions are drawn: (1) the value of k varies with the temperature for abnormal liquids, but not for normal liquids; (2) for normal liquids, the value of k is not constant, but varies within limits the range of which is greater than was formerly supposed.

H. R. Ls S.

Nernst's Osmotic Experiment and a Definition of Osmotic Pressure. By A. CRUM BROWN (*Proc. Roy. Soc. Edin.*, 1899, 22, 439—440).—An osmotic cell of Nernst's type (Abstr., 1890, 1365) may be formed with three liquid layers as follows: (1) water + phenol + calcium nitrate, (2) phenol + water, (3) water + phenol. If (1) is lowermost, and (2) lies above it, then the layer (2), being impermeable for calcium nitrate, gradually rises as water diffuses from (3) to (1).

If two partially miscible liquids A and B are shaken up under the pressure p , and a given solution of a substance N in A is shaken up with B under the pressure p' , the solutions of A in B formed in the two cases will have the same concentration if $p' - p$ is equal to the osmotic pressure.

J. C. P.

Theory of Diffusion. By OTTO WIEDEBURG (*Zeit. physikal. Chem.*, 1899, 30, 586—592).—The author criticises certain tacit assumptions in Bose's paper on the "Theory of Diffusion" (Abstr., 1899, ii, 729), and deduces other expressions. For sufficiently low concentrations, these reduce to one previously obtained empirically, $D = D_0(1 + \gamma c)$, where D_0 and γ are constants, the latter being capable of positive or negative values as the diffusion coefficient may either decrease or increase with dilution. The value for D_0 is $RT.2uv/u + v$, where u and v are the velocity of anion and cation respectively; γ has the value $2/k \cdot \{w \cdot (u + v) / 2uv - 1\}$ where w is the velocity of the undissociated molecule and k the dissociation constant. When γ and k are small, therefore $1/w = \frac{1}{2}(1/u + 1/v)$ and is otherwise calculable where the other constants are known. The values of w and of D_0 are so

calculated for copper sulphate, but the results do not agree with those obtained by extrapolation from measurements of the diffusion.

L. M. J.

Osmotic Pressure of Concentrated Solutions. By THOMAS EWAN (*Zeit. physikal. Chem.*, 1899, 31, 22—34).—When P is the osmotic pressure at the temperature T of a solution of 1 gram of sucrose in m grams of water, thermodynamical considerations lead to the relation:— $Pv_0/JT = W_0(1/F - 1/T_0) - c/2.(T_0 - F)^2/F^2 - dQ_T/dm.(1/F - 1/T) + C_L/2.(T - F)^2/F^2$, where v_0 is the increase of volume accompanying dilution, J the mechanical equivalent of heat, F the freezing point of the solution, W_0 the latent heat of fusion of water at its freezing point T_0 , c the difference between the specific heats of water and ice, dQ/dm the heat of dilution, and C_L the temperature coefficient of the heat of dilution.

The freezing points of several sucrose solutions containing from 30—70 grams of sucrose per 100 grams of water have been carefully determined. The molecular depressions obtained are satisfactorily given by the equation $t/g.342 = 18.58 + 0.97t$, where t is the depression of the freezing point in a solution containing g grams of sucrose in 100 grams of water. The formula gives values about 1 per cent. smaller than those of Raoult (*Abstr.*, 1899, ii, 203).

As regards the heat of dilution, it is found that if Q be the heat developed when a solution of 1 gram of sucrose in 0.6051 gram of water is diluted until it contains m grams of water to 1 gram of sucrose at about 14° , $Q = 1.25(m - 0.6051)/(0.6 + m)$, whence $dQ/dm = 1.506/(0.6 + m)^2$. Equations are also given for calculating the temperature coefficient of dQ/dm and v_0 .

Of various empirical formulæ representing $(dP/dT)_r$ as a function of the concentration, the most satisfactory was found to be $(dP/dT)_r = R/[V - (V - nM_0v_0)/m]$, where V is the volume of solution containing 342 grams of sucrose and nM_0 grams of water; nM_0v_0 is the increase of volume that would occur if nM_0 grams of water were added to the solution without appreciably changing its concentration. $V - nM_0v_0$ is a measure of the volume occupied by the sucrose, and experiment shows it to be nearly constant: the quantity $(V - nM_0v_0)/m$ corresponds with the b of van der Waals's equation.

On the supposition that the dissolved substance does not polymerise or dissociate, an expression is obtained for calculating the molecular weight from the freezing point depression in a concentrated solution; with this expression, values are obtained for the molecular weight of sucrose not differing greatly from 342.

J. C. P.

Hydrates in Solution. By WILDER D. BANCROFT (*J. Physical Chem.*, 1899, 3, 551—554).—Nernst, in his "Theoretische Chemie," considers only very briefly the case in which the solvent actually takes part in the reaction, and there deduces that, in a dilute solution, the percentage of the hydrated substance is independent of concentration. This, however, only holds when no secondary electrolytic dissociation takes place, and the author therefore extends the case to hydrated salts. If A be the total concentration of the salt, c that of the water, x the anhydrous dissociated salt, and y the amount of dissociated salt,

the equilibrium equations are (for a binary salt) $Kx/v = (y/v)^2$ (1); $K_1(A - x - y)/V = x/v \cdot (c/v)^n$ (2); hence by regarding c/v as constant, that is, for dilute solutions, is obtained $K_2(A - x - y)v = (y/v)^2$ (3), from which follows a decrease of hydration by dilution, so that hydrated salts are decomposed by water. By combination of (1) and (3), with elimination of x , there results $K_3(A - y)/v = (y/v)^2$, which is the ordinary dilution law of Ostwald; so that this law is valid for hydrated salts, and the variations are not accounted for by the assumption of hydrates. Cases are considered also where one ion is hydrated, or where only the hydrated salt is an electrolyte, but no essential difference results.

L. M. J.

Solid Solutions and Isomorphous Mixtures. By GIUSEPPE BRUNI (*Real Accad. Lincei*, 1899, [v], 8, ii, 212—219).—A polemical paper in which Bodländer and Küster's views concerning the different behaviour of solid solutions and isomorphous mixtures are combated.

T. H. P.

Reciprocal Solubility of Liquids. By GIUSEPPE BRUNI (*Real Accad. Lincei*, 1899, [v], 8, ii, 141—149).—The author has studied the mutual solubility of water and methyl ethyl ketone in presence of 1.5 per cent. of alcohol. The curve obtained, which is the section of the dimeric surface by a plane parallel to one side of the triangular diagram, is closed and shows that mixtures of water and methyl ethyl ketone in presence of 1.5 per cent. of alcohol can only form two distinct layers at temperatures lying between $+16^\circ$ and $+148^\circ$. For the upper part of the curve, the diameter parallel to the axis of concentrations is nearly a straight line, whilst for the lower portion this is no longer the case.

The freezing point curve for the same mixture has also been determined and is found to have no point in common with the liquid solubility curve. This has never before been observed with curves representing states of stable equilibrium.

T. H. P.

Solubility of Ethyl Acetate in Aqueous Salt Solutions. By HANS EULER (*Zeit. physikal. Chem.*, 1899, 31, 360—369).—Ethyl acetate is less soluble in salt solutions than in pure water. The equivalent diminution of solubility is represented by the expression $(0.825 - l)/m$, where 0.825 is the solubility (in gram-molecules per litre) of ethyl acetate in pure water at 28° , and l its solubility in a salt solution of the concentration m . The value of this expression has been determined for a number of salt solutions of various concentration, and the results resemble those obtained by Roth for the solubility of gases in salt solutions (*Abstr.*, 1898, ii, 18). Thus the equivalent diminution of solubility increases with the dilution of the salt solution, and when the various salts are arranged according to their values for the above expression, the order is the same whether the dissolved substance be hydrogen, nitrous oxide, or ethyl acetate. Comparison of the results obtained in these three cases shows that the percentage diminution of solubility increases with the solubility of the compound investigated.

J. C. P.

Gibbs' Phase Rule. By C. H. WIND (*Zeit. physikal. Chem.*, 1899, 81, 390—397).—A proof of the phase rule, not suitable for abstraction. The author claims to have arrived at a clear formulation of the phase rule with a minimum of initial hypothesis. J. C. P.

Application of the Phase Rule to Alloys and Rocks. By HENRI LE CHATELIER (*Compt. rend.*, 1900, 130, 85—87).—The successive reversible changes which a mixture of molten solids may experience during cooling at constant pressure, such as solidification, crystallisation, separation of solid phases, &c., must finally lead to a univariant system, in which the number of phases is equal to the number of independent constituents, and as an example the cooling of a molten mixture of iron and carbon is considered. As a natural example, granite is cited; here the independent constituents are three in number—silica, alumina, and potash, whilst three phases are also present, namely, quartz, felspar, and mica. If, in a mass thus obtained, there is present a greater number of phases, then the operations leading to its formation are not reversible and the mass is not in stable equilibrium. The principal cause of such unstable systems is too rapid cooling and in alloys a characteristic is that the properties are very variable and dependent on the conditions of preparation.

L. M. J.

Physical Equilibrium in Mixtures of Isomorphous Substances. By GIUSEPPE BRUNI and F. GORNI (*Real. Accad. Lincei*, 1899, 8, ii, 181—190. Compare Abstr., 1899, ii, 356, and 731).—Freezing point curves have been traced for the following mixtures of isomorphous compounds. (1) *p*-Dichlorobenzene (m. p. 52·7°) and *p*-chlorobromobenzene (m. p. 67·0°). (2) *p*-Dichlorobenzene and *p*-dibromobenzene (m. p. 85·9°). In each of these cases, the gradual addition of the component of higher melting point to the other causes, firstly, a lowering of the freezing point, which afterwards rises, the curves being continuous. (3) *p*-Chlorobromobenzene and *p*-dibromobenzene. In this case, the freezing point rises continuously when the component of higher melting point is added to the other. (4) Azobenzene and dibenzyl. On adding azobenzene to dibenzyl, depression of the freezing point takes place until about 30 per cent. of the former is present, after which the curve runs horizontally for some distance and then rises.

Mixtures of cinnamic and phenylpropionic acids give a freezing point curve similar to that given by most isomorphous mixtures, although these acids have crystalline forms which are in no way simply related.

It is concluded that no difference in kind, but only in degree, exists between the freezing point curves of isomorphous mixtures and those of solid solutions of non-isomorphous substances.

The following crystallographic data, from measurements by G. Boeris, are given. *p*-Dibromobenzene: monoclinic [$a : b : c = 2·6660 : 1 : 1·4179$. $\beta = 67°22'$]. *p*-Chlorobromobenzene: monoclinic [$a : b : c = 2·6077 : 1 : 1·4242$. $\beta = 67°0'$]. Phenylpropionic acid: monoclinic [$a : b : c = 1·6054 : 1 : 0·5552$. $\beta = 78°47'$]. T. H. P.

Equilibrium between Sulphuric Acid and Sulphates in Aqueous Solution. By SYDNEY A. KAY (*Proc. Roy. Soc. Edin.*, 1899, 22, 484—522).—The amount of free acid in a mixed solution of sulphuric acid and a normal sulphate has been determined by measuring the rate of catalysis of ethyl acetate, a correction being applied for the influence of the normal salt on the catalytic action of the acid.

The equilibrium may be represented by an equation of the form $[c_1(1 - \alpha_1)]^{0.85}/[c_2(1 - \alpha_2)] = A/[c_3(1 - \alpha_3)]^x$, where c_1, c_2, c_3 are the total concentrations of sulphuric acid, normal sulphate, and acid sulphate respectively, and α_1, α_2 , and α_3 the corresponding degrees of dissociation; x is equal to unity for potassium sulphate, and has the value 1.35 for sodium and lithium sulphates. The constant A has a characteristic value in each case, and in the expressions involving potassium, sodium, and lithium sulphates has the values 0.259, 0.0618, and 0.060. The expression gives results agreeing well with those actually observed.

J. C. P.

Reciprocal Salt Pairs. II. Equilibrium Phenomena in Presence of a Double Salt. By WILHELM MEYERHOFFER and A. P. SAUNDERS (*Zeit. physikal. Chem.*, 1899, 31, 370—389).—A continuation and expansion of the work recorded in an earlier paper (*Abstr.*, 1899, ii, 410). The change of the system $K_2Na(SO_4)_2 + NaCl + Na_2SO_4 \cdot 10H_2O$ at 16.3°, consisting in a dehydration of the sodium sulphate, is fully considered, and the conditions of existence of hydrated sodium sulphate determined and graphically represented. Distinction is drawn between congruent and incongruent cryohydrates; the former solidify regularly, whether solid is present or not, whilst with the latter, the presence of a certain quantity of solid salt is necessary.

It is pointed out that, in many cases of secondary transition, a better review of the phenomena is secured by the use of van't Hoff's theory than by the application of the phase rule.

J. C. P.

Characteristics of certain Chemical Reactions. By JOHN GIBSON (*Proc. Roy. Soc. Edin.*, 1898, 22, 33—37).—The chemical behaviour of hydrochloric, nitric, and sulphuric acids is shown to differ in several special cases, according as the acid is above or below the strength corresponding with maximum conductivity. The author reviews the general connection between chemical reactions and conductivity, and states as a working hypothesis that the degradation of potential chemical energy is generally associated with molecular rearrangement involving diminished electrical resistance.

J. C. P.

Velocity of Graded Actions. By JAMES WALKER (*Proc. Roy. Soc. Edin.*, 1898, 22, 22—32).—When a reaction takes place in two stages, the theory of mass action in its usual form will be applicable only if one stage of the reaction takes place in a very short time as compared with the other. Otherwise it may be shown that, when the two reactions involved are non-reversible and unimolecular,

$$x = A\{1 + ne^{-nt}/(m - n) + me^{-nt}/(n - m)\},$$

where z is the quantity of the final substance, and m and n are the velocity constants of the two separate reactions. The error introduced by calculating z as if the reaction took place in one stage instead of two, depends, of course, on the relative value of m and n , and for the relation $n = 100m$ is of small account except at the beginning of the action.

J. C. P.

Numerical Laws of Chemical Equilibrium. By OCTAVE BOUDOUARD (*Compt. rend.*, 1900, 130, 132—134).—In a gaseous system in equilibrium there exists at all temperatures and pressures a relation between the concentration of the various gaseous phases which is given by the equation $RT \int L.dT/T^2 + N \log P + \log c_1^{n_1} \dots / C^m C_1^{m_1} \dots =$

constant where L is the heat of reaction, P the total pressure, c, c_1, \dots the concentration of the reaction gases, C, C_1, \dots that of the products, $n, n_1, \dots, m, m_1, \dots$ the numbers of the reacting and produced molecules, and N the sum $n + n_1 + \dots - m - m_1, \dots$. In the case of the system, carbon dioxide, carbon monoxide, and carbon, the final equilibrium does not depend on the initial state between 650° and 800° , and the expression reduces in this case to $-21000/T + \log c/C^2 = \text{constant}$, ($L = 42$ Cals.). From this, the ratios of the concentration of the two oxides at various temperatures are calculated, the agreement of result with experimental determinations being seen in the following table:

Temp.	Carbon dioxide.		Carbon monoxide.	
	Found.	Calc.	Found.	Calc.
650°	0.61	0.61	0.39	0.39
800	0.07	0.10	0.93	0.90
925	0.04	0.03	0.96	0.97

L. M. J.

Kinetics of Reactions with Auxiliary Reactions. By RUDOLF WEGSCHEIDER (*Zeit. physikal. Chem.*, 1899, 30, 593—600).—In the *Lehrbuch der Allgemeinen Chemie*, 2, ii, 247 *et seq.*, Ostwald considers the case of reaction, accompanied by collateral reactions, that is, a reaction in which two distinct sets of products result, but the cases examined are specially chosen as simplified examples, and in each lead to but one differential equation for the reaction velocity. The author considers the case more fully, and shows that in general there are as many differential equations needed as there are collateral reactions. The ratio of the sets of products is also in general a time function, but is constant in those cases in which the left sides of the equations representing the various reactions are identical, and the observation of this constancy is a sufficient proof of this identity obtaining.

L. M. J.

Velocities of Reaction. By ALEXANDRE DE HEMPTINNE (*Zeit. physikal. Chem.*, 1899, 31, 35—41).—Velocity constants are given for the hydrolysis of methyl acetate by mixtures of varying composition of hydrochloric acid and acetone, together with the electrical conductivities of the different mixtures. The velocity constant and the conductivity both decrease as the proportion of hydrochloric acid present decreases, but not to the same degree, the ratio of speed to conductivity increasing. Thus, besides the ionic action, the solvent exerts

further action on the velocity of hydrolysis, and, in the case of acetone this action is catalytic, since acetone has no action either on methyl acetate, or its products of hydrolysis.

In presence of glycerol, neither hydrochloric nor sulphuric acid gives constant velocity numbers for the hydrolysis of methyl acetate; the promotion of the hydrolysis by glycerol depends on the slight affinity the latter possesses for the acetic acid produced. T. H. P.

Velocity of Reaction in Heterogeneous Systems. By HEINRICH GOLDSCHMIDT [with ANTON MISSERSCHMITT] (*Zeit. physikal. Chem.*, 1899, 31, 235—249).—The difficulty of keeping a solution saturated with a slightly soluble substance in a heterogeneous system may be avoided by dissolving the substance in a liquid which does not mix with the solvent used; experience shows that in this case equilibrium is rapidly established between the two solutions.

The author has examined the rate of hydrolysis of ethyl acetate by dilute hydrochloric acid, dissolving the ester in benzene, and shaking the benzene solution with the hydrochloric acid solution. The equation for the velocity constant is $k = 1/t \cdot (v_2 + v_1 C) / v_1 C \log a / (a - x)$, where a is the initial quantity of ester, x the acetic acid formed after time t , v_1 and v_2 the volumes of hydrochloric acid and benzene respectively, and C ($= 0.079$) the partition coefficient of ethyl acetate between water and benzene. The values of k calculated with this equation are fairly constant, but show a tendency to fall with the time. This is accounted for by the action not going completely from left to right of the equation, a small quantity of the ester remaining undecomposed in the benzene. When allowance is made for this, a very satisfactory series of values is obtained for the constant.

A bimolecular reaction, the hydrolysis of ethyl acetate with baryta, has also been studied in a similar way. The velocity constant was found to have the same value as in a homogeneous system, provided the concentrations of the reacting substances were not over $1/20$ th normal. J. C. P.

The Velocity of Reaction before complete Equilibrium and before Transition Points. True meaning of the Law of Chemical Equilibrium of Heterogeneous Systems. Reactions in Heterogeneous Systems. By MEYER WILDERMANN (*Zeit. physikal. Chem.*, 1899, 30, 341—382).—See Proc., 1899, 15, 175.

Influence of Catalytic Agents on the Oxidation of Oxalic Acid Solutions. By W. P. JORISSEN and LODEWYK TH. REICHER (*Zeit. physikal. Chem.*, 1899, 31, 142—163).—The paper contains a full review of investigations hitherto published on the influence of catalytic agents on oxidation generally. Experiments made by the authors show that in diffuse light the oxidation of oxalic acid solutions is accelerated by the presence of iron, chromium, cerium, thorium, and erbium sulphates, sodium fluoride, and manganese sulphate, acetate, butyrate, benzoate, and oxalate. Potassium, magnesium, and yttrium sulphates have no accelerating influence. In sunlight, manganese sulphate, oxalate, acetate, butyrate, and benzoate increase the rate of oxidation. The extent of the acceleration depends on the nature of

the catalytic agent and grows with the concentration of the latter. The accelerated oxidation of oxalic acid, due to manganese salts, cannot be accounted for by the formation of manganese oxalate, which is much more slowly oxidised than oxalic acid itself. J. C. P.

Change in the Strength of Weak Acids by the Addition of Salts. By SVANTE ARRHENIUS (*Zeit. physikal. Chem.*, 1899, 31, 197—229).—When normal salts in small quantity are added to solutions of acetic, formic, and phosphoric acids, the inversion of sugar by these acids is accelerated; the amount of acceleration depends on the quantity of salt added, and is independent of the nature of the salt, although sodium bromide and potassium chlorate behave exceptionally. The observed acceleration is corrected (1) for the effect of the normal salt itself on the inversion, (2) for the formation by double decomposition of new undissociated electrolytes. Both corrections are small when the concentration of the salt solution added is small. After these two factors have been allowed for, it is seen that the addition of the normal salt increases the dissociation constant of the weak acid—exactly what happens in the case of an ordinary salt solution; further addition of salt, that is, increase of concentration, increases the dissociation constant, so that normal salts, strong acids, and bases do not obey Ostwald's dilution law.

The correction applied in conductivity experiments for the conductivity of the solvent water is probably too small, for the dissociation of the carbonic acid contained in the water would, in view of the above results, be much increased on the addition of salts. If this is so, the degree of dissociation of a salt, as hitherto calculated from the conductivity, is too small. The author points out that Noyes' method of calculating the conductivity of a mixed salt solution from that of the separate solutions leads to results at variance with observation; experiment, on the other hand, confirms the view that the conductivity of an electrolyte depends only on the total number of ions per litre (see Abstr., 1888, 1144). The author holds that Noyes' method of calculating the diminution of solubility of a salt on the addition of one of its ions to the saturated solution must be given up; experiments with the sodium and silver salts of fatty acids show that the undissociated portion of the sparingly soluble salt is by no means constant, as has hitherto been assumed. In these experiments, it was found that the first addition of the sodium salt had a much greater effect on the solubility of the silver salt than the later additions. J. C. P.

Nature of Soap Emulsions. By FREDERICK G. DONNAN (*Zeit. physikal. Chem.*, 1899, 31, 42—49).—When oil drops are allowed to ascend from a pipette through an alkaline liquid, the number of drops formed from a given volume of oil increases rapidly with the concentration of the alkali, owing to the diminution of surface tension caused by the formation of a soap. Commercial oils, which exhibit this phenomenon, have an acid reaction, and if the oil be first purified, the number of ascending drops is practically the same in N/1000 NaOH solution as in pure water. Solutions of fatty acids in a pure neutral hydrocarbon of the paraffin series behave similarly to

the commercial oils; the number of drops formed depends on the concentration of the acid as well as of the alkali, although the lower fatty acids are without action at all. The diminution of surface tension due to the salts of the higher fatty acids was confirmed by comparing the levels in a U-tube of two contiguous hydrocarbon and alkaline solutions.

The peculiar boiling phenomena of soap solutions, investigated by Krafft (Abstr., 1896, i, 80; ii, 468), cannot in the light of the above experiments be attributed to high surface tension, as has been done by Kahlenberg and Schreiner (Abstr., 1899, ii, 202), but is due to the frothing of the liquid, as shown by Lord Rayleigh.

It appears that the soap is concentrated in the layer between oil and aqueous solution, with the effect that the formation of small drops is favoured. The stability of an emulsion is due to this concentrated surface layer resisting the union of the already existing small drops; from this point of view, emulsions are akin to frothing, and it is suggested that froth is a sort of air emulsion. J. C. P.

Experiments on Adsorption. By JOHANNES G. C. VRIENS. (*Zeit. physikal. Chem.*, 1899, 31, 230—234).—When a centinormal solution of nitric acid is run through a number of filter papers successively, the concentration diminishes, and the fall of concentration, as determined by the change in conductivity, is proportional to the number of filters. J. C. P.

Inorganic Chemistry.

Distillation of Water. By W. MAREK (*J. pr. Chem.*, 1899, [ii], 60, 582—584).—The apparatus described is for the preparation of moderately large quantities of specially pure distilled water; it consists of a copper still of some 36 litres capacity internally tinned and fitted with a tin head and worm. The various parts are joined by flanges which are ground into one another, so that no organic or inorganic cementing material is required. Ordinary distilled water (30 litres) is introduced and is boiled for several minutes before the worm is cooled, 0.3 gram of potassium permanganate in concentrated aqueous solution is introduced, and the distillation carried out in the ordinary manner; the first 3 litres are rejected and the following 18 litres collected in large glass bottles previously treated with nitric acid. The flame employed is small, and the whole operation requires some 15 hours. J. J. S.

Nature of Water of Crystallisation. By FRIEDRICH RINNE (*Jahrb. f. Min.*, 1899, i, 1—31).—The water of crystallisation of a salt behaves in many ways like ordinary free water; for example, it gradually evaporates, especially at a slightly elevated temperature,

and in some salts there are certain points analogous to the boiling point of ordinary water. Copper sulphate ($\text{CuSO}_4 + 5\text{H}_2\text{O}$), when quickly heated, gradually rises in temperature to 105° , and remains at this temperature until $2\text{H}_2\text{O}$ has been expelled; the temperature then again gradually rises to 117° , when the boiling point of the second $2\text{H}_2\text{O}$ is reached; the boiling point of the last H_2O is 258° . A less sharply marked point is 99° , where $\frac{1}{2}\text{H}_2\text{O}$ is lost. For barium chloride ($\text{BaCl}_2 + 2\text{H}_2\text{O}$), the boiling point of each molecule of water is 105° and 162° . These boiling points vary with the atmospheric pressure.

Heulandite and stilbite are examples of another group of substances in which the water of crystallisation behaves in a different manner; here, there is nothing analogous to boiling point, the water being lost gradually and *pari passu* with the rise in temperature; at the same time, there is a gradual change in the optical orientation of the crystals (Abstr., 1896, ii, 368; 1897, ii, 327). The amount of water lost at any particular temperature is less the greater the atmospheric pressure and the greater the amount of moisture in the air.

In these two groups, the relation of the water of crystallisation to the salt can be considered to be, in the first case, that of a molecular compound, and, in the second, that of a solid solution. L. J. S.

Action of Persulphates on Iodine. BY HUGH MARSHALL (*Proc. Roy. Soc. Edin.*, 1898, 22, 388—390).—When solutions of potassium iodide and potassium persulphate are mixed and warmed, iodine is liberated; investigation shows that this iodine is oxidised to iodic acid by excess of persulphate. If iodine is digested in a loosely corked flask at a moderate temperature with a strong solution of ammonium persulphate, the iodine gradually dissolves, and crystalline ammonium hydrogen iodate is obtained. In Price's experiments on the reaction between potassium iodide and potassium persulphate (Abstr., 1899, ii, 147), there may have been catalytic action, the iodine being alternately oxidised by the persulphate, and reduced by hydriodic acid. J. C. P.

Vapour Density of Sulphur. By OTTO BLEIER and LEOPOLD KORN (*Ber.*, 1900, 33, 50—51. Compare Biltz, Abstr., 1888, 1027; 1889, 340; Biltz and Meyer, 1889, 674; Krause and Meyer, 1890, 1365; Riecke, 1891, 381; Schall, 1889, 331.—The following results have been obtained with the aid of the apparatus previously described (Abstr., 1899, ii, 643):

<i>t</i>	310°	262°	236°	212°	193°
<i>p</i>	42.6	15.0	9.4	4.2	2.1
$D(\text{O}_2 = 1)$	7.44	7.5	7.66	7.80	7.85

from which it follows that the undissociated sulphur molecule consists of eight atoms. J. J. S.

Hyposulphurous Acid. By AUGUST BERNTHSEN and MAX BAZLEN (*Ber.*, 1900, 33, 126—132. Compare Abstr., 1881, 508, 976).—By passing sulphur dioxide into a solution of sodium hydrogen sulphite in contact with zinc, it is converted quantitatively into the

hyposulphite according to the equation $2\text{NaHSO}_3 + \text{SO}_2 + \text{Zn} = (\text{Na}_2\text{S}_2\text{O}_4 + \text{ZnSO}_3) + \text{H}_2\text{O}$; by adding chalk, the zinc sulphite can be removed, and a solution of sp. gr. 15—16° Bé. obtained, which will reduce a fifth of its weight of indigo. From this solution, the sodium hyposulphite separates in crystals on adding salt or sodium hydroxide, and when washed with aqueous, and then with dry acetone, has the composition $\text{Na}_2\text{S}_2\text{O}_4 + 2\text{H}_2\text{O}$, thus confirming the authors' earlier conclusions, and disproving the formula NaHSO_3 given to the salt by Schützenberger [compare Nabl's zinc salt, ZnS_2O_4 (this vol., ii, 13)]; Grossmann's acid salts (*J. Soc. Chem. Ind.*, 1898, 17, 1109; 1899, 18, 452—453) cannot be prepared from the pure material, as sodium hyposulphite solutions deposit sulphur on adding a single drop of acid. Sodium hyposulphite forms large, thin, glistening prisms, which are fairly stable, but gradually effloresce and oxidise to sodium pyrosulphite, $\text{Na}_2\text{S}_2\text{O}_5$; the dry salt is more stable, but when heated to dull redness burns with a blue flame and liberates sulphur dioxide.

T. M. L.

Oxidation of Hydroxylamine. By GEORG VON KNORRE and KURT ARNDT (*Ber.*, 1900, 33, 30—42).—Either the acid hydroxylamine solution, or the oxidising solution, was boiled in a stout conical flask fitted with a funnel and a delivery tube until the air was expelled; the flask was then connected with a vessel filled with mercury, the second solution (freed from dissolved gas by boiling) was run in, and the gas evolved driven over by boiling into the vessel mentioned, transferred from this to a gas burette, and analysed. The oxidising agents tried were potassium nitrate and sulphuric or hydrochloric acid; hydrated manganese peroxide, potassium permanganate, potassium dichromate, vanadic acid, and potassium persulphate, all with sulphuric acid; alkaline copper sulphate and mercuric chloride; also hydrogen peroxide. Nitrous oxide is usually the main product, but nitric oxide is often mixed with it, and the solution nearly always contains nitric (or nitrous) acid. The relative amounts of the two oxides vary with the oxidising agent and with the concentration of the latter. With vanadic acid, the gas consists chiefly of nitrogen; with potassium persulphate, it is pure oxygen, and also with hydrogen peroxide, but in the last case only a small amount is formed.

C. F. B.

Action of very dilute Nitric Acid [on Metals]. By A. VAN BILJERT (*Zeit. physikal. Chem.*, 1899, 31, 103—113).—The products of the action of nitric acid on metals result from (1) the oxidising action of the non-dissociated portion of the acid, and (2) the reducing action brought about by the dissociated acid. The oxidising action is hence the greater the stronger the acid, and the reducing action is more evident when weaker acid is employed. For the metals magnesium, zinc, or cadmium the reaction, $2\text{M} + 2\text{HNO}_3, \text{Aq} = 2\text{MNO}_3, \text{Aq} + \text{H}_2$, is exothermic, and ammonium nitrate is among the products obtained; whilst, for copper, silver, or mercury, this decomposition absorbs heat, and in these cases no ammonium nitrate is found.

A series of experiments on the action of dilute nitric acid (N/20 to N/10) on zinc at about 25° shows that the amount of ammonia formed,

bears to the amount of zinc used, a ratio varying from 1 : 33 to 1 : 40, the ratio required by the equation $4\text{Zn} + 10\text{HNO}_3 = 4\text{Zn}(\text{NO}_3)_2 + \text{NH}_4\text{NO}_3 + 3\text{H}_2\text{O}$ being 1 : 15 or 16. This deviation is ascribed to the intermediate formation of the other reduction products, such as nitrous acid, nitric oxide, nitrogen, &c. No hydroxylamine was detected.

T. H. P.

Spontaneous Combustion of Coal. By RUD. GRIMM (*Zeit. angew. Chem.*, 1899, 1242).—A heap of slag containing furnace ashes mixed with a small proportion of unconsumed coal, became ignited internally on being left exposed to the air, probably owing to the presence in the interior of a small quantity of still glowing clinker; the outer crust of the heap was riven, and clouds of steam were evolved. In the rents so formed, large, rhombic crystals of sulphur and crusts of ammonium chloride were observed; the author explains the liberation of sulphur thus: $\text{FeS} + \text{H}_2\text{O} = \text{H}_2\text{S} + \text{FeO}$; $2\text{H}_2\text{S} + \text{SO}_2$ (from FeS_2) = $3\text{S} + 2\text{H}_2\text{O}$.

W. A. D.

Solubility of Argon and Helium in Water. By TADEUSZ ESTREICHER (*Zeit. physikal. Chem.*, 1899, 31, 176—187).—The absorption coefficient of argon is 0.05612 at 1°, and 0.02567 at 50°, falling regularly between those temperatures. The absorption coefficient of helium is 0.01487 at 0.5°, and 0.01404 at 50°, but at 25° it has a minimum value 0.01371; these values are about twice as large as that provisionally given by Ramsay, namely, 0.0073 at 18.2°. The minimum solubility of helium seems to be connected with the difficulty of liquefaction, for the solubility curve of hydrogen shows the same peculiarity (compare Abstr., 1892, 107); other gases with a higher critical temperature will probably be found to have a minimum solubility above 100°.

A full account is given of the apparatus and method employed.

J. C. P.

Electrolysis of Potassium Chloride. By ANDRÉ BROCHET (*Compt. rend.*, 1900, 130, 134—137).—A yield of over 70 per cent. of potassium chlorate is obtained when a neutral or slightly alkaline, 20 per cent. solution of potassium chloride, containing a small quantity of potassium dichromate is electrolysed with a current of 2 ampères, the temperature of the solution being maintained between 16° and 20°. If the solution is made more strongly alkaline, the yield of chlorate, and also of hypochlorite, is decreased, and if no potassium dichromate is present, the yield of potassium chlorate is never more than 35 per cent. (compare Foerster, *Zeit. Elektrochem.*, 1, 854).

H. R. LE S.

New Explosive and Detonating Materials. By UGO ALVISI (*Gazzetta*, 1899, 29, 478—490. Compare Abstr., 1899, ii, 414, 647, and 748).—The author gives the name *cremonites* to explosives composed of picric acid, or a picrate mixed with ammonium perchlorate. They keep well, require very powerful detonators, are more powerful than picric acid alone, and have a propulsive force nearly equal to that of the most powerful gelatin-dynamite.

Cannel powder is the name given to mixtures of coal and ammonium

perchlorate, 5 parts of the latter to 1 part of Scotch cannell giving the best results. It is simply prepared, has great resistance to shock, keeps well, is non-hygroscopic, and requires powerful detonators.

Ammonium perchlorate can be made on a commercial scale by the interaction of concentrated solutions of ammonium nitrate and sodium perchlorate. T. H. P.

Crystalline Hydrates of Sodium Thiosulphate. By W. W. TAYLOR (*Proc. Roy. Soc. Edin.*, 1898, 22, 248—251).—Crystals of the composition $\text{Na}_2\text{S}_2\text{O}_3 + 2\text{H}_2\text{O}$ may be obtained by driving off part of the water from the fused pentahydrate and allowing the solution to cool. The solubility curves of the pentahydrate and dihydrate intersect at 50° , which is accordingly the transition temperature of the two hydrates. To obtain the dihydrate in quantity, anhydrous thiosulphate is dissolved in fused pentahydrate and the solution kept at 53° . Crystallisation is induced by adding a few fragments of dihydrate, and the crystals formed are dried in an oven at 53° .

J. C. P.

Preparation of Metallic Lithium. By LOUIS KAHLENBERG (*J. Physical Chem.*, 1899, 3, 602—603).—Lithium may be obtained very readily by the electrolysis of solutions of lithium chloride in pyridine. A beaker with a concentrated solution of the salt in pyridine served as a cell, no diaphragm being used; a carbon pole was used as anode, and an iron plate as cathode; the E.M.F. was about 14 volts, the current density about 0.25 ampère per 100 sq. cm.; under these conditions, an adhering, silver-white deposit of metallic lithium was obtained. L. M. J.

Action of Magnesium on Saline Solutions. By HENRI MOURAOUR (*Compt. rend.*, 1900, 130, 140—141. Compare Abstr., 1899, ii, 656).—A rapid evolution of hydrogen takes place when magnesium powder is added to cold solutions of ammonium chloride, ammonium carbonate, ammonium oxalate, ammonium sulphide, sodium carbonate, borax, common alum, and chrome alum. With solutions of sodium phosphate, sodium acetate, sodium nitrite, sodium thiosulphate, potassium sodium tartrate, potassium chloride, potassium ferrocyanide, barium chloride, calcium chloride, and strontium chloride, the evolution of hydrogen is slow, and with a solution of ammonium fluoride, hydrogen is not evolved. H. R. LÉ S.

Metallic Borates. By LÉON OUVRARD (*Compt. rend.*, 1900, 130, 172—175).—The only well defined metallic salt of orthoboric acid is Ebelmen's magnesium borate, $\text{Mg}_3(\text{BO}_3)_2$ (*Ann. Chim. Phys.*, 1851, [iii], 33, 50). The evidence in support of the tribasic character of the acid is derived chiefly from the study of its esters.

Cadmium orthoborate, $\text{Cd}_3(\text{BO}_3)_2$, prepared by adding cadmium oxide (1 mol.) to a fused mixture of potassium hydrogen fluoride (1 mol.) and boric oxide (1 mol.), and treating the cooled product with water, separates in the form of prismatic needles not affected by water, but readily soluble in dilute acids. The crystals produce a

marked effect on polarised light, the plane of extinction being inclined at 9° to the principal axis. G. T. M.

Borates of Zinc, Manganese, Nickel, and Cobalt. By LÉON OUVREAU (*Compt. rend.*, 1900, 130, 335—338).—The compound, $3\text{ZnO} \cdot \text{B}_2\text{O}_3$, obtained by fusing zinc oxide with molecular proportions of potassium hydrogen fluoride and boric oxide, forms flat prisms which belong to the orthorhombic system and have a marked action on polarised light; they are decomposed by hot water and are readily soluble in dilute acids.

The following compounds were prepared in a similar manner: $3\text{MnO} \cdot \text{B}_2\text{O}_3$, from manganese chloride, carbonate, or precipitated borate, forms light-brown, transparent needles, which are not decomposed by hot water but are very soluble in dilute acids; $3\text{NiO} \cdot \text{B}_2\text{O}_3$, from nickel chloride, carbonate, or amorphous borate, forms short, clear, green prisms which are not attacked by hot water but are soluble in acids. In the case of cobalt, the borate obtained had the formula $2\text{CoO} \cdot \text{B}_2\text{O}_3$; if, however, less boric oxide is employed, then the compound $3\text{CoO} \cdot \text{B}_2\text{O}_3$ is obtained as rose-coloured, rhombic crystals.

H. R. LE S.

Behaviour of Zinc Oxide at High Temperatures. By ROBERT C. SCHÜPPHAUS (*J. Soc. Chem. Ind.*, 1899, 18, 987—989).—In heating a mixture of zinc oxide and carbon under pressure, a powder of a permanent canary-yellow hue was obtained; this when analysed shows a higher percentage of zinc than is contained in zinc oxide. Similar compounds may also be obtained by heating zinc oxide in a current of pure nitrogen, or in a vacuum, or with zinc dust under pressure. In each case, the product must be allowed to cool out of contact with the air.

L. DE K.

Hydrolysis of Thallic Sulphate. By HUGH MARSHALL (*Proc. Roy. Soc. Edin.*, 1899, 22, 596—597).—A slightly acid solution of thallic sulphate gives a brown precipitate of hydroxide on dilution; the same precipitate is formed when the solution is warmed, probably owing to an increase of hydrolysis with temperature; ammonium sulphate seems to prevent the formation of the precipitate on warming, but it redissolves in any case on cooling.

J. C. P.

New Micro-chemical Reactions of Copper. By Pozzi-Escot (*Compt. rend.*, 1900, 130, 90—91).—The iodide, $\text{CuI}_2 \cdot 4\text{NH}_3 \cdot \text{H}_2\text{O}$, is obtained in the form of small, blue tetrahedrons by adding ammonium iodide or sodium iodide to an ammoniacal solution of a cupric salt. An unstable compound, probably $\text{CuI}_2 \cdot 4\text{NH}_3$, is formed by adding ammonium iodide or sodium iodide to an ammoniacal solution of a cupric salt which is heated at 40° and contains sufficient ammonia to give a clear solution when hot. Under these conditions, the solution turns a yellowish-green colour, and deposits dark brown rhomboidal plates mixed with prismatic crystals of the same colour, and sometimes also with orange, orthorhombic plates. The colour and crystalline form of the deposit soon change, and after 10—40 minutes the deposit consists entirely of short, thick, flat prisms and triclinic

plates of a yellow colour and possessing a coppery lustre. When seen under the microscope, these changes are very characteristic.

H. R. LE S.

Action of Bromine on Copper Salts in Presence of Alkali Hydroxides. A New Test for Copper Salts. By DIOSCORIDE VITALI (*Chem. Centr.*, 1899, ii, 990—991; from *Boll. Chim. Farm.*, 38, 665—668).—When copper salts are treated with an alkali hydroxide in presence of an excess of bromine water, a brown to black precipitate of the peroxide CuO_2 is formed. Chlorine or iodine may be used instead of bromine, but the reaction then takes place much more slowly. The presence of 1/100000th part of copper in 1 c.c. of a solution of crystallised copper sulphate may be detected by the intense yellow coloration produced by evaporating the solution and treating the residue with potassium hydroxide solution and bromine water. By evaporating the solution to dryness, then adding a few drops of bromine water and again evaporating, a black residue of anhydrous copper bromide is left and by this method even 1/1000000th part of copper in 1 c.c. of a solution of the sulphate, may be detected. The black stain may be rendered more distinct by moistening the residue with concentrated sulphuric acid after evaporating with bromine water. By the action of alkali hydroxides and bromine on nickel and cobalt salts, the black hydroxides $\text{Ni}_2(\text{OH})_6$ and $\text{Co}_2(\text{OH})_6$ are formed. Platinum salts form the brown hydroxide $\text{PtO}_2(?)$. Manganese salts give a black and mercury salts a yellow precipitate. When bismuth oxide is treated with alkali and bromine water, the yellow hydroxide, $\text{Bi}(\text{OH})_3$, is first formed by the action of the alkali, and on heating is, by the action of the potassium hypobromite present, converted into a heavy brown powder of the oxide Bi_2O_3 . Lead salts behave in a similar manner, the yellow precipitate of lead oxybromide, which is first formed, being converted into the dioxide on heating; this oxide, unlike that of bismuth, is insoluble in a small quantity of dilute nitric acid. E. W. W.

Action of Ammonia on Diammoniomercuric Iodide. By MAURICE FRANÇOIS (*Compt. rend.*, 1900, 130, 332—335. Compare *Abstr.*, 1899, ii, 657).—When a solution of ammonia of sp. gr. 0.923 is added to mercuric iodide, white diammoniomercuric iodide is first formed. This, on the further addition of a large excess of ammonia, is converted into ammoniodimercuric iodide. The latter change is limited and also reversible, for on the addition of a solution of ammonia containing a large proportion of ammonium iodide to ammoniodimercuric iodide, the latter is partly converted into diammoniomercuric iodide.

H. R. LE S.

[Luminosity of Mixtures of Thoria and Ceria.] By HERMANN THIELE (*Ber.*, 1900, 33, 183—187).—The luminosity of mantles prepared from mixtures of thoria and ceria and heated in the Wehnelt arc (*Ann. Phys. Chem.*, 68, 260), is not appreciably changed by increasing the amount of ceria from 0—5 per cent., but with larger amounts the luminosity decreases owing to the increased resistance thereby caused.

In the flame of the Wehnelt arc, however, as with the Bunsen flame, the luminosity is a maximum with mixtures containing from 1—2 per cent. of ceria. W. A. D.

Separation of Gadolinite Earths and the Preparation of Pure Yttria. By WILHELM MUTHMANN and R. BÖHM (*Ber.*, 1900, 33, 42—49. Compare this vol., ii, 18).—The normal chromates of the rare earths are all more soluble than the corresponding sulphates. They have the general formula $M_2(\text{CrO}_4)_3 \cdot n\text{H}_2\text{O}$, and as a rule $n=8$. Separations of the rare earths may be more rapidly effected by the aid of these chromates than by any other known method, the separation being best accomplished by fractionally precipitating solutions of the readily soluble dichromates with potassium chromate. In the separation of yttria earths, it is essential that (1) both solutions must be extremely dilute; (2) the liquid must be kept in rapid ebullition during the precipitation; (3) the precipitate must be in an extremely finely divided state, and must be kept in intimate contact with the liquid. Minute directions are given in the original for securing these conditions. By employing this method, the authors have succeeded in obtaining pure yttria from commercial yttrium oxide after six fractionations, the last fraction consisting of pure yttrium chromate in the form of minute, deep red prisms.

The atomic weight of yttrium, determined from this fraction by conversion into sulphate and then igniting for 15—20 hours to convert into oxide, was found to be 88.97. Cleve (*Abstr.*, 1883, 292) gives 89.92.

The specific gravities of the earths from the six different fractions were found to be 6.06, 5.62, 5.43, 4.87, 4.83 (pure yttria), and that of the original mixture 5.62. Cleve and Höglund give 5.028, Nilson and Pettersson (*Compt. rend.*, 1880, 91, 232) give 5.06, and Ekeberg (*Phil. Mag.*, 14, 346) 4.842 for pure yttria.

The other constituents of the crude oxide are erbia, which yields olive-coloured octahedra with potassium chromate, and an earth which yields a chromate in the form of small, golden needles. J. J. S.

Gadolinium. By CARL BENEDICKS (*Zeit. anorg. Chem.*, 1900, 22, 393—421).—Gadolinium is separated from the other rare earths by crystallising the nitrates from nitric acid (*Abstr.*, 1896, ii, 475), and when a fairly pure nitrate is obtained, this is subjected to partial precipitation with dilute ammonia (*Abstr.*, 1891, 17). A determination of the atomic weight, by conversion of the oxide into sulphate, gave Gd = 156.38 (6 experiments: O = 16). The following compounds are described. Gadolinium oxide, Gd_2O_3 , is a white powder, easily soluble in acids, absorbs carbon dioxide from the air, is somewhat hygroscopic, and is not reduced by heating in a current of hydrogen. The *hydroxide* is a gelatinous precipitate, which rapidly absorbs carbon dioxide. The salts of gadolinium are mostly colourless, show no absorption spectrum, have a sweet, astringent taste, and are very similar to the salts of yttrium. The *chloride*, $\text{GdCl}_3 \cdot 6\text{H}_2\text{O}$, crystallises in thick, tabular, quadratic pyramids, and has a sp. gr. 2.424. The *bromide*, with $6\text{H}_2\text{O}$, crystallises in small,

pointed, rhombic tablets, of sp. gr. 2·844. The *platinichloride*, $\text{GdCl}_3 \cdot \text{PtCl}_4 + 10\text{H}_2\text{O}$, crystallises in orange-yellow, prismatic needles of sp. gr. 2·719. The *aurichloride* crystallises, with $10\text{H}_2\text{O}$, in yellow tablets of sp. gr. 2·706. *Gadolinium platinocyanide*, $2\text{Gd}(\text{CN})_3 \cdot 3\text{Pt}(\text{CN})_2 + 18\text{H}_2\text{O}$, obtained by the action of the sulphate on barium platinocyanide, crystallises in long, pointed, and tabular, red crystals of the rhombic system, having a green metallic lustre, and is isomorphous with the corresponding yttrium and erbium salts; sp. gr. 2·563. The *nitrate*, $\text{Gd}_3\text{NO}_3 + 6\frac{1}{2}\text{H}_2\text{O}$, separates over sulphuric acid, or by evaporation in the air, in large, triclinic crystals of sp. gr. 2·332. It also crystallises with $5\text{H}_2\text{O}$ from concentrated nitric acid in prisms of sp. gr. 2·406. The *double salt*, with ammonium nitrate, $\text{Gd}_3\text{NO}_3 \cdot 2\text{NH}_4\text{NO}_3$, crystallises in long, hair-like, deliquescent crystals. The *sulphate*, $\text{Gd}_2\text{SO}_4 + 8\text{H}_2\text{O}$, separates in small, lustrous, monoclinic crystals, and is isomorphous with yttrium sulphate; sp. gr. 3·007. The anhydrous salt has a sp. gr. 4·139. The double salt, with potassium sulphate, $\text{Gd}_2\text{SO}_4 \cdot \text{K}_2\text{SO}_4 + 2\text{H}_2\text{O}$, has a sp. gr. 3·503. 100 c.c. of a saturated potassium sulphate solution will hold 0·87—0·77 gram Gd_2O_3 in solution. The *selenate*, $\text{Gd}_2\text{SeO}_4 + 10\text{H}_2\text{O}$, crystallises at the ordinary temperature in large, colourless, rhombic prisms, is isomorphous with the yttrium and erbium selenates, and rapidly effloresces; sp. gr. 3·048. It separates, with $8\text{H}_2\text{O}$, at the temperature of the water-bath in nacreous crystals of sp. gr. 3·309. The anhydrous salt has a sp. gr. 4·175. The *double salt*, with potassium selenate, $\text{Gd}_2\text{SeO}_4 \cdot 3\text{K}_2\text{SeO}_4 + 4\text{H}_2\text{O}$, crystallises in slender, microscopic needles. *Gadolinium hydrogen selenite*, $\text{Gd}_2\text{SeO}_3 \cdot \text{H}_2\text{SeO}_3 + 6\text{H}_2\text{O}$, is an amorphous precipitate, which gradually forms aggregates of small needles. *Gadolinium ethyl sulphate*, $\text{Gd}_3\text{EtSO}_4 + 9\text{H}_2\text{O}$, obtained from the sulphate and barium ethyl sulphate, crystallises in large, transparent tablets belonging to the hexagonal system [$a:c=1:0\cdot5014$], is stable in the air, effloresces over sulphuric acid, and, when heated at 115° , loses $3\text{EtOH} + 6\text{H}_2\text{O}$; sp. gr. = 1·923. The *vanadate*, $\text{Gd}_2\text{O}_5\text{V}_2\text{O}_5 + 26\text{H}_2\text{O}$, crystallises in the triclinic system [$a:b:c=1\cdot7083:1:0\cdot9894$; $\alpha=84^\circ51'$, $\beta=94^\circ51'$, $\gamma=82^\circ13\cdot5'$]. The basic *carbonate*, $\text{OH}\cdot\text{GdCO}_3 + \text{H}_2\text{O}$, obtained by treating the hydroxide with carbon dioxide, crystallises in small, microscopic needles. The *normal carbonate*, $\text{Gd}_2\text{CO}_3 + 13\text{H}_2\text{O}$ (?), is obtained by prolonged action of carbon dioxide on the hydroxide. The *oxalate*, with $10\text{H}_2\text{O}$, crystallises from concentrated nitric acid in large, monoclinic crystals; 1 gram of ammonium oxalate dissolved in 38 grams of water will hold 0·00083 gram of gadolinium oxide in solution. The *acetate* crystallises with $4\text{H}_2\text{O}$ in sparingly soluble, colourless, triclinic crystals of sp. gr. 1·611. The *propionate* crystallises in a vacuum desiccator in crusts of large, rhombic tufts. E. C. R.

Stable Hydrates of Manganese Chloride above 0° . By HARRY M. DAWSON and P. WILLIAMS (*Zeit. physikal. Chem.*, 1899, 31, 59—68).—Investigation with the dilatometer shows that the ordinary hydrate of manganese chloride, $\text{MnCl}_2 + 4\text{H}_2\text{O}$, is transformed into the dihydrate at $57\cdot9^\circ$, at which temperature also the vapour tension of the dry tetrahydrate becomes equal to the vapour pressure of the saturated

solution; at the same temperature, there is a corresponding discontinuity in the solubility curve and in the density of the saturated solution. When a manganese chloride solution crystallises at about 70° , large, well-formed crystals are obtained which, after draining, washing with alcohol, and drying between filter paper, are found to have the composition $\text{MnCl}_2 + 2 \cdot 2\text{H}_2\text{O}$, confirming the dilatometer result. A better method of preparing the dihydrate is to pass hydrogen chloride into an alcoholic solution of manganese chloride saturated at the ordinary temperature; the crystals of the dihydrate which separate are pink, but deeper in tint than the ordinary tetrahydrate. The dihydrate is stable from 58 — 198° ; at the latter temperature, it is transformed into the anhydrous salt.

Marignac's β -tetrahydrate, obtained by crystallisation at 0 — 6° of a solution saturated at a higher temperature, represents a labile form at all temperatures. J. C. P.

Peroxides. By SIMEON M. TANATAR (*Ber.*, 1900, 33, 205—208).—Peroxides are usually divided into two classes, the members of one of which yield hydrogen peroxide on treatment with acids, whilst those of the other do not. Piccini (*Abstr.*, 1897, ii, 9) further states that the true (hydrogen peroxide yielding) peroxides reduce certain compounds, such as manganese dioxide, lead dioxide, and potassium permanganate, in presence of acids, and that they are never produced by oxidation carried out with nitric or hypochlorous acid.

The author suggests that the two classes of peroxides may not differ in chemical constitution, but that the differences between their reactions may be accounted for by thermochemical considerations. The heat developed by the action of acids on the "false" peroxides is less than that required for the formation of hydrogen peroxide. Nickel peroxide, which acts in most respects as a false peroxide, develops, however, sufficient heat to render possible the formation of hydrogen peroxide, and the author has found that perceptible amounts of hydrogen peroxide are actually produced by the decomposition of nickel peroxide with sulphuric acid. The peroxides of nickel and cobalt, moreover, appear capable of converting barium hydroxide into the peroxide, for in their presence barium hydroxide brings about the reduction of potassium permanganate. Potassium permanganate is also slowly decolorised in the cold when it is mixed with solutions of sodium hypochlorite and barium hydroxide. A. H.

Nature of the Change from Violet to Green in Solutions of Chromium Salts. By WILLIS R. WHITNEY (*J. Amer. Chem. Soc.*, 1899, 21, 1075—1084. Compare *Abstr.*, 1896, ii, 525).—The author considers that the conclusions of Venable and Miller (*Abstr.*, 1898, ii, 592) are erroneous, and describes experiments which confirm the observations of Recoura (*Abstr.*, 1896, ii, 27) and of Favre and Valson (*Compt. rend.*, 1872, 74, 1032). [Compare also Dougal (*Trans.*, 1896, 69, 1526).] E. G.

A New Crystalline Molybdenum Sulphide. By MARCEL GUICHARD (*Compt. rend.*, 1900, 130, 137—140).—When molybdenum disulphide is heated in the electric furnace, it is decomposed, and a

new compound, *molybdenum sesquisulphide*, Mo_2S_3 , is formed; this crystallises in steel-grey needles of sp. gr. 5.9 at 15° . When slightly heated, it is readily decomposed by fluorine and chlorine, but only at a red heat by bromine, whilst iodine is without action on it, even at the higher temperature. When strongly heated in oxygen, molybdenum trioxide is formed, and in atmosphere of sulphur, it is converted into the disulphide. Hydrochloric and sulphuric acids have no action on it, but hot concentrated nitric acid and aqua regia readily dissolve it with formation of molybdic and sulphuric acids. If molybdenum sesquisulphide is heated to a temperature slightly higher than that at which it is formed, it is decomposed into metallic molybdenum, and, if carbon is present, the carbide CMo_2 is formed.

H. R. LE S.

Enantiotropy of Tin. II. By ERNST COHEN and C. VAN ELJK (*Proc. K. Akad. Wetensch. Amsterdam*, 1899, 2, 149—153; *Zeit. physikal. Chem.*, 1899, 30, 601—622. Compare this vol., ii, 83).—The velocity of change of the white into the grey modification of tin has been determined, with the aid of a dilatometer, at various temperatures from 0° to -83° , and has a maximum at about -48° , which is accordingly the most favourable temperature for the conversion of white tin into grey tin.

Further qualitative investigation at a temperature of -4° to -7° shows that the change of dry white tin into grey tin takes place slowly, beginning at the edges. If the white tin has powdered grey tin in contact with it, the change is accelerated, and begins at the points of contact. White tin filings are much more rapidly converted than white block tin.

J. O. P.

Enantiotropy of Tin. III. By ERNST COHEN (*Proc. K. Akad. Wetensch. Amsterdam*, 1899, 2, 281—286. Compare preceding abstract).—White tin can be inoculated with grey tin; a large block treated thus and kept at -5° for 3 weeks was photographed and seen to be covered with grey nodules.

Previous investigation has shown that the velocity of change of white tin into grey tin is a maximum at -40° , and zero at 20° . At the ordinary temperature, the velocity is small, and a very long time would be necessary for the transformation. This condition was regarded as fulfilled in the case of an antique vase dug up in Hampshire, and supposed to date from the fourth century; on examination, the vase was found to consist almost entirely of grey tin.

The velocity of the change of grey tin to white tin above 20° has been investigated with the aid of a dilatometer, and found to increase very rapidly, rendering measurement impossible at 40° .

J. C. P.

Bismuth Suboxide and Subsulphide. By R. SCHNEIDER (*J. pr. Chem.*, 1899, [ii], 60, 524—543. Compare Abstr., 1899, ii, 227).—The following method for the preparation of bismuth suboxide, Bi_2O_3 , is simpler, and yields better results, than the two methods previously described by the author. A solution of bismuth oxide, Bi_2O_3 , in nitric acid, is poured slowly and with constant stirring into excess of dilute potassium hydroxide; the precipitate of bismuth hydroxide is washed by decantation, and then suspended in 2 per cent. potassium hydroxide in a

capacious flask; a solution of freshly prepared stannous chloride is slowly added, the flask completely filled with air-free water, tightly closed, and the contents well shaken. Bismuth suboxide is thus obtained as a light, perfectly homogeneous, black powder. If freely exposed to the air in a moist state, it is completely converted into ordinary bismuth hydroxide.

Bismuth subsulphide, Bi_2S_3 , is conveniently prepared by heating bismuth suboxide in a stream of dry hydrogen sulphide. It forms a slate-grey, dense, entirely homogeneous powder. When moderately heated in absence of air, it remains unchanged; at a low red heat, it melts and decomposes into bismuth and the ordinary bismuth sulphide. If heated in a current of hydrogen, it is reduced to the metal; the reduction begins at the temperature of melting sulphur, and then proceeds smoothly and rapidly.

The author replies in detail to the criticisms of Vanino and Treubert (*Abstr.*, 1899, ii, 428) on his previous communications, and adheres to his former conclusions. E. G.

Isomorphous Compounds of Gold and Mercury. By THEODOR H. BEHRENS (*Proc. K. Akad. Wetensch. Amsterdam*, 1899, 2, 163).—The halogen salts of these metals have been found to yield complete series of compound crystals. These were prepared by adding chlorides or bromides of thallium, caesium, and rubidium to mixed solutions of the chlorides and bromides of gold and mercury. J. C. P.

Preparation of Colloidal Metallic Solutions by the Disintegrating Action of an Electric Discharge. By GEORG BREDIG (*Zeit. angew. Chem.*, 1898, 951–954).—Hitherto colloidal metallic solutions have been obtained by the action of chemical reducing agents. The author describes how an electric discharge between poles of gold, silver, and platinum, immersed in water, disintegrates the cathode, and gives a solution of the metal. In the case of gold, reddish-purple or dark blue solutions are thus obtained, which can be filtered without change and keep their colour for months; the gold may be precipitated from the solution by freezing or by the addition of electrolytes; non-electrolytes, on the other hand, are ineffective. When the colloidal solution is subjected to electrolysis, the metal is separated at the anode as a black slime.

Silver and platinum give clear, dark brown solutions, which even with a small metal concentration absorb light almost entirely and are generally similar in properties to the colloidal gold solution. The colloidal platinum solution behaves like platinum black in decomposing hydrogen peroxide with evolution of oxygen.

Careful microscopic investigation reveals no heterogeneity, but the author is nevertheless of opinion that these solutions are really heterogeneous systems of the very finest structure, the particles having probably about a thousand times the molecular dimensions. The colours observed are regarded as due to this state of fine division. J. C. P.

Inorganic Ferments. I. Catalytic Action of Platinum, and the Chemical Dynamics of Hydrogen Peroxide. By GEORG BREDIG and R. MÜLLER VON BERNECK (*Zeit. Physikal. Chem.*, 1899, 31, 258–353).—Close analogy exists between the decomposition of

hydrogen peroxide by organic ferments (Jacobson, *Abstr.*, 1892, 899), and by colloidal platinum. The latter agent is formed by the action of an electric discharge between platinum wires immersed in water, and the dark brown solution so obtained (with a maximum possible concentration of 1 gram-atom of platinum in 1300 litres of water) behaves in numerous cases exactly like platinum black. As this colloidal platinum is precipitated by electrolytes, its action is advantageously studied on hydrogen peroxide, which is practically a non-conductor, and yields non-electrolytic decomposition products.

Solutions of hydrogen peroxide were prepared with the conductivity 1.5×10^{-5} — 3.7×10^{-5} ; to a suitably diluted portion, some of the platinum solution was added, and the mixture was kept at a constant temperature (generally 25°); portions extracted from time to time were titrated with permanganate solution, and the progress of the decomposition of hydrogen peroxide thus determined. Even a solution of 1 gram-atom of platinum in about 70 million litres of water markedly accelerates the decomposition of hydrogen peroxide. The authors have compared with this the catalytic action of the peroxides of manganese, cobalt, copper, and lead, in both acid and alkaline solution.

The decomposition of hydrogen peroxide in acid and neutral solution in presence of colloidal platinum of constant quantity and condition, proceeds strictly according to the unimolecular equation, $2\text{H}_2\text{O}_2 = 2\text{H}_2\text{O} + \text{O}_2$. In alkaline solution, the catalytic action of colloidal platinum first increases, reaches a maximum, and then diminishes again, as the alkali concentration increases; this is exactly what happens in the action of organic ferments on hydrogen peroxide. The values for the velocity constant obtained in alkaline solution are not steady, probably owing to the partial combination of the hydrogen peroxide and the alkali, as indicated by freezing point and other experiments.

Colloidal platinum and organic ferments are both alike affected by the addition of electrolytes, but the analogy is perhaps most strikingly illustrated by the effect of certain poisons, such as hydrocyanic acid, hydrogen sulphide, and mercuric chloride; the colloidal platinum is, as it were, paralysed by these agents, but recovers itself after a certain time.

The catalytic action of the colloidal platinum solution increases with its concentration, although not proportionally, and is favoured by rise of temperature; the increase of the velocity constant in the latter case agrees well with Arrhenius' equation $\log k_1/k_2 = A(T_1 - T_2)/(T_1 \cdot T_2)$, where k_1 and k_2 are the velocity constants corresponding to the temperatures T_1 and T_2 , and A is a constant (*Abstr.*, 1889, 1103). Light does not affect the catalytic action of the colloidal platinum.

The view that platinum acts on hydrogen peroxide as certain solids do on supersaturated gas solutions is not confirmed. The paper contains a review of various theories of catalytic action. J. C. P.

Platinum Tetrachloride. By ARTURO MIOLATI (*Zeit. anorg. Chem.*, 1900, 22, 445—465).—The electric conductivity of aqueous solutions of platinum tetrachloride is not constant, but alters with the

time, and the values are dependent on the dilution; the results are essentially those given by a weak acid, and are similar to those obtained with selenious acid. An aqueous solution of platinum tetrachloride, when titrated with sodium hydroxide, using phenolphthalein as indicator, is neutralised with two equivalents of alkali; and by determining the specific conductivity of solutions to which successive quantities of alkali are added, unmistakable evidence of the formation of an acid and a normal salt is obtained. This is more clearly shown when ammonia is used to neutralise the solution. It is therefore evident that a solution of platinum tetrachloride contains a dibasic acid. The silver salt, $\text{Ag}_2\text{PtCl}_4(\text{OH})_2$, has been known for some time. The author was unable to isolate the alkali salts from their solution. Copper, zinc, or cadmium hydroxides dissolve in the aqueous solution, but the resulting salts do not crystallise, and yellowish-brown gums are obtained, easily soluble in water and alcohol. The alcoholic solution, when precipitated with ether, yields yellow, gummy flocks, which solidify after a time, and these, on analysis, gave numbers agreeing fairly well with the formulæ $\text{ZnPtCl}_4(\text{OH})_2 + 3\text{H}_2\text{O}$ and $\text{CdPtCl}_4(\text{OH})_2$. The *thallium* salt, $\text{Tl}_2\text{Pt}_2\text{Cl}_8\text{H}_6\text{O}_4$, obtained by precipitating an aqueous solution of the tetrachloride with a thallium salt, is a yellow, amorphous powder. The *lead* salt, $\text{PbPtCl}_4(\text{OH})_2$, is obtained as a yellow precipitate by adding a mixture of lead and sodium acetates to the aqueous solution; the *lead* salt, $\text{PbPtCl}_4(\text{OH})_2 \cdot \text{Pb}(\text{OH})_2$, obtained in alcoholic solutions, is a brownish powder. E. C. R.

Nature of Palladium Hydrogen. By JOHN SHIELDS (*Proc. Roy. Soc. Edin.*, 1898, 22, 169—186).—The E.M.F. of the combination—palladium containing a small quantity of hydrogen | dilute sulphuric acid | palladium containing a large quantity of hydrogen—is zero, or nearly so. Thus the cell does not behave like a true concentration cell, as would probably be the case were the absorption of hydrogen by palladium simply a process of solution. The view that a chemical compound is formed would agree better with the facts, for the E.M.F. in this case would be independent of the quantity of compound formed. The experiments are insufficient to determine whether the compound formed is Pd_3H_2 , or whether it contains more hydrogen than corresponds with this formula. J. C. P.

Mineralogical Chemistry.

Accumulation of Iron in Peat. By JACOBUS M. VAN BENMELLEN [with C. HOITSEMA and EDUARD A. KLOBBIE] (*Zeit. anorg. Chem.*, 1899, 22, 313—379).—This paper covers, but in greater detail, much the same ground as one already noticed (*Abstr.*, 1899, ii, 371). Several more analyses of impure chalybite, iron ochre and vivianite are given. L. J. S.

Formation of Petroleum. By CARL ENGLER (*Ber.*, 1900, 33, 7—21).—Krämer and Spilker's arguments (this vol., i, 73) are inconclusive, and their experiments were hardly needed, for the author had shown already that all fats and waxes, whether of animal or vegetable origin, yield petroleum when distilled under pressure. He explains at some length his view of the mode of formation of petroleum. This was, he thinks, formed in the main by the decomposition of animal deposits of marine origin; the nitrogenous matter in this decomposed comparatively rapidly, leaving a wax almost free from nitrogen; this became buried under subsequent deposits, and was in consequence subjected to greater pressure and a higher temperature, under the influence of which it yielded petroleum. C. F. B.

Graftonite, a new Mineral. By SAMUEL L. PENFIELD (*Amer. J. Sci.*, 1900, [iv], 9, 20—32).—The new mineral is found associated with beryl, tourmaline, &c. in pegmatite on Melvin Mountain, near Grafton, New Hampshire. The fragments and indistinct crystals have a rough, weathered appearance, and are striking in being built up of thin, alternately light and dark lamellæ, the light material being graftonite and the dark oxidised triphylite; in a fresh specimen, the two minerals are salmon-coloured and pale green respectively. The graftonite has a vitreous to resinous lustre and closely resembles salmon-coloured lithiophilite in appearance. Analyses of the separated minerals are given under I (grafftonite, sp. gr. 3·672) and II (triphylite, $\text{Li}(\text{Fe}, \text{Mn})\text{PO}_4$, sp. gr. 3·58); analysis III, by W. E. Ford, was made on partly oxidised graftonite imperfectly separated from triphylite. Details of the method of analysis are given.

	P_2O_5	FeO	MnO	Fe_2O_3	CaO	MgO	K_2O	Na_2O	Li_2O	H_2O	Total
I. 41·20	30·65	17·62	—	9·23	0·40	—	—	—	0·33	0·75	100·18
II. 42·3	33·4	9·9	—	0·2	1·3	—	—	—	9·2	1·7	98·0
III. 40·80	24·28	15·38	10·16	7·25	—	0·14	1·15	—	1·17	100·33	

These analyses (in III calculating the whole of the iron as ferrous) give the formula for graftonite as $(\text{Fe}, \text{Mn}, \text{Ca})_3\text{P}_2\text{O}_8$ or $\text{R}''_3\text{P}_2\text{O}_8$. Few other anhydrous, normal phosphates are known amongst minerals. Crystals of graftonite are monoclinic with approximately $a:b:c = 0·886:1:0·582$; $\beta = 66^\circ$. The peculiar intergrowth of the monoclinic graftonite and the orthorhombic triphylite is discussed in detail; there appears to be a definite crystallographic relation between the two minerals. Similar cases are the intergrowth of albite and orthoclase, rutile and hæmatite. L. J. S.

Anhydrite and Gypsum Deposits at Oulx, Piedmont. By LUIGI COLOMBA (*Jahrb. f. Min.*, 1900, i, Ref. 26—28; from *Atti Accad. Sci. Torino*, 1898, 33, 779—796).—The deposits of gypsum and anhydrite near Oulx, in an upper valley of the Dora Riparia, occur with beds of limestone, sometimes dolomitic, from which, it is suggested, the calcium sulphate has been derived by the action of volcanic gases. A description is given of each of the following minerals which occur in both the limestone and the gypsum: mica, tourmaline, quartz, chalcedony, pyrites, sulphur, dolomite, halite, hæmatite and blende.

The optically uniaxial mica occurs as minute scales, and is shown

by the following analysis to be a biotite containing lithium; it differs from ordinary lithia mica in containing much magnesia.

SiO ₂ .	Al ₂ O ₃ .	MgO.	CaO.	Li ₂ O.	Na ₂ O, (K ₂ O).	Loss on ignition (H ₂ O, F).	Total.
42.40	12.66	20.10	6.76	5.21	4.68	6.82	98.63

Analysis of the dolomite gave MgCO₃, 42.75; CaCO₃, 57.21 = 99.96.

L. J. S.

[Celestite from Baltschiederthal, Switzerland.] By CARL SCHMIDT (*Jahrb. f. Min.*, 1900, i, 16—21).—The fissured masses of Triassic dolomitic limestone folded in the gneisses of the Baltschiederthal, Wallis, contain in the crevices, crystals of dolomite, celestite, fluor, calcite, quartz, barytes, adularia, anatase, blende, &c. A description is given of each of these minerals. Bluish crystals of celestite gave the following results on analysis by M. Scheid:

SrO.	BaO.	CaO.	SO ₂ .	SiO ₂ .	Al ₂ O ₃ .	Fe ₂ O ₃ .
54.29	0.25	0.17	42.72		traces	

L. J. S.

[Mineral Analyses.] By KARL BUSZ (*Jahrb. f. Min.*, 1899, *Beil. Bd.*, 13, 90—139).—In a petrological paper describing the granite and contact rocks of the Dartmoor Forest, Devonshire, the following analyses are given of minerals from the metamorphosed Devonian limestone at South Brent.

Garnet occurs abundantly, in one case as a vein two metres wide; the brownish-green, rhombic dodecahedra and granular masses show marked optical anomalies; Analysis I (contains also traces of manganese, magnesium and sodium) shows the mineral to be andradite with the formula $9(\text{Ca}_2\text{Fe}_2\text{Si}_3\text{O}_{12}) + \text{Ca}_2\text{Al}_2\text{Si}_2\text{O}_{12}$.

Datolite occurs as a white, saccharoidal mass in which the garnets are embedded; anal. II (B₂O₃ by difference 21.65; also a trace of sodium). This is a very unusual mode of occurrence of datolite.

Augite occurs in large, grey-green masses which are fibrous or compact: Analysis III shows it to be hedenbergite; the ferric oxide is due to oxidation, as the mineral is not quite fresh.

	SiO ₂ .	Al ₂ O ₃ .	Fe ₂ O ₃ .	FeO.	MnO.	CaO.	MgO.	K ₂ O.	H ₂ O.	Total.	Sp. gr

III.	49.29	0.29	4.92	16.70	0.86	22.55	5.49	—	—	100.10	—

Other secondary minerals present in the limestone are axinite and quartz.

L. J. S.

Theory of Tourmaline Mixtures. By GUSTAV TSCHERMAK (*Tsch. Min. Mitth.*, 1899, 19, 155—164. Compare Abstr., 1899, ii, 304, 601, 767).—From a consideration of Riggs's analyses (Abstr., 1888, 659), Wülfing showed (Abstr., 1889, 765) that tourmalines may be considered to be isomorphous mixtures of the two silicates, Si₁₂B₆Al₁₆Na₄H₃O₆₃ and Si₁₂B₆Al₁₀Mg₁₂H₃O₆₃, in which aluminium may

be replaced by iron, and magnesium by iron, calcium, &c. Each of these may be written partly as a borate and partly as a silicate :

These formulae, the silicate portions of which represent paragonite and merzoxene respectively, express the relations existing between the micas and tourmalines as shown by their modes of origin, occurrence, alteration, &c. The relation is similar to that shown by the author to exist between the plagioclase and scapolite groups. Most tourmaline analyses can be explained by mixtures of the above molecules ; for example, Penfield and Foote's recent analyses (Abstr., 1899, ii, 304) give $\text{Tu}_{44}\text{Tr}_7$ (Haddam Neck), and $\text{Tu}_{13}\text{Tr}_{37}$ (De Kalb). A few analyses are explained by the presence of a third molecule :

$\text{Si}_{12}\text{B}_6\text{Al}_8\text{Mg}_{12}\text{H}_8\text{O}_{61} = \text{B}_6\text{Al}_4\text{O}_{15}, 2(\text{Si}_3\text{Al}_3\text{H}_3\text{O}_{12}), \text{Si}_3\text{Mg}_6\text{O}_{12} = \text{Tr.}$, of which the silicate portion has the phlogopite formula. L. J. S.

Kelyphite. By JOSEF MRHA (*Tsch. Min. Mitth.*, 1899, 19, 111—143).—A microscopical examination of the fibrous shells of kelyphite surrounding garnets in serpentine shows the material to consist of a mixture of augite, spinel, bronzite and hornblende. The composition of the kelyphite from near Steinegg, Austria, is given under I, and the spinel (picotite), isolated from it, gave II. The garnet (pyrope) gave III. The alteration of olivine and pyrope to augite and spinel is accompanied by an increase in molecular volume.

	SiO ₂	Al ₂ O ₃	Cr ₂ O ₃	Fe ₂ O ₃	FeO	MnO	CaO	MgO	Loss on ignition.	Total.	Sp. gr.

[Allophane from Italy.] By GIOVANNI D'ACHIARDI (*Jahrb. f. Min.*, 1900, i, Ref. 16, 29 ; from *Proc. Verb. Soc. Toscana Sci. Nat.*, 1898, 12, 26—39).—Sky-blue to grey-blue, optically isotropic allophane fills crevices and forms reniform crusts in zinc ores at Valdaspra, Massa Maritima, Tuscany, where it is associated with linarite, aurichalcite (Abstr., 1898, ii, 604), &c. After deducting zinc, copper and calcium as hemimorphite, chrysocolla and calcite, analysis I. gives the formula $\text{Al}_2(\text{OH})_2\text{SiO}_4 + 5\text{H}_2\text{O}$.

Allophane from Rosas, Sulcis, Sardinia, gave II (also contains Cr_2O_3 , trace) from which, after deducting excess of silica as hyalite, the formula is deduced as $\text{Al}_2(\text{OH})_2\text{SiO}_4 + 4\text{H}_2\text{O}$.

	SiO ₂	Al ₂ O ₃	ZnO	CuO	CaO	(below 350°). H ₂ O.	H ₂ O, ignition.	Total.	Sp. gr.
I.	24.00	32.01	1.44	1.21	0.66	32.90	6.49	98.72	1.93
II.	30.39	32.63	1.63	1.18	0.23	27.18	5.88	99.12	2.00—2.086

Cupriferrous allophane is also described from a copper mine at Cascine, Mezzanago ; it contains no zinc and only a trace of calcium.

L. J. S.

New Occurrence of Laumontite. By OTTO LUEDECKE (*Zeit. f. Naturwiss.*, 1899, 72, 101—104).—The quartz-porphyry on Peters-

berg, near Halle, contains embedded laumontite, associated with secondary fluorite, calcite, epidote and quartz. The laumontite has been apparently derived from oligoclase; it is reddish-yellow, and without crystal faces. The mean of two analyses is, after deducting a little calcite,

Action of Ammonium Chloride on Analcite and Leucite.

By FRANK W. CLARKE and GEORGE STEIGER (*Amer. J. Sci.*, 1900, [iv], 9, 117—124; and *Zeit. anorg. Chem.*, 1900, 23, 135—145).—In a previous paper (this vol., ii, 25), it was shown that analcite, when heated at 350° in an open crucible with ammonium chloride, gave up part of its soda and absorbed some ammonia; at a higher temperature, ammonia is again liberated. Further experiments have now been made on analcite from North Table Mountain, near Golden, Colorado, the composition of which is given under I. When the material is heated at 350° in a sealed tube with ammonium chloride, the whole of the soda is converted into sodium chloride, and all the liberated ammonia absorbed by the silicate; the residue has the composition $\text{NH}_4\text{AlSi}_2\text{O}_6$, and appears to be the first ammonium silicate that has been prepared. In the presence of excess of free ammonia there is no further absorption of ammonia. On boiling this ammonium compound with caustic soda solution, the whole of the ammonia is expelled and sodium again taken up. The product previously obtained with analcite is now to be regarded as a mixture.

Leucite (from Vesuvius, anal. II.), when heated in a sealed tube with ammonium chloride, yields the same compound, $\text{NH}_4\text{AlSi}_2\text{O}_6$, as does analcite. When this ammonium leucite, the composition of which is given under III, is fused with calcium chloride, a product approximating in composition to the corresponding calcium salt, $\text{CaAl}_2\text{Si}_4\text{O}_{13}$, is obtained. This ammonium leucite is not a metasilicate, as shown by the fact that no soluble silica is liberated when the material is ignited.

	SiO ₂	Al ₂ O ₃	CaO.	K ₂ O.	Na ₂ O.	H ₂ O.	NH ₃ .	Total.
I.	55.72	23.06	0.17	—	12.46	8.39	—	99.80
II.	55.40	23.69	0.16	19.54	1.25	0.24	—	100.28
III.	60.63	26.44	trace	0.50	0.25	5.17	7.35	100.34

Preliminary experiments show that several other zeolites behave in a similar manner when heated with ammonium chloride.

L. J. S.

Granitoid Rocks from Cape Marsa. By LOUIS DUPARC and F. PEARSON (*Compt. rend.*, 1900, 130, 432—434).—Petrographical descriptions, with analyses, are given of granulite, tonalite and microtonalite.

L. J. S.

Eruptive Rocks from the Salekammergut. By CONRAD H. VON JOHN (*Jahrb. k.k. geol. Reichs. Wien*, 1899, 49, 247—258).—Quartz-diorite (= tonalite) from the Pöllagraben, St. Gilgen, consisting of plagioclase, hornblende and biotite with some orthoclase and

quartz, gave analysis I; the large crystals of white felspar (andesine) isolated from the rock gave II.

	SiO ₂	TiO ₂	Al ₂ O ₃	Fe ₂ O ₃	FeO	CaO	MgO	K ₂ O	Na ₂ O	P ₂ O ₅	Loss on ignition	Total.
I.	58.20	0.21	19.20	2.01	4.42	5.60	3.25	1.81	4.53	0.38	1.28	100.84
II.	58.97	—	25.21	0.65	—	6.82	0.21	0.71	6.02	—	0.50	99.09

Analyses of several other rocks are given.

L. J. S.

Analyses of Italian Volcanic Rocks. II. By HENRY S. WASHINGTON (*Amer. J. Sci.*, 1900, [iv], 9, 44—54. Compare this vol., ii, 27).—Six analyses are given of various volcanic rocks from Tuscany and Rome.

L. J. S.

Plagioliparites of Cape Marsa, Algeria. By LOUIS DUPARC and F. PEARCE (*Compt. rend.*, 1900, 130, 56—58).—The plagioliparites of Cape Marsa, in Algeria, consist of plagioclase, biotite and quartz in a matrix which may be vitreous, globular, felsitic or perlitic with large spheruliths, but in all cases the composition is practically the same: SiO₂, 72.74—77.99; Al₂O₃, 12.46—12.70; Fe₂O₃, 1.06—1.91; CaO, 1.21—1.59; MgO, 0.05—0.15; K₂O, 4.10—5.71; Na₂O, 2.85—3.60; loss on heating, 0.24—2.92 per cent.

C. H. B.

Meteorites from Jamyscheff and Tubil River, Siberia. By J. A. ANTIPOFF (*Chem. Centr.*, 1899, i, 801; from *Bull. Acad. St. Pétersbourg*, 1898, [v], 9, 91—103).—Analysis I is of the metallic portion of the meteorite which fell in the neighbourhood of the village of Jamyscheff, Pawlodarsk district in Semipalatinsk (it contains also graphite, 0.115; howardite, 0.395; magnetite, 2.284; Cr, trace); the olivine gave the results under II, agreeing with the formula (Mg,Fe)₃SiO₃.

Analysis III is of the meteoric iron found on the Tubil river, Ats-hinsk district, Gov. Yeniseisk.

	Fe.	Ni.	Co.	SiO ₂	Ca.	Mn.	Mg.	As.

L. J. S.

Waters of the Salt Lake of Urmi, Persia. By R. T. GÜNTHER and J. J. MANLEY (*Proc. Roy. Soc.*, 1899, 65, 312—318).—The water has the specific gravity 1.113 at 15° and contains about 15 per cent. of solid matter; of this, 86 per cent. is estimated to be sodium chloride, the rest consisting of magnesium chloride, magnesium sulphate, calcium sulphate, and potassium sulphate. No iodide or bromide can be detected.

J. C. P.

Physiological Chemistry.

Action of certain Derivatives of Morphine on Respiration in Man. By HUGO WINTERNITZ (*Chem. Centr.*, 1899, ii, 884—885, from *Therap. Monatsk. Sept.*).—Whilst the alkyl-morphine derivatives codeine and dionine hardly affect respiration, the acetyl derivatives, diacetylmorphine and monoacetylmorphine exacerbate breathing by stimulation of the respiratory centre. The action of morphine on respiration is thus weakened by the introduction of alkyl radicles, and increased by that of acetyl. W. D. H.

Action of the Constant Current on the Respiration of 'Surviving' Muscle. By TH. GUILLOZ (*Compt. rend.*, 1900, 130, 200—203).—In view of the treatment of maladies of nutrition (gout, obesity) with the constant current, advocated by the author, experiments on the respiration of the excised muscles of the frog were undertaken: the evolution of carbon dioxide and using up of oxygen were found to be increased during and after the use of the electrical stimulation. W. D. H.

Carbonic Oxide in Tobacco Smoke. By FRITZ WAHL (*Pflüger's Archiv*, 1899, 78, 262—285).—The carbonic oxide in tobacco smoke is taken up by the blood, but when highly diluted in this way, the gas may be breathed for 4 hours without ill results. W. D. H.

The Supposed Oxidation of Carbonic Oxide in the Living Body. By JOHN SCOTT HALDANE (*J. Physiol.*, 1900, 25, 225—229).—Wachholtz and Saint Martin have stated that carbonic oxide is converted into carbon dioxide in the body. The present experiments on mice entirely negative this. W. D. H.

The Influence of Animal Membrane on the Diffusion of Various Substances. By SVEN G. HEDIN (*Pflüger's Archiv*, 1899, 78, 205—261).—The diffusion of a large number of organic and inorganic substances was investigated with and without a membrane. The membrane used was prepared from the intestine; previous heating of the membrane makes no difference to the dialysis quotient. In all cases, the presence of a membrane hinders diffusion, but to an unequal extent. Taking dextrose as a standard, it was found that mannitol, erythritol, glycerol, glycocine, and alanine were hindered to the same extent as dextrose. The dialysis of some substances, such as alcohol, urea, urethane, and ethylene glycol, was less hindered than that of dextrose. The same is true for many neutral salts of the alkalis and alkaline earths; here the dissociation of the salts in solution forms one of the determining factors. Ammonium salts with two ions have often a greater dialysis quotient than the equally dissociated salts of the fixed alkalis, but ammonium sulphate behaved like the sulphates of the fixed alkalis. W. D. H.

Pressure Filtration of Proteids. By DAVID FRASER HARRIS (*J. Physiol.*, 1900, 25, 207—211).—The following proteids pass under pressure through a Chamberland filter: egg-albumin, serum-globulin (from sheep), serum-albumin, gelatin, acid-albumin, alkali-albumin, hæmoglobin, proteose, lactalbumin, caseinogen dissolved in alkali (1 to 30 per cent. of sodium hydroxide). The following do not: caseinogen of normal milk, caseinogen of decalcified or oxalated milk, caseinogen dissolved in lime-water, serum-globulin (from ox). The assumption drawn is that caseinogen in milk is particulate, or that its molecules are larger than those of the other proteids examined.

W. D. H.

Metabolism of a Vegetarian. By THEODOR RUMPF and O. SCHLUMM (*Zeit. Biol.*, 1899, 39, 153—158).—Particulars of the diet and excreta of the young vegetarian under observation are given. He took purely vegetable food, and presented nothing noteworthy in general health, weight, or appearance. His fæces, however, were extraordinarily voluminous. He took daily 11·82 grams of nitrogen, 698·21 grams of carbohydrate, and 28·64 grams of fat, and excreted daily 6·91 grams of nitrogen in his urine, and 4·01 in fæces; the fæces contained 7·58 grams of fat.

W. D. H.

Metabolism in Children. By WILLIAM CAMERER and FRIEDRICH SÖLDNER (*Zeit. Biol.*, 1899, 39, 37—72).—The observations first recorded were made on a girl thirty-nine weeks old, taking mixed diet. The results are given in tables, showing the composition of the diet, the growth of the child, and the composition of the excreta, including sweat. The second set of observations were similar ones upon twins; their nutriment was mother's milk. The presence of soaps in human milk is noted. The methods used are described in detail.

W. D. H.

Metabolism in Ruminants. By OSKAR HAGEMANN (*Chem. Centr.*, 1899, ii, 1030; from *Arch. Anat. Physiol.*, 1899, Suppl., 111—140 and 382).—If the oxygen used is taken as a measure of the energy that results, the sheep is much under the average values, and this is also lower than the digestive value. After the taking of food, the oxygen used increases by 5·5 per cent., which is a proof of anabolic processes that are furthered by digestion. Calorimetrically, a food of the value of 3705 Cal. is accompanied with an output of 1487 Cal., and proteid built up, 8 Cal.; this leaves 2210 Cal. for fat deposition and the needs of respiration. In the second paper, some of these figures are corrected; the figures relate only to the 8 or 10 hours following digestion, and the figure 2210 must be lessened to 1983 Cals. in order to allow for the methane that leaves the body.

W. D. H.

Metabolism of Phosphorus. By DIARMID NOËL PATON, J. CRAUFURD DUNLOP, and R. S. AITCHISON (*J. Physiol.*, 1900, 25, 212—224).—In dogs on a vegetable diet, much of the phosphorus in the food is not excreted in the urine; also a large proportion of phosphoric acid subcutaneously injected as sodium phosphate does not reappear in the urine; in the goat, none reappears, whether it is given in the food or injected under the skin. During lactation in the goat, the excretion

of phosphorus by the bowel is diminished, but under other circumstances, with the animal in phosphorus equilibrium, the absorption and excretion of phosphorus by the intestine are equal. In the dog, during lactation, the phosphorus in the urine is diminished. Goat's milk contains a high proportion of phosphorus, but less of it is in organic combination than in cow's or human milk. The administration of calcium glycerophosphate causes no rise in the phosphorus of the urine of the dog, or in the urine or milk of the goat. W. D. H.

Metabolism with Edestin. By RICHARD LEIPZIGER (*Pflüger's Archiv*, 1899, 78, 402—422).—Steinitz (Abstr., 1898, ii, 615) showed that feeding with proteids containing phosphorus yields better results so far as the putting on of phosphorus is concerned than feeding with phosphorus-free proteids *plus* inorganic phosphates. It was considered desirable to repeat this. Edestin was used instead of the myosin employed by Steinitz. The experiments were made on dogs, and Steinitz's results are confirmed. Another point investigated was the metabolic processes in which calcium and magnesium are concerned. Two experiments are recorded; in both there was a laying on of calcium in the body; in one there was a small gain, in the other a small loss, of magnesium. The results cannot be alone explained on the supposition of metabolic processes taking place in the bony tissues. W. D. H.

Metabolism during Poisoning by Pulegone. By W. LINDEMANN (*Zeit. Biol.*, 1899, 39, 1—17).—Substances which produce fatty degeneration, such as phosphorus, chloroform, and many other less thoroughly investigated materials, cause also a destructive metabolism of proteid. Pulegone, the active constituent of the ethereal oil of *Mentha pulegium*, is one of these. The substance was given subcutaneously to dogs. It causes great fatty degeneration of liver, kidneys, and heart, with hyperæmia and ulcerations of the intestines and other parts. The metabolic phenomena during the poisoning were investigated in the usual way by examining the ingesta and excreta, including the expired air. Proteid katabolism is much increased. The figures given support Voit's view that the fat originates from proteid. W. D. H.

Absorption and Excretion of Iron. By EMIL ABDEBHILDEN (*Zeit. Biol.*, 1899, 39, 113—152).—This is a contribution to a much discussed question. In the main the methods (microchemical, &c.) are like those employed by others. The animals chiefly used were rats. The principal results are that inorganic iron given by the mouth as ferric chloride is absorbed in small doses. The iron of hæmoglobin and hæmatin is also absorbable. The duodenum is the principal seat of absorption; probably Peyer's patches are also seats of absorption. Iron is excreted in cæcum, colon, and rectum. The most trustworthy method of detecting iron is by ammonium sulphide and ammonia. W. D. H.

Absorption of Sugars in the Intestine. By E. HÉDON (*Compt. rend.*, 1900, 130, 265—266).—The absorption of sugars in the intestine is related to their osmotic pressures. It is greatest for the two

hexoses studied (dextrose and galactose), less for arabinose, and very feeble in the case of raffinose.

W. D. H.

Digestion of Starch in the Stomach of Carnivora. By HANS FRIEDENTHAL (*Chem. Centr.*, 1899, ii, 1030; from *Arch. Anat. Physiol.*, 1899, Suppl., 383—390).—Although the saliva of dogs contains no ptyalin, energetic digestion of starchy food occurs in their stomachs. This is not due to a zymogen in the swallowed saliva being rendered active when it reaches the stomach, for it occurred also in the stomach of an animal fed by an oesophageal fistula, in which no saliva was allowed to enter the stomach. The starch is changed into erythrodextrin; only quite small quantities of maltose were found.

W. D. H.

Relative Digestibility of Certain Fats in the Human Intestine. III. Butter and Margarine. By H. LÜHRIG (*Chem. Centr.*, 1899, ii, 1029—1030; from *Zeit. unters. Genussm.*, 2, 769—783).—The digestibility of margarine is given as 96.75; that of butter from 96.86 to 97.13 per cent. These numbers are rather higher than those of Hultgren and Landergren. Ox-fat appears to diminish digestibility. In estimating the fat of the faeces, allowance is made for lecithin and unsaponifiable substance.

W. D. H.

Nutritive Value of Margarine compared with Butter. By E. BERTARELLI (*Exper. Stat. Rec.*, 1899, 11, 375—376; from *Riv. Ig. San. Pubbl.*, 1898, 9, 538—545 and 570—579).—The results of experiments with men showed that margarine, when properly prepared, does not differ much from butter in chemical and physical properties. When margarine was consumed, 93.5 to 96 per cent. of fat was assimilated; with butter, 94 to 96 per cent. There was no disturbance of the digestive tract when margarine was consumed in moderate amounts.

N. H. J. M.

Effects of Thyroid Feeding on Monkeys By WALTER EDMUNDS (*Proc. Roy. Soc.*, 1899, 65, 368—369).—The effect of feeding monkeys on powdered thyroid, or Hutchison's thyrocolloid, in doses varying from the equivalent of one-half to that of three sheep's thyroids daily, is exophthalmos, wasting, weakness, and death. Other symptoms noted were erection of the hair on the head, falling off of hair in patches in other parts, and paralysis of one or more limbs. Some of these are due to stimulation of the cervical sympathetic nerve. The increased secretion of the enlarged and altered thyroid in Graves's disease probably explains the exophthalmos there.

W. D. H.

The Thyroid as a Poison-removing Organ. By FRITZ BLUM (*Virchow's Archiv*, 1899, 158, 495—513. Compare Abstr., 1899, ii, 125, 779).—This is a re-statement of the author's views on the functions of the thyroid.

W. D. H.

Defence of the Organism against the Toxic Properties of Glandular Secretions. By ALBERT CHARRIN and LEVADITI (*Compt. rend.*, 1900, 130, 262—264).—If digestion juices, especially pancreatic juice, are introduced into the tissues, injury occurs. In

the intestine, it is harmless. The protection is considered to be due to the action of the mucous membrane (removal of which leads to loss of protection), of intestinal parasites, and perhaps of the blood. In the upper part of the intestine, this is believed to be aided by the layer of mucus, and the glandular secretions from the wall of the intestine.

W. D. H.

Physiology of the Suprarenal Capsules. By H. BORUTTAU (*Pflüger's Archiv*, 1899, 78, 97—128).—The paper is mainly a review of previous work on the subject; some points are amplified. The suprarenals are considered to have nothing to do with blood and skin pigments; their chief use is to render harmless the products of muscular activity, and so to regulate the nutrition and innervation of the whole motor apparatus.

W. D. H.

Influence of Alcohol on Milk Formation. By RUDOLF ROSEMAN (*Pflüger's Archiv*, 1900, 78, 466—504).—Numerous analyses, given in full detail, show that the administration of alcohol has no influence on the formation of milk, either qualitatively or quantitatively. With moderate doses, no alcohol passes into the milk; with larger doses, only from 0.2 to 0.6 per cent. of the alcohol given passes into the milk.

W. D. H.

Sodium and Potassium in the Red Corpuscles of the Blood of Animals of different Species, and in Cases of Anæmia caused by Bleeding. By FILIPPO BOTTAZZI and I. CAPPELLI (*Real. Accad. Lincei*, 1899, 8, ii, 65—73).—The authors find that with animals having nuclear red corpuscles, the latter, without exception, contain much more potassium than sodium; of the mammals examined, dog, cat, and rabbit, the last also has red corpuscles richer in potassium than in sodium. It is hence supposed that the red corpuscles of the mammals contain nucleins, the relative quantity of which determines the proportion of potassium present.

The influence of anæmia, especially when serious and protracted, is in all cases to produce a diminution in the amount of sodium and potassium in the red corpuscles. This fact, together with the decrease in the amount of nitrogen under similar circumstances, indicates that whenever the red corpuscles suffer a loss of proteids, a corresponding loss of mineral matter also occurs.

T. H. P.

Sodium and Potassium in the Red Corpuscles of the Blood during Fasting, Phosphorus Poisoning, &c. By FILIPPO BOTTAZZI and I. CAPPELLI (*Real. Accad. Lincei*, 1899, 8, ii, 107—114. Compare preceding abstract).—Fasting and phosphorus poisoning also determine diminutions in the amounts of sodium and potassium in the red corpuscles of the blood, whilst splenotomy gives no such effect. The red corpuscles of the arterial blood of a dog suffering from leucocythemia were found to contain more potassium and less sodium than the normal

From these and former researches (*loc. cit.*), it is concluded that the red corpuscles participate to some extent in the general organic metabolism and in some special cases in the progressive destruction of

the organs and that sodium and potassium are normal constituents of the proteid molecule. T. H. P.

Localisation, Elimination, and Origin of Arsenic in Animals. By ARMAND GAUTIER (*Compt. rend.*, 1900, 130, 284—291. Compare this vol., ii, 152, 168.)—The following organs (human and animal) contain arsenic: thyroid gland, 0.75 mg. per 100 grams; mammary gland, 0.13 per 100 grams; brain, variable quantity, sometimes *nil*; thymus, appreciable amount; hair, horn, skin, milk, and bone, traces only.

No arsenic could be detected in: liver, kidney, spleen, muscle, testicle, seminal fluid, pituitary gland, pancreas, mucous membrane, cellular tissue, salivary glands, suprarenal capsules, ovary, uterus, marrow, blood, urine, and faeces.

In order to ascertain the source of the arsenic found in the above organs, bread, eggs, and fish were examined, but no arsenic could be detected in them.

From these results, it will be seen that those organs which are most commonly examined for arsenic in cases of poisoning are normally free from that substance. Even if the examination be made after putrefaction has set in, and when the small amount of arsenic which is normally present in some of the organs may have possibly diffused throughout the whole system, the dilution of the arsenic would then be so great as to preclude its detection. H. R. LE S.

Universal Distribution of Titanium. By CHARLES BASKERVILLE (*J. Amer. Chem. Soc.*, 1899, 21, 1099—1101).—Beef bone is found to contain 0.0195 per cent., beef flesh 0.013 per cent., human bone, a trace, and human flesh 0.0325 per cent. of titanic oxide. E. G.

Transformation of Nitrobenzene into Aniline by a Reducing and Hydrogenating Enzyme in the Animal Organism. By J. E. ABELOUS and ERNEST GÉRARD (*Compt. rend.*, 1900, 130, 420—422. Compare Abstr., 1899, ii, 680 and 681).—When the aqueous extract of the kidney of the horse is digested with nitrobenzene and a little chloroform in an atmosphere of hydrogen at 42°, aniline is formed, but no reduction takes place if the extract is previously boiled. It thus appears that the enzyme which has previously been described as having the property of reducing nitrates to nitrites possesses an hydrogenating, as well as a deoxidising, action, a fact which is of importance in connection with the production of animal bases in the organism. N. L.

Excretion of Sulphur in Infants. By WALTHER FREUND (*Zeit. physiol. Chem.*, 1900, 29, 24—46).—The amount of the sulphur in its various forms (sulphates, alkyl hydrogen sulphates, &c.) is given for numerous sucking infants, both in health, and various forms of disease. Many cases are described in detail, and the analyses are arranged in tabular form. General conclusions from the variable results obtained are not easy to draw. W. D. H.

Influence of Peptone and Albumoses on Urinary Secretion. By WILLIAM H. THOMPSON (*J. Physiol.*, 1900, 25, 179—190).—The excretion of proteose or peptone injected into the venous system

of dogs is confined to the hour after the injection. During this time, the output of urinary nitrogen is increased, principally in the form of urea. This, however, is largely due to the salt solution used as the solvent of the proteids. At least 60 per cent. of the injected material is retained in the body; the proportion retained is greatest when deuteroproteose, amphopeptone, or antipeptone is used. It is suggested that the proteoses are held in combination as proteose-globulins in the blood.

W. D. H.

Diazo-reactions of Urine. By P. CLEMENS (*Chem. Centr.*, 1899, ii, 1028—1029; from *Deutsch. Arch. klin. Med.*, 63).—An account of numerous experiments made to ascertain the nature of the substance which gives Ehrlich's diazo-reaction in urine, but which led to no very definite result.

E. W. W.

The Pigment of the Arenicolæ. By PIERRE FAUVEL (*Compt. rend.*, 1899, 129, 1273—1275).—There exist in the integument of the *Arenicolæ* two pigments, generally described as distinct, a yellow lipochrome in the epithelial cells, and a black pigment in the form of fine granules in the upper layers of the epidermis. A solution of the lipochrome becomes brown, then black on the addition of various acids; and, it is considered probable that the formation of black granules in the cells is due to a chemical modification of the yellow pigment, under the influence of acidity, produced either in the neighbourhood of the digestive tube, or from the accumulation of waste products, the result of metabolic activity. Details concerning the pigmentation in different species are added.

W. D. H.

Ion-proteid Compounds; the Poisonous Character of Pure Sodium Chloride. By JACQUES LÆB (*Amer. J. Physiol.*, 1900, 3, 327—338).—The experiments recorded were made on fish, medusæ, and cilia. The general conclusions drawn are believed to be also true for air-breathing animals. They principally consist in translating into the new nomenclature which has arisen in connection with the modern theory of solution the work which Ringer did some years ago.

W. D. H.

Physiological Action of Bromine. By F. FESSEL (*Chem. Centr.*, 1899, ii, 885, from *Munch. med. Woch.*, 46, 1270—1273).—The experiments were performed with sodium and potassium bromide. The toxic action of bromine salts is greater in cats than in dogs. The excretion of the bromine does not rise equally with that administered until 'bromine equilibrium' is established with a sufficient dose. The chief amount of the bromide is found in the blood, where it partially replaces sodium chloride. Among the organs, the brain was the only one where it was discovered. Whether bromine will take the place of the iodine of the thyroid, is to be the subject of further work.

W. D. H.

Physiological Action of Protamines and their Decomposition Products. By WILLIAM H. THOMPSON (*Zeit. physiol. Chem.*, 1900, 29, 1—19).—The protamines are toxic; they cause a fall of blood pressure, acting like albumoses on the peripheral vessels directly; blood

coagulation is slowed, and the number of leucocytes in the circulation is lessened. The heart and respiration are also affected. Histons have a very similar action. The substances obtained by the hydrolysis of protamines (protons, hexon bases) have no such effects.

W. D. H.

Physiological Action of Morphine and its Allies. By E. IMPENS (*Pflüger's Archiv*, 1900, 78, 527—596).—The action on respiration was specially investigated. Of the substances used, heroine (diacetylmorphine) produces an effect with the smallest dose; five times as much morphine, twelve times as much dionine (ethylmorphine), twenty times as much codeine are required to produce the same or even a less effect. Peronine (benzylmorphine) has very little action at all. The danger is in about the proportion just quoted, being least with heroine and greatest with codeine. With heroine the energy of breathing and the volume of air inspired are increased, but the act is quieter, and its use is recommended in cases of tuberculosis. The other alkaloids are more uncertain and less sedative in their action. Heroine lessens the amount of oxygen consumed; codeine and dionine increase it at first and then lessen it. Morphine paralyses the irritability of the respiratory centre to stimulation by carbon dioxide, and codeine has a weaker action in the same direction. Dionine, peronine, and heroine do not act in this way. The results obtained from experiments on rabbits are applicable to man.

W. D. H.

Hæmolytic Action of Snake Toxins and Toxic Sera. By J. W. W. STEPHENS (*J. Pathol. and Bacteriol.*, 1900, 6, 273—302).—The following general conclusions are drawn from the experiments recorded:—(1) that an antitoxic serum can act on toxins other than, but allied to, that used in the preparation of the serum; (2) that the hæmolytic constituents of snake toxins, and hence snake toxins as a class, are not identical; (3) that against a minimum lethal dose of daboia toxin 0.5 c.c. of Calmette's anti-venom has very little action; (4) that the anti-hæmolytic properties of anti-venomous sera must be increased in order to afford any efficient protective serum, for instance against *Pseudechis* or daboia toxin.

W. D. H.

Sandy Matter from the Human Intestine. By R. S. THOMSON and ALEXANDER R. FERGUSON (*J. Pathol. and Bacteriol.*, 1900, 6, 334—338).—Sandy matter, passed with the fæces by a female patient suffering from a dyspeptic condition, was subjected to analysis. It was found to consist of 71.5 per cent. of inorganic, and 28.5 per cent. of organic matter. The inorganic material consisted of calcium carbonate (11.7), tricalcium phosphate (87.3), and insoluble residue (silica) (1 per cent.). Among the organic materials, particular attention was directed to the brown pigment. It was not, however, identified; its solubilities exclude any known derivative of bile pigment. It is possibly an intermediate substance between bile pigment and stercobilin. The sand is readily soluble in dilute acids. It is suggested that it is formed in the ileum, where the intestinal contents are alkaline.

W. D. H.

Milky Serous Effusions. By H. BATTY SHAW (*J. Pathol. and Bacteriol.*, 1900, 6, 339—355).—The appearance of milky, dropsical effusions is familiar to the clinical observer. This is due, in many instances to actual injury to the lacteals and escape of chyle into the body-cavity. In many cases, called chyloform, microscopic examination reveals no fat globules, and chemical examination no great quantity of fat. Often, however, minute particles, probably proteid in nature, are seen; in other cases, the opalescence may be due to proteid in solution. A case of chylous ascites and hydrothorax is here fully recorded, and compared with numerous cases described by others. The cause of the affection was a mass of lymphadenomatous glands pressing on the thoracic duct. There were no visible fat particles in the fluid, and it did not clear with ether, but became jelly-like. The urine also became jelly-like with ether, even when the albumin it contained had been removed by boiling. Normal urine does not behave so, but the same effect was noticed in other cases of albuminuria. The ascitic fluid contained 4 per cent. of solids, 2·2 per cent. of proteid, 0·52 per cent. of fat, and 0·7 per cent. of ash. W. D. H.

Acetonuria. By HUGO LÜTHJE (*Chem. Centr.*, 1899, ii, 972; from *Centr. inn. Med.*, 20, 969—973).—The appearance of acetone in the urine is held to indicate the excessive formation of acids in the organism. As strychnine produces an increased production of acids in the body (Meyer), it was given to animals; but in strychnine convulsions no acetone appears in the urine. In epileptic fits, it is also absent. It is not therefore every acid, including the lactic acids produced by muscular activity, that leads to acetonuria. W. D. H.

Excretion of Diamines in Cystinuria. By P. J. CAMMIDGE and ARCHIBALD E. GARROD (*J. Pathol. and Bacteriol.*, 1900, 6, 327—333).—Another case of cystinuria is added to the four previously recorded in which diamines have been extracted from the urine; it is the second case in which they have been extracted from the fæces also, Baumann and Udranszky's case being the first. A note added to the paper mentions a new case recorded by C. E. Simon (*Amer. J. Med. Sc. Philadelphia*, 1900, 119, 39); here they were found both in fæces and urine. In the present case, cadaverine was present in the urine, putrescine in the fæces. The diamine excretion is extremely intermittent; for no less than twenty-three successive days no diamine was found. This emphasises the necessity for prolonged investigations in other cases.

W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

Reproduction of Yeast without Fermentation in a Limited Supply of Air. By AUGUSTE ROSENSTIEHL (*Compt. rend.*, 1900, 136, 195—198).—The vital activities of yeast cells immersed in sugar solutions manifest themselves in either of two ways, according as to

whether air is freely admitted or not; in the former case, they multiply, and in the latter they induce fermentation. Yeast colonies in apple juice from which air is excluded are frequently seen to grow without evolving any carbon dioxide, although, under these conditions, fermentation should occur. The vitality of the cell seems to be impaired by the tannin or other astringent compounds present, for when these are precipitated by gelatin, fermentation sets in; if excess of gelatin is added, so that these substances are re-dissolved, the yeast cells continue to multiply, but without evolving any gas. The addition of tannin to an artificial wort prevents its fermentation by yeast cells cultivated in apple juice. When the wort is carefully freed from dissolved oxygen, neither fermentation nor reproduction is noticed; the gelatin added to precipitate the tannin has no direct influence on the vitality of the yeast cells. G. T. M.

Decomposition of Diastase during Fermentation. By G. HEINZELMANN (*Bied. Centr.*, 1899, 25, 863; from *Zeit. Spiritusind.*, 1898, No. 41, 357).—In solutions of cane-sugar containing 0.6 per cent. of diastase, it was found that yeast destroys the diastase during fermentation. In the case of malt mash, the diastatic power decreased much less than with sugar solutions; and it was found that the presence of asparagine and other nitrogenous substances economised diastase.

A mixture of starch (160 grams) with water (to 1000 grams), to which diastase (2 grams) was added, lost 14.3 per cent. of diastase in 10 minutes at 61°. During the next 20 minutes (at 62.5°), 45.7 per cent. of the diastase was destroyed, but there was no further change during the next half-hour. N. H. J. M.

Rate of Alcoholic Fermentation. By JAMES O'SULLIVAN (*Bied. Centr.*, 1899, 25, 863; from *Zeit. Spiritusind.*, 1898, 351).—Stirring the liquid expedites fermentation, with or without an excess of yeast. In the case of maltose and dextrose, the rate of fermentation is in proportion to the amount; the rate of alcoholic fermentation of the two substances differs from the rate of the hydrolytic action of yeast on sucrose.

In presence of nutrients, fermentation is quickened, even when the amount of yeast is not increased; the cells have a more healthy appearance than in absence of nutritive matters. N. H. J. M.

Influence of Metals on Broth-cultures of Bacteria. By B. ISACHENKO (*Exper. Stat. Record*, 1899, 11, 123; from *Selsk. Khoz. Lyssov.*, 1898, 189, 35—42).—The results of experiments with *Bacillus spermophilinus* showed that when broth-cultures have to be kept more than a month, only iron vessels may be employed. Tinned iron (or lead), nickel-plated, zinc, or zinc-plated iron vessels are absolutely unsuitable for growing bacteria. Copper apparatus can only be used for keeping the culture of sterilised broth for a very short time. N. H. J. M.

Butyric Acid Fermentation. By ARTHUR SCHATTENFROH and R. GRASSBERGER (*Chem. Centr.*, 1899, ii, 1060—1061; from *Centr. Bakt. Parasit.*, 5, ii, 697—702).—Butyric acid fermentation, at any

rate as regards sugar and starch, seems only to be produced by two very similar bacteria. The one variety of butyric acid bacilli, which is mobile and does not liquefy gelatin, includes the butyric bacillus I. of Gruber, *Bacterium saccharobuty.* of Kleckli, and others. It occurs in milk, cheese, soil, and in other materials, but is not so common as the second variety which liquefies gelatin and is not mobile.

It seems probable that a pure butyric fermentation of sugar and starch does not exist, and that both the mobile and non-mobile variety always produce lactic acid as well as butyric acid, carbon dioxide, and hydrogen. Just as the quantity of alcohol produced varies, there is a difference in the relative amounts of the two acids. The production of butyric acid depends on the nature of the carbohydrate. Lactose is almost completely fermented to butyric acid by the mobile variety. The non-mobile variety produces from lactose sometimes butyric acid and a small amount of lactic acid, sometimes butyric acid alone. Dextrose, sucrose, and starch are fermented by the mobile variety mainly with production of butyric acid, whilst the non-mobile variety produces more lactic than butyric acid. The latter variety ferments galactose, maltose, and lævulose, but not cellulose and mannitol, and it attacks glycerol only slightly, with production of volatile acids and aldehyde. Both varieties coagulate casein, but without peptonisation. It is proposed to designate both varieties *Granulobacillus saccharobuty.*, with addition of *immobilis liquefac* and *mobilis non liquefac*.

N. H. J. M.

Bacteria which produce Esters. By ALBERT MAASSEN (*Chem. Centr.*, 1899, ii, 1058—1059; from *Arb. Kais. Ges.-A.*, 15, 500—513).—*Bacillus esterificans*, from putrefying litmus, in broth containing much peptone, produced hydrogen sulphide and mercaptan, but not indole or phenol, and reduced nitrate to nitrite; it did not ferment glycerol or carbohydrates, but decomposed them with production of acid.

Bacillus esterificans fluorescens (from cereals) produces a green, fluorescent dye and, during the first few days, an ester-like aroma, and subsequently an odour resembling that of trimethylamine; it does not peptonise, and reduces nitrates only slightly, does not decompose mannitol or glycerol, but decomposes dextrose and organic acids with production of acid and carbonates. *B. præpollens* (from intestine) peptonises gelatin, decomposes albumin with production of hydrogen sulphide and mercaptan, and produces much ammonium carbonate in cultures containing proteids. In cultivations, in 10 per cent. peptone, two months old, tyrosine, leucine, ammonium propionate, valerate, formate, and succinate, hydrogen sulphide, mercaptan, and an ester (probably amyl) of valeric acid were formed. It rapidly converts urea into ammonium carbonate, but does not produce carbonates from organic salts. It has no effect on nitrates, but decomposes nitrites with liberation of free nitrogen. It is pointed out that the bacillus is the first instance of a microbe which is both beneficial and injurious in agriculture. The bacillus produces esters in all nutritive media (aëration and the presence of proteids are favourable in this respect), and, unlike the

other ester-producing bacilli, retains this property. The aroma produced in milk is very agreeable.

Ester-producing bacilli were isolated from milk, Spree water, soil, and faeces. N. H. J. M.

Magnesia-gypsum as a Solid Medium for the Cultivation of Nitrifying Organisms. By V. OMELIANSKY (*Chem. Centr.*, 1899, ii, 725; from *Centr. Bakt. Parasit.*, 5, ii, 652—655).—The substance, which gave excellent results with nitrous organisms, is prepared by adding a solution of potassium phosphate (0.1), sodium chloride (0.2), magnesium, ammonium, and ferrous sulphates (0.05, 0.2, and 0.04 per cent. respectively) to a mixture of gypsum and magnesium carbonate. The mixture, which should have the consistence of sour cream, is poured on to a glass plate and then transferred to Petri-dishes or test-tubes. Plates sterilised at 120° generally absorb most of the liquid, in which case a sterilised solution of the same composition is added. After inoculation, the substance is kept in a thermostat at 25—30°.

N. H. J. M.

Denitrification Bacteria and Sugar. By HJALMAR JENSEN (*Chem. Centr.*, 1899, ii, 1061; from *Centr. Bakt. Parasit.*, 5, ii, 716—720).—In reply to Stutzer and Hartleb (this vol., ii, 97), the author expresses the opinion that the results adduced, as well as his own, do not justify the conclusion that carbohydrates as well as organic salts can serve as source of food and energy for denitrifying bacteria. N. H. J. M.

Decomposition of Nitrates by Bacteria. By S. A. SEWERIN (*Bied. Centr.*, 1899, 25, 854—856; from *Centr. Bakt. Parasit.*, 1897, 504, 554).—Out of 29 bacteria obtained from horse-dung, which were cultivated in broth containing peptone and sodium nitrate (0.3 per cent.), 18 had no effect on the nitrate, 9 reduced the nitrate to nitrite, and 2 (*Bacillus pyocyaneus*, not previously known as a denitrifying organism, and *Vibrio denitrificans*) caused still greater reduction. When the amount of nitrate was less (0.1—0.05 per cent.), 6 of the 9 cultivations reduced the nitrate completely. It is improbable that the whole of the nitric nitrogen was converted into organic nitrogen.

B. pyocyaneus and *V. denitrificans* reduce the whole of the nitrate present in 10 days when the amount is less than 7 grams per litre of broth; potassium nitrate is reduced in greater quantity than the sodium salt. The reduction also proceeds when both cultures are present, but *B. pyocyaneus* hinders the growth of *V. denitrificans*; the latter does not produce nitrites. The exhaustion of broth cultures is due to increasing alkalinity, and addition of phosphoric acid revives the denitrifying power. A portion of the nitrogen is probably converted into organic nitrogen, and a very small quantity into ammonia, when there is a slight surface aëration. Nearly all the nitrogen is liberated in the free state, perhaps mixed with oxides of nitrogen. Both microbes are undesirable in soils, especially as they are destructive both with and without access of air.

Aëration is decidedly a means of hindering denitrification and should be employed as a means of diminishing loss of nitrates.

N. H. J. M.

Soil Bacteria. By R. KOLKWITZ (*Chem. Centr.*, 1899, ii, 917; from *Centr. Bakt. Parasit.*, 5, ii, 670—678).—The so-called alinit bacillus is neither *B. megatherium* nor *B. subtilis*. Cultivations of the bacillus made in media prepared from earth-worms (which contain a substance which reduces Fehling's solution, and proteid substances which show the biuret reaction) failed to reduce nitrate, although the bacillus possesses denitrifying properties. N. H. J. M.

Soluble Ferments produced during the Germination of Seeds with Horny Albumen. By ÉMILE BOURQUELOT and HENRI HÉRISSEY (*Compt. rend.*, 1900, 130, 42—44).—The seeds of fenugreek (*Trigonella Fœnum græcum*) and lucerne (*Medicago sativa*) like the carob bean (this vol., ii, 35), when germinating, produce a soluble ferment capable of hydrolysing, in the same manner as hot dilute sulphuric acid, the carbohydrates forming part of certain horny albumens. From the albumens of the carob bean and cassia, these ferments produce mannose and galactose, together with a residue that is not readily attacked by dilute sulphuric acid (compare *loc. cit.*, and *Abstr.*, 1899, i, 839). C. H. B.

Nutrition of Plants with Organic Nitrogenous Compounds. By L. LUTZ (*Exper. Stat. Record*, 1899, 11, 316—317; from *Ann. Sci. Nat. Bot.*, 1899, [viii], 7, 1—103).—Under conditions of sterilisation, phanerogams readily assimilate methylamines, but not benzylamine and pyridine. "Phenolamines" are strong poisons, whilst compound ammonium salts and alkaloids are not available as sources of nitrogen.

Algæ and fungi gave similar results.

The organic nitrogen of beet, fruit, and fish refuse may therefore be made available for plants without nitrification or conversion into ammonia. N. H. J. M.

Regeneration of Proteids from their Products of Decomposition. By DMITRI N. PRIANISCHNIKOFF (*Landw. Versuchs-Stat.*, 1899, 52, 347—381. Compare *Abstr.*, 1899, ii, 787; also Schulze, *ibid.*, 628; Kinoshita, *ibid.*, 1896, ii, 54, and Hansteen, *ibid.*, 1898, ii, 179).—In 1896, Salezsky showed that in bulbs of *Allium cepa*, germinating in darkness, there was a possible production of proteids from carbohydrates in conjunction with amino-compounds other than asparagine, the amount of which did not decrease.

In presence of light, proteids are destroyed during germination with as much energy as in darkness. Later, when leaves develop, reproduction of proteids begins: with some plants, 10 to 15 days after germination commences, with other plants (such as *Vicia faba*), much later. Regeneration of proteids takes place either from asparagine and other amides simultaneously, or the utilisation of asparagine lingers behind that of other amino-compounds. No case, however, in which asparagine is chiefly utilised has been observed.

It is probably in the leaves that proteids are regenerated with most energy.

The experiments were made with vetches, peas, beans, yellow lupine, *Cucurbita pepo*, and *Allium cepa*. N. H. J. M.

Decomposition of Chlorophyll by Oxidising Enzymes. By ALBERT F. WOODS (*Chem. Centr.*, 1899, ii, 1126; from *Centr. Bakt. Parasit.*, 5, ii, 745—754).—Oxydases and peroxydases, which regularly occur in small quantity in all higher plants, rapidly decompose chlorophyll. Under certain conditions, not yet understood, the oxydases increase in activity or in quantity, and produce various diseases. The mosaic disease of tobacco is more probably due to enzymes than to Beijerinck's "vivum fluidum."

Oxydases and peroxydases can remain some months in the soil. The former are destroyed within five minutes at 65—70°, the latter in the same time at 80—85°. Oxydases often fail to give the blue reaction with guaiacum extract in presence of egg-albumen. N. H. J. M.

Root Secretions. By FRIEDRICH CZAPEK (*Landw. Versuchs-Stat.*, 1899, 52, 467—475).—A criticism of Kohn's experiments and conclusions (*Abstr.*, 1899, ii, 791). The author, however, considers that electrochemical methods are of importance in physiology (compare *Jahrb. Wiss. Bot.*, 1896, 29, 321, and 1898, 32, 210; also *Ber. deut. bot. Ges.*, 1897, 15, 516). N. H. J. M.

Action of Leguminous Root Nodules in Water Cultures. By FRIEDRICH NOBBE and LORENZ HILTNER (*Landw. Versuchs-Stat.*, 1899, 52, 455—465).—Experiments made with *Robinia pseudacacia* showed, in accordance with what had been previously observed, that root nodules were of little use to the host plant when grown in water culture. The structure of the nodules is altered, and they are filled with water instead of air. On pouring off some of the solution, so as to expose the upper nodules to air, the plant recovered in a few days, and soon produced new leaves of a bright green colour. Similar results were obtained by gradually replacing the water by sand; in this case, the recovery of the plants was slower, and was found to be due to the production of fresh nodules.

Whilst the nodules kept under water seemed to increase very little in size, those above the water increased greatly, many being as much as 45—50 mm. in diameter. In some cases, where the development of the nodules was greatest, the plants themselves became unhealthy, presumably owing to the withdrawal of excessive amounts of nutritive substances by the nodules. In the large nodules, the new year's growth was seen to be distinct from the older portions, and it is thought that in the case of trees a new growth in the nodules is essential for the continued supply of nitrogen.

When nodules which had been kept above the water (in 1897), and were consequently normal, were afterwards (May, 1898) covered with the solution, the growth of the plants was checked, probably owing to the nodules being prevented from forming new growth.

The results make it evident that it is in the nodules, and not in the leaves, that free nitrogen is fixed. N. H. J. M.

Physiological Functions of Solanine. By G. ALBO (*Ann. Agron.*, 1899, 25, 621—622; from A. Borzi, *Contrib. biol. veg.*, 1899, 2, Part 3).—Solanine occurs in all parts, especially in the grain, of several varieties of *Solanaceae* cultivated under ordinary conditions.

It decreases in amount during germination, and again increases when the plant is well developed. When the plants are screened from light, solanine is found in the shoots during the first period of development, but diminishes in quantity as the reserve substances are used up, and finally disappears altogether; the same occurs in presence of light when the surrounding air is freed from carbon dioxide.

When seeds of *Solanum sodomaeum* are germinated in the dark until all the solanine has disappeared, and then exposed to light, solanine is again observed as soon as the chlorophyll is well developed. *Solanum melongena*, *S. tuberosum*, and *S. lycopersicum* gave similar results.

It is concluded that solanine is not a migratory form of proteid substances, but a true reserve substance, which the plant utilises during early periods of growth, possibly after hydrolysis by acids or some diastase. Its physiological function is totally different from that of asparagine.

N. H. J. M.

Distribution of Lithium in Plants. By ERICH TSCHERMAK (*Chem. Centr.*, 1899, ii, 1127; from *Zeit. Landw. Versuchs-Wesen. Oesterr.*, 2, 560—572).—A large number of plants from the neighbourhood of Halle a/S and Geneva, and of plants which only occur in Austria, were examined. The results indicate that lithium occurs in plants to a far greater extent than was supposed. In accordance with Focke's observations, lithium is found only in the leaves, the finer portions of the stems, the flowers, and fruit. A list of plants is given in the original paper.

N. H. J. M.

Copper in Plants. By D. T. MACDOUGAL (*Exper. Stat. Record*, 1899, 11, 24; from *Bot. Gaz.*, 1899, 27, 68—69. Compare *Abstr.*, 1896, ii, 486).—The dry wood of a dead specimen of *Quercus macrocarpa* was found to contain nearly 0.05 per cent. of copper which was visible as reddish-brown particles in the tracheides, vessels, and medullary parenchyma. Plants grown in ordinary soils may contain 0.003 per cent. of copper (in the dry matter), whilst according to Lehmann (*loc. cit.*) as much as 0.056 per cent. of copper may be present in plants growing in soils containing much copper.

N. H. J. M.

Presence of Vanadium, Molybdenum, and Chromium in Plants. By EUGÈNE DEMARÇAY (*Compt. rend.*, 1900, 130, 91—92).—The ash of Scotch fir, silver fir, vine, oak, poplar, or horn-beam, when treated with boiling water, gives a solution from which hydrogen sulphide precipitates a brown substance, which is soluble in hydrochloric acid. On spectroscopic examination of this hydrochloric acid solution, vanadium, molybdenum, and chromium are found to be present, together with traces of silicon, aluminium, manganese, and zinc.

H. R. LE S.

Green Pigment of Amanita Muscaria. By ARTHUR B. GRIFFITHS (*Compt. rend.*, 1900, 130, 42).—*Amanita (Agaricus) muscaria* contains a green pigment of the composition $C_{29}H_{20}O_{10}$, which dissolves in chloroform and ether, but the solutions show no characteristic absorption bands.

C. H. B.

Poisonous Properties of Sodium Chloride and Sea-water towards Plants. By HENRI COUPIN (*Exper. Stat. Record*, 1899, 11, 24; from *Rev. Gen. Bot.*, 1898, 10, 177—190).—Solutions containing 0.125—5 per cent. of sodium chloride were employed. The toxic strength for the different plants were: vetches, 1.1; peas, 1.2; maize, 1.4; wheat, 1.8, and lupins, 2.2 per cent.

Beta maritima and *Cakile maritima* were killed by a 4 per cent., and *Atriplex hastata maritima* by a 5 per cent. solution. These plants can withstand the amounts of sodium chloride which usually exist in sea-water.

The toxic strength of magnesium chloride and sulphate for these maritime plants is about 2.5 and 3 per cent. respectively.

N. H. J. M.

Effect of Food on the Quality of Milk. By E. O. ARENANDER (*Exper. Stat. Record*, 1899, 11, 184—185; from *Nord. Mejeri. Tidn.*, 1899, 14, 76—77 and 91).—The results of about 2000 analyses of milk showed that the percentage of fat may be reduced 1—2 per cent. below the normal by insufficient food. In Norrland (Sweden), the cows are fed from January to May on a small allowance of poor hay, from June to September on pasture, and from October to December they are liberally fed in stalls. The average amounts of fat found during the three periods are 3.2—3.3, 3.71—4.25, and 3.32—3.52 per cent. Whilst poor feeding will reduce the amount of fat, it is not believed that the fat can be increased above the normal by increasing a normal ration.

N. H. J. M.

Effect of Food on the Quality of Butter. By JOSEF L. HILLS (*Exper. Stat. Record*, 1899, 11, 385; from *Vermont Stat. Rep.*, 1898, 347—350).—The cows received, besides hay and silage, (1) gluten meal, maize meal, and wheat bran; (2) maize and bran; (3) cotton seed, linseed meal, maize, and bran; (4) bran and cotton-seed meal and (5) bran. The butter made from cows fed on ration (4) ranked lowest.

N. H. J. M.

Natural Butter, showing the Sesamé Oil Reaction. By ANTON SCHEIBE (*Bied. Centr.*, 1899, 25, 858; from *Milchzeit.*, 1897, No. 47).—A cow which received, in addition to hay, 2 kilos. of sesamé cake for a week, yielded butter which showed distinctly the Baudouin sesamé oil reaction. Pure butter is therefore liable, in Germany, to be considered as adulterated with margarine when sesamé cake is employed as food.

N. H. J. M.

Sesamé Oil Reaction of Pure Butter. By PAUL VIETH (*Bied. Centr.*, 1895, 25, 859; from *Milchzeit.*, 1898, 536).—Lehmann (*Protokoll d. Sitz. d. Centralausschusses d. k. Landw. Ges. Hann.*, Jan., 1898) showed that feeding with sesamé cake resulted in milk fat which showed the Baudouin reaction, although very slightly. Reactions of varying strength, which, if not identical with the sesamé oil reaction, differ from it inappreciably, have been universally obtained. It is therefore concluded that the admixture of sesamé oil with margarine is not suitable as a means for enabling the adulteration of butter with margarine to be detected.

N. H. J. M.

Effect of Feeding Cotton and Sesamé Cake on Butter. By THOMAS E. THORPE (*Journ. South-Eastern Agr. Coll. Wye*, 1899, No. 8, 64—65).—Three lots of four cows each received, first, linseed cake, and, subsequently, linseed, cotton and sesamé cake respectively. At the commencement, the cows received 4 lbs. of cake, in addition to dried grains (4 lbs.), bean meal (2 lbs.), hay and straw (25 lbs.), and roots (40 lbs.); afterwards, the cotton and sesamé cake were increased to 6 and 7 lbs., the bean meal being discontinued, and the grains reduced in quantity. Finally, the cows went to grass, and the oil cake was discontinued.

Under the influence of cotton cake, butter was obtained which gave the cotton seed oil reaction; the reacting substance passed into the milk within 24 hours after the cake feeding began, and continued to do so for several days after the cake was discontinued. In the case of mixed milk from several cows, the reaction is, as a rule, less than would be due to 1 per cent. of the oil. In most cases, it would be possible to differentiate between the cotton seed oil reaction due to feeding cotton cake and that due to any considerable addition to butter of margarine containing cotton-seed oil.

In the case of sesamé cake, the butter gave no sesamé oil reaction, even after the feeding, with as much cake as the cows would eat, had been continued for over two months. With large amounts of cake, the yield of milk was well maintained for some time, but the quality deteriorated and became poor in fat. As the flow of milk decreased, the cows began to get very fat.

N. H. J. M.

Nutritive Value of Asparagine. By B. K. BRUTSKUS (*Exper. Stat. Record*, 1899, 11, 275—276; from *Zap. Novo-Alexandri Inst. Selsk. Khoz. Lyesov.*, 1898, 11, 145—228. Compare Bahlmann, *Abstr.*, 1887, 512).—Experiments are described in which rabbits were fed with rice starch (640), birch sawdust (120), sugar (75), oil (30), salt (20), hay ash (20), barley ash (10), and water (34.4 grams), both with addition of and without, asparagine (150 grams). When no asparagine was given, the amount of starch was 725 grams. The nitrogen of the fæces and urine were determined.

The results indicate that the value of asparagine is much greater than that of an isodynamic amount of starch, and, that whilst asparagine cannot take the place of protein in a diet, it may economise about one-fourth of the protein in the body which would be consumed if the food contained no nitrogen.

N. H. J. M.

Vegetation Experiments in 1897. By DMITRI N. PRIANISCHNIKOFF (*Bied. Centr.*, 1899, 25, 809—815. Compare *Abstr.*, 1899, ii, 514).—Sand culture experiments were made in which barley was manured with the same amount of nitrogen in different forms. The relative yields with the different manures were: sodium nitrate, 100; blood meal, 56; stable manure, 15; and fæces, 6.5. Further experiments are described in which the various manures (N=0.5 gram) were applied to a poor, sandy soil manured with potassium sulphate. Taking the yield of the pots which had no nitrogen as 100, the yields were as follows: urine, 182; green manure (clover leaves), 156; stable

manure, 150 ; ammonium sulphate, 132 ; sodium nitrate, 126 ; blood meal, 113 ; and faeces, 86.

As regards the effect of different amounts of water in the soil on the growth of plants, it is concluded that dryness of the soil does not cause greater rapidity of growth, and that early crops in dry seasons are due to increased temperature and greater amount of light.

N. H. J. M.

Influence of Fermentation on the Value of Hay. By FRIEDRICH HOLDEFLEISS (*Mitt. Landw. Inst. kgl. Univ. Breslau*, 1899, *Heft.* 1, 59—74).—Haymaking is essentially a process of fermentation in which the amount of crude fibre is diminished whilst the remaining crude fibre is probably loosened. The amounts of other food constituents, especially the nitrogen-free extract, are relatively increased, and the hay not only acquires a better taste but its digestibility is probably greater when properly made than when dried too quickly.

Fermentation seems to diminish the amount of pentosans in hay, or at any rate in grass hay. In the one experiment with clover hay, the amount of pentosans differed very slightly in the dry matter of hay which took 9 and 16 days respectively to make (17·69 and 17·26 per cent.).

N. H. J. M.

Cultivation of White Lupins. By PIERRE P. DEHÉRAIN and E. DEMOUSSY (*Compt. rend.*, 1900, 130, 20—24).—The results of experiments extending over three years showed that white lupins only develop satisfactorily when their roots are provided with nodules, and that the nodules vary in form and size according to the source of inoculation. Nodules were produced by inoculation from vetches and from lucerne as well as from soil.

In suitable soil, the nodules are small and contain forked bacteroids, which were not found in the large nodules ; vigorous plants are then produced the dry matter of which may contain as much as 3 per cent. of nitrogen. Plants with large, smooth nodules surrounding the root contained 2 per cent. of nitrogen in the dry matter. In some cases, very large nodules like raspberries were produced ; these seem to act as parasites, the plants being much less nitrogenous ($N = 0·6—0·8$ per cent. in the dry matter).

Hairy vetch inoculation produced hemispherical nodules, whilst lucerne inoculation produced detached nodules ; the dry matter of the host plants contained 1 per cent. of nitrogen.

The frequent failure of white lupins at Grignon is attributed to absence of suitable microbes in the soil rather than to the presence of lime.

N. H. J. M.

Experiments on Potatoes. By JAMES S. GORDON (*Cheshire County Council Rep.*, 1899).—Farmyard manure gave much better results than artificial manures alone, but addition of artificial manures to farmyard manure was beneficial. Ammonium sulphate gave better results, both as regards yield and quality, than sodium nitrate, and potassium chloride produced a greater yield and better potatoes than kainite.

N. H. J. M.

Tobacco Plant. By JOHANNES BEHBENS (*Land. Versuchs-Stat.*, 1899, 52, 431—454. Compare Abstr., 1899, ii, 745).—The substance to which the brown colour of tobacco is due is not present in the fresh leaves, but is produced shortly before the natural death of the leaves when the carbohydrates are mostly consumed. When the chromogen is once formed, its oxidation proceeds in the dead leaf when sufficient moisture is present; light is unnecessary. The supposition that only ripe leaves can become brown is shown to be incorrect. Green leaves which have been killed by chloroform are unable to acquire a brown colour.

Tobacco leaves contain glucosides (probably several) and emulsin. It is thought probable that the chromogen is produced from a glucoside (compare O. Loew, *Rep.* No. 59, *U.S. Dept. of Agric.*, 1899).

N. H. J. M.

Experiments with Tobacco Fertilisers, 1892—1896. By EDWARD H. JENKINS (*Ann. Rep. Agr. Expt. Stat. Connecticut*, 21, for 1897, 243—256).—Whilst no manure will always produce the best results even on the same land, owing to the effects of climate, certain manures gave on the whole better results than others.

The liberal, but not greatly excessive, amounts of available plant food required for a good crop of tobacco may be applied in a variety of forms, and occasional changes in the forms of nitrogen and potash may be advantageous. Large amounts of chlorides and sulphates injure the quality of the leaves.

N. H. J. M.

Effect of Fertilisers on the Composition of Wrapper Leaf Tobacco. By EDWARD H. JENKINS (*Ann. Rep. Agr. Expt. Stat. Connecticut*, 20, for 1896, 322—333).—Field experiments are described in which the same manures (mostly vegetable matters, with and without addition of minerals) were applied to the same plots for four or five years.

The short wrappers were found to contain rather more ash, ether extract, and nitrogen-free extract than the long ones, and correspondingly less fibre, nicotine, nitrates, and proteids.

The different manures had no effect on the amounts of ether extract, fibre, and nitrogen-free extract; but an excess of nitrogenous manure resulted in a much larger percentage of nitrates in the leaf, amounting in one case to 1.56 per cent. of nitric nitrogen, and the percentages of proteids and nicotine were also raised. Potash manures increased the amount of potassium in the leaf ash, but the effect varies greatly with the same quantity of potassium in different forms. The leaves of plants manured with potassium sulphate may contain even less potassium than those of plants which receive half the amount of potassium in the form of carbonate. The leaf ash containing the highest amount of calcium (and the least amount of potassium) was obtained by manuring with potassium sulphate.

Tobacco manured with stable-manure yielded an ash containing five times as much chlorine as the ash from any of the other plots.

N. H. J. M.

Manurial Experiments on Permanent Pasture. By W. J. MALDEN (*East Sussex County Council Rep.*, 1899).—The soil on which the experiments were made was more or less exhausted by dairying and stock raising, and the pasture poor. As regards mineral manures, phosphoric acid, in which the soil was deficient, gave much the best results when applied in the form of basic slag. Kainite had very little effect.

Nitrogen as sodium nitrate was useless without phosphates, whilst ammonium sulphate alone slightly improved the quality of the grasses. In conjunction with basic slag, sodium nitrate produced inferior grasses as compared with basic slag and ammonium sulphate.

Farmyard manure, in conjunction with basic slag, gave a great increase in weight, and at the same time improved the quality.

Detailed results of botanical separations of the herbage of the various plots are given as well as percentages of gramineous, leguminous and miscellaneous plants.

N. H. J. M.

Field Experiments for determining the general Manurial Requirements of Typical Soils with Reference to Chemical Soil Analysis. By P. BAESSLER (*Bied. Centr.*, 1899, 25, 815—820; from *Ber. Agrik.-Chem. Versuchs-Stat. Köslin* for 1897, 45).—Field experiments were made on soils of different kinds after the soil had been analysed by the official methods. The total and citrate soluble phosphoric acid, the total calcium and calcium carbonate, potassium soluble in 10 per cent. hydrochloric acid, and the nitrogen were determined.

The results of field experiments showed that relations existed between the effects of potash manures and the percentage of potassium in the soil; in the case of phosphoric acid, the results were more irregular, whilst with nitrogen the results were indefinite.

With lime and complete minerals, 21 per cent. of the phosphoric acid was utilised; in absence of potassium and in absence of nitrogen, only 18 and 14 per cent. respectively of the phosphoric acid was utilised. When nitrogenous manure alone was applied, only 28 per cent. of the nitrogen of the manure was taken up by the crop, the amount being increased to 59, 74, and 86 per cent. respectively, when in addition to nitrogen, potassium, phosphoric acid, and complete minerals respectively were applied.

Analyses of the soils and of the crops are given.

N. H. J. M.

Pot Experiments on the Action of Lime and Magnesia in Burnt Lime and Marls. By RICHARD ULBRICHT (*Landw. Versuchs-Stat.*, 1899, 52, 383—430).—A large number of experiments are described in which different amounts of calcium and magnesium oxides and carbonates were applied to different plants, chiefly lupins.

Even with abundance of potash, lupins were injured by slight amounts of lime, and 500 or 1,000 kilos. of lime per morgen caused a considerable reduction in the yield. Lime, containing magnesia (250 kilos.) gave irregular results, but 500 kilos. of the mixtures much reduced the yield, especially when the percentage of magnesia was high. Similar results were obtained with barley and vetches. In experiments with lupins after radish, it was found that the injurious effects of excessive liming extended to the second year.

Application of powdered magnesite (MgCO_3 , 76.4; CaCO_3 , 18.4 per cent., 500 kilos. per morgen) applied in the spring increased the yield of lupins considerably.

Calcium carbonate, as marls and powdered marble, invariably reduced the total yield of the leguminous plants when applied in large amounts, but in the case of lupins to a less extent than burnt lime. (compare R. Heinrich : *Mergel und. Mergeln Berlin*, 1896).

Analytical Chemistry.

Ammonium Dithiocarbonate as a Substitute for Hydrogen and Ammonium Sulphides. By M. VOGTHER (*Zeit. anal. Chem.*, 1900, 39, 44; from *Ber. deutsch. pharm. Ges.*, 8, 228).—The reagent is prepared by shaking 5 parts of carbon disulphide with 9 parts of 22 per cent. ammonia until it is completely dissolved. Hydrochloric or acetic acid is then added until the precipitate produced dissolves only slowly, and the mixture is diluted with water to three or four times its volume. In most, but not in all cases, this reagent can be employed instead of hydrogen sulphide or ammonium sulphide, and in the original paper a scheme for its employment in qualitative analyses is drawn up.

M. J. S.

Volumetric Estimation of Hydrogen. Diffusion of a Solid into a Gas. By ALBERT COLSON (*Compt. rend.*, 1900, 130, 330—332. Compare this vol., ii, 140).—Silver hydroxide, obtained by adding a solution of potassium hydroxide to a solution of silver nitrate, when dried at 110° — 120° , has very nearly the composition AgOH . This compound absorbs hydrogen even at 0° , but more readily when heated at 100° , water and metallic silver being produced; neither methane, ethane, nor oxygen are absorbed by it, so that it may be used for the estimation of hydrogen in a mixture of one or more of the above gases.

At 0° , the rate of absorption of hydrogen by silver hydroxide does not vary with the amount of surface of solid in contact with the gas. When the amount of hydroxide present is from 2.0—0.75 grams, then the rate of absorption is practically constant, and this may be explained, if we assume that, in the presence of hydrogen, the hydroxide exerts a true vapour pressure. The reduced silver is deposited along the sides of the tube and not at the place where the hydroxide originally was, and since this phenomenon occurs even at 0° , it must be regarded as a true example of the diffusion of a solid into a gas.

H. R. LE S.

Iodometric Process for the Analysis of Mixtures of Chlorate and Hypochlorite. By HUGO DITZ and HEINRICH KNÖPFELMACHER (*Zeit. angew. Chem.*, 1899, 1195, 1198, 1217—1220).—Chlorates, in the presence of potassium iodide and hydrochloric acid, liberate iodine,

but the reaction is slow and uncertain and therefore not suitable for quantitative purposes. If, however, a solution of a chlorate is mixed with potassium bromide and a sufficiency of hydrochloric acid, bromine is liberated quantitatively and may then be estimated by the usual iodometric method. Hypochlorites behave similarly. 25 c.c. of the solution containing approximately 0.06 gram of the chlorate are mixed in a generating flask with 20 c.c. of a 5 per cent. solution of potassium bromide and 50 c.c. of strong hydrochloric acid are added from a separating funnel, the air which escapes from the flask passing through a bulb containing solution of potassium iodide to retain any bromine vapour. After 1 hour, the liquid is titrated as usual. Any hypochlorite is estimated by the Penot method and allowed for.

L. DE K.

Estimation of Sulphuric Acid in the presence of Iron. III. By FRIEDRICH W. KÜSTER and A. THIEL (*Zeit. anorg. Chem.*, 1900, 22, 424—444. Compare Abstr., 1899, ii, 247 and 611).—A large number of experiments on the estimation of sulphuric acid in the presence of iron gave the following results. When a hot solution of sulphuric acid containing ferric salts is precipitated with barium chloride, the barium salt of the complex ferrisulphuric acid, $\text{Ba}(\text{Fe}_2\text{S}_2\text{O}_8)_2$, is contained in the precipitate, and this causes a loss which may amount to as much as 7 per cent. of the sulphuric acid. This formation of the complex salt can be prevented (i) by previous precipitation of the ferric salt with ammonia (ii) by converting the ferric salt into a complex salt, as, for instance, with ammonium oxalate; (iii) by precipitation in the cold, and (iv) by adding the hot solution of sulphuric acid and ferric salt to the barium chloride. The conversion of the ferric salt into ferrous salt by means of zinc, &c., is not recommended, for although the loss due to the formation of the complex acid is avoided, other much smaller errors are introduced by the precipitation of zinc sulphate and ferrous sulphate together with the barium sulphate.

E. C. R.

Estimation of Nitric Acid in Water. By MAX HÖNIG (*Chem. Centr.*, 1199, ii, 1032; from *Festschr. Hochschule Brünn*, 1899).—The Marx-Trommsdorff process is recommended. The sample should contain about 0.001 gram of nitric pentoxide per 25 c.c. and must therefore, if needful, be suitably diluted or concentrated.

The indigo solution is prepared by dissolving 1.4200 grams of sodium or 1.5407 grams of potassium indigotintrisulphonate in 1 litre of water; of this, 5.5 c.c. mixed with 50 c.c. of sulphuric acid are used in the test.

L. DE K.

Estimation of Nitrates. By CHARLES M. VAN DEVENTER (*Zeit. physikal. Chem.*, 1899, 31, 50—58).—A new method is described, depending on the brown coloration produced on mixing solutions of ferrous sulphate and a nitrate in presence of sulphuric acid. If the ferrous sulphate solution is gradually added to the nitric acid solution, the brown coloration, which is due to the evolved nitric oxide dissolving in the ferrous sulphate solution, is not persistent until all the nitric acid has been used up in oxidising the ferrous salt. As the accuracy of the

reaction necessitates the absence of air, the method is carried out as follows. A non-graduated tube, open at one end and fitted at the other with a tap and funnel, is filled with mercury and placed funnel upwards in a mercury trough; into this tube about 1 c.c. of bromoform is introduced in order that the nitric and sulphuric acids may not come into direct contact with the mercury. By means of the funnel and tap, a measured volume (5 c.c.) of the nitrate solution, and, after the funnel has been washed with a little water, 8 c.c. of concentrated sulphuric acid are brought into the tube. Standardised ferrous sulphate solution is then allowed to flow up into the tube from a burette with a turned up point; when the end of the reaction is near, a further 8 c.c. of concentrated sulphuric acid are added by the funnel and the addition of the ferrous solution carefully continued until the liquid in the tube is of a distinct reddish-brown tint, the volume of ferrous solution added being read off. The presence of an excess of ferrous salt is confirmed by pouring the contents of the tube into water and adding potassium ferricyanide solution. Although it is known that 1 mol. of nitric acid oxidises 3 mols. of ferrous salt, it is best to determine the strength of the ferrous solution by carrying out a test with a nitrate solution of known strength. The funnel tube should not be too long, or the contents are liable to become too cold.

As regards substances interfering with the process, coloured solutions are of course inadmissible, as also is the presence of compounds giving a precipitate or coloration with sulphuric acid. Any carbonates in the liquid to be tested should be removed by the addition of a little acid.

T. H. P.

Detection and Estimation of very small quantities of Nitrous Acid. By HUGO ERDMANN (*Ber.*, 1900, 33, 210—215).—1-Amino-8-hydroxynaphthalene-4:6-disulphonic acid, which is prepared from 1:3:5-naphthalenetrisulphonic acid by nitration, reduction and treatment with soda (*Chem. Ind.*, 1898, 523), gives in acid solution a bright Bordeaux-red coloration with nitrous acid. The reaction is more delicate than that given by the other reagents proposed for the detection of nitrous acid in water, and is employed in the following manner: 50 c.c. of the water to be tested are mixed with 5 c.c. of an acidified solution of sodium sulphanilate (containing 2 grams of the sodium salt per litre) and about 0.5 gram of the solid aminonaphtholdisulphonic acid added in the form of acid sodium salt mixed with sodium sulphate. The coloration reaches its maximum intensity in about an hour and may be compared colorimetrically with that produced by a known amount of a standard nitrite solution.

A. H.

Estimation of Phosphoric Acid Soluble in a 2 per cent. Solution of Citric Acid. By ALEXANDER HERZFELD (*Chem. Centr.*, 1899, ii, 1139; from *Zeit. Ver. Rüben-Zuck. Ind.*, 1899, 862—863).—When basic slags are treated with a 2 per cent. solution of citric acid, a notable amount of silicic acid dissolves, and passes first into the phosphomolybdate and afterwards into the magnesium phosphate precipitate. In one instance, the amount of phosphoric acid as estimated in this manner was found to be 3.6 per cent. in excess of the truth.

L. DE K.

Phosphates and the Humic Acid Process. By WILHELM HOFFMEISTER (*Landw. Versuchs-Stat.*, 1899, 52, 329—345. Compare Abstr., 1898, ii, 538).—In the extraction of phosphates by ammonium humate, the lime of the calcium phosphate is converted into carbonate or humate, whilst the phosphoric acid enters into combination with ammonia and alkalis. The solution takes place most readily in such phosphates as superphosphate and basic slag.

Silicic acid always dissolves along with the phosphoric acid, and as a rule the silica dissolved increases with the phosphoric acid. The presence of soluble silica increases the solubility of the phosphoric acid, so that more phosphoric acid is dissolved when fresh sand (containing soluble silica) is employed than with exhausted sand. It was found that whilst 150 grams of pure sand yielded 0.0104 gram of silica soluble in ammonium humate, the addition of 5 grams of sodium phosphate increased the amount of silica to 0.0368 gram.

It is probable, therefore, that in soils the soluble silica is of importance in increasing the availability of the phosphoric acid, and it is supposed that the supply of soluble silica becomes periodically exhausted.

Estimations of phosphoric acid and potash in soil were made by the humic acid method, and the results compared with the amounts dissolved by hydrochloric acid.

N. H. J. M.

Biological Detection of Arsenic in Skin, Hairs, Perspiration, and Urine. By W. SCHOLTZ (*Chem. Centr.*, 1899, ii, 1032—1033; from *Berl. klin. Woch.*, 36, 913—915).—Abba's process of acting on these substances with the fungus *Penicillium brevicaulis* and observing the garlic odour given off after some time if arsenic should be present, is much more delicate than Marsh's test: even 1/200—1/500 part of a milligram may still be detected.

The odour of urine, which interferes somewhat with the test, may be removed by means of animal charcoal.

L. DE K.

Stannous Chloride and Bettendorf's Test for Arsenic. By F. DIETZE (*Zeit. anal. Chem.*, 1900, 39, 44—45; from *Pharm. Zeit.*, 1897, 191).—Stannous chloride, to be fit for use in Bettendorf's test, must be free from ammonium salts, sulphates, iron and arsenic, all of which, besides other impurities, may be present in the commercial salt. When a solution of 1 gram dissolved in 5 c.c. of hydrochloric acid of sp. gr. 1.19, is boiled for several minutes, the solution must remain clear and colourless for an hour. When titrated with iodine, it should show a purity of at least 98.5 per cent.

M. J. S.

Bettendorf's Arsenic Test. By HENRIK ENELL (*Zeit. anal. Chem.*, 1900, 39, 45; from *Nord. Farm. Tidsskrift.*, 1896, No. 12).—Arsenic acid is much more slowly reduced by stannous chloride than is arsenious acid; heat accelerates the reaction. To detect traces of arsenic, the author filters the liquid through a very small filter, which is then spread out upon white paper. Arsenic appears as a reddish-brown stain.

M. J. S.

Bettendorf's Arsenic Test. By G. FREERICHs (*Zeit. anal. Chem.*, 900, 39, 45—46; from *Apoth. Zeit.*, 1897, 176).—The reaction is

capable of detecting 0.06 milligram of arsenic in the form of arsenic acid or 0.013 milligram in the form of arsenious acid. Gutzeit's test is equally sensitive. The test cannot be absolutely depended upon; traces of mercury may be mistaken for arsenic. M. J. S.

Constitution of the Ammonium Magnesium Arsenate of Analysis. By MARTHA AUSTIN (*Amer. J. Sci.*, 1900, [iv], 9, 55—61).—A precipitate of ideal condition may be obtained by adding to the faintly acid solution of an arsenate (not exceeding 200 c.c.) magnesia mixture (110 grams of crystallised magnesium chloride, and 58 grams of ammonium chloride are dissolved in water and diluted to 2 litres; 10 c.c. of ammonia are then added) amounting to about 30 c.c. in excess of that theoretically needed. The precipitate is collected and transferred to the filter by means of the filtrate, when washing with about 25 c.c. of faintly ammoniacal water will be sufficient to free it from soluble impurities. No arsenic will be found in the filtrate or washings. If, however, the liquid contains excess of ammonium chloride, a precipitate is obtained which is richer in ammonia and yields on ignition a residue containing some meta-arsenate. Much ammonium chloride also increases the solubility of the compound, although this is again lessened by excess of magnesia mixture. L. DE K.

Estimation of Carbon, Copper, and Manganese in Iron By OTTO HERTING (*Zeit. angew. Chem.*, 1899, 1193—1194).—A reply to Murmann on the subject of the estimation of carbon, copper, and manganese in pig-iron, wrought-iron, and steel.

Heid's process is recommended for the estimation of the carbon. The iron is dissolved in copper-ammonium chloride, the impure carbon is collected on an asbestos filter, and well washed with hot water, and then with alcohol and ether. The filter is transferred to a Rose's crucible, dried at 120°, and weighed; the carbon is then burnt in a current of oxygen, and is represented by the loss in weight. To estimate graphite, the sample is dissolved in dilute nitric acid and the insoluble matter treated as above. Murmann's statement, that the copper cannot be estimated in the liquid obtained when dissolving the sample in hydrochloric acid for the purpose of estimating the sulphur, is baseless, as small quantities of copper entirely dissolve.

Manganese is best estimated volumetrically.

L. DE K.

Microchemical Detection of Potassium, Rubidium, Cæsium, Indium, and Thiosulphates. By A. C. HUYSE (*Zeit. anal. Chem.*, 1900, 39, 9—11).—Sodium bismuth thiosulphate, prepared as follows, is a highly sensitive reagent for the detection of potassium, cæsium, and rubidium. A little basic bismuth nitrate is dissolved in the smallest possible quantity of hydrochloric acid, and water is added until a thick, white precipitate is formed, which is then dissolved by the addition of sodium thiosulphate, avoiding excess. Strong alcohol is added until a permanent turbidity is produced, and this is cleared up by adding a little water. The reagent must be freshly prepared. The liquid to be tested must either be evaporated to dryness on a glass slide, or mixed with the same

proportion of alcohol as is contained in the reagent. Salts of potassium, caesium, and rubidium give with this reagent characteristic, yellowish-green, acicular, monoclinic crystals. Salts of the alkaline earths produce a white precipitate, which cannot be confused with the above, but salts of ammonium and the other metals give no precipitate, and do not interfere with the test. Visible crystals were obtained from 0.002 mg. of potassium nitrate.

Cæsium chloride produces, in solutions of indium sulphate containing a little free sulphuric acid, octahedra of caesium indium alum. Ammonium fluoride also produces octahedral crystals, resembling those obtained from aluminium salts. For the employment of these two tests, aluminium, and, for the latter, iron, must be absent. Mercuric thiocyanate is also a sensitive reagent, yielding crystals which differ somewhat from the zinc and cadmium mercuric thiocyanates. Oxalic acid and ammonium oxalate are highly sensitive tests, producing crystals which resemble zinc oxalate, but are insoluble in ammonia. These two reactions are only characteristic of indium in the absence of zinc, cadmium, cobalt, copper, and iron.

Minute quantities of sodium thiosulphate (0.01 mg.) can be detected by adding thallous nitrate in excess, when tabular and cruciform crystals are formed. Sulphates, nitrates, and acetates do not interfere with the reaction, but haloid salts prevent it.

M. J. S.

Precipitation of Silver Chloride by Dimercurous Ammonium Chloride. By F. LETEUR (*Compt. rend.*, 1900, 130, 248—250).—In the ordinary method for the detection of silver in the presence of mercurous salts, the chlorides of the two metals are treated with ammonia, and if the silver chloride is present in relatively large quantities, a considerable amount is rendered soluble. When the mercurous salt preponderates, a large proportion, or even the whole, of the silver chloride remains undissolved, the precipitate of dimercurous ammonium chloride always retaining a notable quantity of the silver salt; under these conditions, the insoluble portion is treated with aqua regia, in order to convert the mercury compound into soluble mercuric chloride, and the final residue is examined for silver.

G. T. M.

Estimation of Calcium by the Citrate Method. By MAX PASSON (*Zeit. angew. Chem.*, 1899, 1153—1155. Compare Abstr., 1898, ii, 642).—The process has been slightly modified. Instead of a 10 per cent., a 2 per cent. solution of citric acid is employed. The solution containing the calcium, and also iron, aluminium, and perhaps phosphoric acid, is neutralised with ammonia, and the precipitate formed redissolved by means of the citric acid solution; 20 c.c. more of this are then added, and after diluting with water, the solution is heated to boiling and precipitated with large excess of ammonium oxalate.

Manganese, if present to any large extent, must be previously removed. It has been found that the results are trustworthy; those obtained by precipitating the iron and aluminium by the acetate method, and then precipitating the calcium in the filtrate, are in excess of the truth.

L. DE K.

Estimation of Thallium as the Acid and Normal Sulphates. By PHILIP E. BROWNING (*Amer. J. Sci.*, 1900, 9, 137—138).—Thallium may be accurately weighed as normal sulphate, as already suggested by Crookes. The solution containing thallous nitrate or chloride is mixed with sulphuric acid, evaporated to dryness, and gradually heated to redness, until the weight is constant. Normal thallous sulphate is thus formed.

The author states that, by drying at 220—240° to constant weight, the acid sulphate is obtained, which may then be weighed. The results are quite satisfactory. L. DE K.

Detection of Copper. By DIOSCORIDE VITALI (*Chem. Centr.*, 1899, ii, 990—991; from *Boll. Chim. Farm.*, 38, 665—668).—See this vol., ii, 208.

Estimation of Mercury in Urine. By SCHUMACHER and W. L. JUNG (*Zeit. anal. Chem.*, 39, 12—18).—A litre of the urine is warmed on the steam-bath, with addition of 100 c.c. of concentrated hydrochloric acid and 15—20 grams of potassium chlorate, in a flask with inverted condenser. When the mixture, which at first is deep red, has become pale coloured, it is left for 12 hours in the cold to complete as far as possible the destruction of the organic matter by the nascent chlorine. It is then warmed to expel most of the chlorine, and precipitated with about 100 c.c. of strong, clear, stannous chloride solution. The precipitate is collected on an asbestos filter, which is then transferred to a small flask and warmed with potassium hydroxide solution. Potassium chlorate and excess of hydrochloric acid are again added, by which means the last traces of organic matter are destroyed and the mercury again dissolved. The solution is filtered, and again reduced with stannous chloride. The mercury is now collected on a filter of gilt asbestos mixed with small granules of gold. The gilt asbestos is prepared by steeping purified asbestos in a strong solution of gold chloride, and reducing by heating for 15 minutes in pure hydrogen; it is then washed with dilute hydrochloric acid and hot water, and dried. Such a filter arrests every trace of mercury. The filter is then washed with hydrochloric acid, water, alcohol, and ether, and dried in a current of dry air until its weight is constant. It is then heated strongly enough to expel the mercury from the gold amalgam and again weighed. Test analyses in which 2.5 and 4.4 mg. of mercury (in the form of mercuric chloride) were added respectively to a litre of urine, gave fairly close results, but when less than 1 mg. is present the results are only approximate. M. J. S.

New Method of Estimating Aluminium. By ALFRED STOCK (*Compt. rend.*, 1900, 130, 175—178, and *Ber.*, 1900, 33, 548—553).—When a neutral or slightly acid solution of aluminium sulphate is treated with excess of a solution containing potassium iodide (5 mols.) and potassium iodate (1 mol.), iodine is liberated, and aluminium hydroxide is precipitated in accordance with the following equation: $\text{Al}_2(\text{SO}_4)_3 + 5\text{KI} + \text{KIO}_3 + 3\text{H}_2\text{O} = 2\text{Al}(\text{OH})_3 + 3\text{K}_2\text{SO}_4 + 3\text{I}_2$. The free iodine is removed by adding sodium thiosulphate, and the mixture heated to boiling, the hydroxide being thus obtained as a flocculent precipitate readily filtered and washed. The precipitation is complete, and unless

a large excess of sulphate is present in the original solution, the product is free from sulphur. When phosphoric acid is present, the precipitate, after ignition, has the composition $2\text{Al}_2\text{O}_3, \text{P}_2\text{O}_5$. If the mixture is heated for one hour, and if sufficient potassium iodide is added to redissolve the liberated iodine, the use of thiosulphate may be avoided and the aluminium hydroxide thus produced is even more amenable to subsequent treatment, but on account of the difficulty attending the filtration of a hot solution of iodine the author recommends the first method.

G. T. M.

Estimation of Titanic Acid in Iron Ore. By JAS. BRAKES (*J. Soc. Chem. Ind.* 1899, 18, 1097).—One gram of the ore is dissolved in hydrochloric acid, the solution is diluted and filtered; the undissolved matter is fused with potassium-sodium carbonate, the fused mass dissolved in hydrochloric acid and united with the main solution. After nearly neutralising with ammonia, 50 c.c. of sulphurous acid are added, and when the liquid has become colourless it is boiled for 30 minutes, the volume being kept constant with sulphurous acid. This causes a precipitate of titanate of iron, which is then collected and washed with hot water. After burning it in a platinum crucible, it is moistened with dilute sulphuric acid, a few c.c. of hydrofluoric acid are added, the whole is evaporated to dryness to expel any silica, and then strongly ignited; the titanium is then weighed as dioxide.

L. DE K.

Quantitative Separation of Tin, Antimony and Arsenic. By RICHARD MARBURG (*Zeit. anal. Chem.*, 1900, 39, 47—56).—The author reproduces Dancer's paper on this subject (*Abstr.*, 1898, ii, 311) with remarks on the various stages of the process. He confirms the exactness and convenience of the lime method for separating tin from antimony, but regards the separation of arsenic and antimony in the filtrate as less exact, and prefers to operate as follows. The antimony and arsenic are precipitated as sulphides, which after washing are digested with a large quantity of potassium hydroxide. The solution is saturated with chlorine and the two metals then separated by Bunsen's method (*Annalen*, 1878, 192, 317). In this separation the presence of too much hydrochloric acid must be avoided. The antimony pentasulphide must be converted into trisulphide by prolonged heating at 230° in Paul's apparatus (*Abstr.*, 1893, ii, 90), but it is better to convert it into tetroxide. Sulphides of the three metals, when precipitated by hydrogen sulphide from an acid solution, are very slowly attacked by lime-water; it is preferable to redissolve them in colourless potassium sulphide and reprecipitate by an acid in the cold.

M. J. S.

Simplification of the Phenylhydrazine Test for Sugar. By ALBERT NEUMAN (*Chem. Centr.*, 1899, ii, 1033; from *Arch. Anat. Phys. Physiol. Abt.*, 1899, *Suppl.*, 549—552).—5 c.c. of the liquid to be tested, for example, diabetic urine, are mixed with 2 c.c. of acetic acid previously saturated with sodium acetate, 2 drops of phenylhydrazine added, and the liquid concentrated to 3 c.c. When cold, characteristic crystals of the osazone will be noticed if sugar is present.

L. DE K.

Estimation of Sucrose in Condensed Milk. By LEO GRÜNHUT and SEVERIN H. R. RIIBER (*Zeit. anal. Chem.*, 1900, 39, 19—36).—For the estimation of two sugars occurring together, three methods are possible; (1) Estimation of the reducing power before and after inversion; (2) estimation of the optical rotation before and after inversion; (3) estimation of reducing power and rotation without inversion. The authors discuss the advantages of the three methods for the purpose of estimating the sucrose in condensed milk in the presence of the lactose, and find the first and third methods wholly inapplicable. The second method, with certain precautions, gives satisfactory results. The solution must be prepared by treating the condensed milk with boiling water and cooling the solution to exclude the influence of multirotation. Hydrochloric acid is employed for the inversion. If used according to the so-called *Zollvorschrift* (*Zeit. anal. Chem.*, 32), it is found to have no influence on the rotatory power of any of the constituents of normal milk. Both the optical observations must be made at exactly the same temperature; 20° is preferred. Lead acetate, avoiding a large excess, may be employed for precipitating the casein, &c., but the volume of the precipitate must not be neglected. The adoption of Scheibler's method of two different dilutions overcomes this difficulty. Thus, if R is the rotation when the total volume is V , and r when the volume is v , the equation $V - x/v - x = R/r$ gives x , the volume of the precipitate, and, by subtraction, the real volume of the solution. The conventional method of multiplying by the empirical factor 0.962 gives accurate results with only one particular mixture. The Clerget formula employed by Herzfeld, $Z = 100(P - J)/131.84 - 0.05 J$ is to be preferred to $Z = R - J/1.3266$. M. J. S.

Source of Error in the Detection of Sugar in Urine by means of Fehling's Solution. By J. EURY (*Bull. Soc. Chim.*, 1900, [iii], 23, 41—44).—Certain specimens of urine, which are shown by their density and by polarimetric observations to contain notable quantities of sugar, decolorise Fehling's solution when boiled therewith, but yield no precipitate of cuprous oxide. When left to cool, the upper layers of the liquid assume a reddish-brown colour, and a brown precipitate is gradually deposited; this, however, does not take place when the liquid is cooled out of contact with air, nor when the liquid, thus cooled, is afterwards exposed to the air. The reaction is shown to be due to the combination of creatinine and similar bases with cuprous oxide to form soluble compounds, which subsequently undergo oxidation with the precipitation of cupric oxide or a compound thereof with the base. The substances thus interfering with the detection of sugar in urine may be removed by precipitation with mercury, but not with lead salts. N. L.

Caramel Substances. II. Estimation of Caramel in Aqueous Solutions by means of the Spectroscope. By F. STOLLE (*Chem. Centr.*, 1899, ii, 1099; from *Zeit. Ver. Rübenzuck.-Ind.*, 1899, 839—841).—The method of determining the amount of caramel by means of the spectroscope is based on the property of aqueous solutions of this substance of partially absorbing the rays of the blue end of the spectrum. Caramel is insoluble in absolute ethyl alcohol, but easily

soluble in methyl alcohol, hence it may be readily separated from solutions which contain other active substances. The results obtained are accurate within 0.05 per cent. E. W. W.

Estimation of Cellulose in Fæces. By KONRAD MANN (*Chem. Centr.*, 1899, ii, 1139; from *Arch. Hyg.*, 36, 158—165).—The process recommended by Weender, does not yield a pure cellulose, as this still retains nitrogenous matters, notably elastin. L. DE K.

König's Process for the Estimation of Crude Fibre free from Pentosan. By OSCAR KELLNER, FR. HERING and O. ZAHN (*Chem. Centr.*, 1899, ii, 1033—1034; from *Zeit. Unters. Nahr.-Genussm.*, 2, 784—786).—König's glycerol process (*Abstr.*, 1899, ii, 68) is recommended as being a notable improvement in fodder analysis. L. DE K.

Separation and Estimation of Formic, Acetic, Propionic, and Butyric Acids. By J. SCHÜTZ (*Zeit. anal. Chem.*, 1900, 39, 17—18).—The author is unable to confirm the accuracy of Haberland's method (*Abstr.*, 1899, ii, 531) on the ground that formic, acetic, and butyric acids when evaporated with excess of zinc oxide are not completely converted into their zinc salts, but partially volatilise. The loss increases with increase of the molecular weight of the acid; in one experiment with butyric acid, it amounted to 82 per cent. Similar results were obtained with lead oxide. M. J. S.

Determination of the Solidifying Point of Fatty Acids. By I. FREUNDLICH (*Chem. Zeit.*, 1899, 23, 1014).—This is a slight modification of the Dalican process, consisting in stirring with a delicate thermometer and noticing the sudden rise of the mercury. It is now recommended not to commence the final stirring until the solidifying point is almost reached. L. DE K.

Estimation of Unsaturated Fatty Acids in Fish Oils. By HENRIK BULL (*Chem. Zeit.*, 1899, 23, 1043—1044).—7 grams of the sample are saponified by boiling with 25 c.c. of solution of sodium ethoxide made by dissolving 23 grams of metallic sodium in absolute alcohol and diluting to a litre; the flask containing the mixture is attached to a reflux condenser. When cold, 144.2 c.c. of anhydrous ether are added, the flask stoppered, and frequently shaken for some hours, when the solution is passed through a dry filter, precautions being taken to minimise loss by evaporation. 100 c.c. of the filtrate (= 4 grams of sample) are now shaken thrice in succession with 20 c.c. of water containing a little sodium hydroxide; this treatment removes the sodium salts of the saturated fatty acids, whilst the unsaturated compounds remain in the ethereal liquid. The acids may then be recovered in the usual manner.

A table is given of the analytical data of a large number of marine and fish-oils. L. DE K.

[**Estimation of Calcium Malate in Crude Tartar.**] By CHARLES ORDONNEAU (*Bull. Soc. Chim.*, 1900, [iii], 23, 14—15).—2 grams of the finely powdered tartar are boiled with 100 c.c. of water,

and the liquid filtered, evaporated to about 20 c.c., mixed with 2 c.c. of acetic acid, agitated, and left to cool. The precipitated calcium tartrate is separated by filtration and the filtrate and washings concentrated to about 10 c.c., mixed with 75 c.c. of 93 per cent. alcohol, and the calcium malate thus precipitated collected, washed with alcohol, and dried at 100°. The small quantity of calcium tartrate still mixed with the malate may be estimated by washing the precipitate with water and again drying at 100°. This process, which is based on the properties of calcium tartromalate, may be used for the estimation of malic acid in green grapes, but is not applicable to wines, which contain gummy substances precipitated by alcohol along with the calcium malate.

N. L.

Estimation of Uric Acid based on Precipitation as Ammonium Urate. By EMIL WÖRNER (*Zeit. physiol. Chem.*, 1900, 29, 70—77).—The process recommended is a modification of Hopkins' method. The urine is treated with ammonium chloride, the precipitated ammonium urate washed with a saturated solution of ammonium sulphate, and then the nitrogen determined in the precipitate by Kjeldahl's method. Edmund's statement (*Abstr.*, 1895, ii, 237), that ammonium sulphate is a less ready precipitant of the urate than the chloride, is confirmed, in spite of what Folin (*Abstr.*, 1898, ii, 196) says to the contrary. The readiness with which the precipitation occurs with ammonium sulphate increases, however, with rise of temperature.

W. D. H.

The Inner Saponification Number. By WILHELM FAHRION (*Zeit. angew. Chem.*, 1899, 1221).—The "inner saponification number" is the figure showing the number of milligrams of potassium hydroxide required to neutralise the non-volatile and non-oxidised fatty acids from 1 gram of fat. The author regards Lewkowitsch's objection to this name and his proposal to call it the "saturation number" as unwarranted.

L. DE K.

Constancy in the Composition of Cow's Milk and Detection of its Adulterations. By H. TIMPE (*Chem. Zeit.*, 1899, 23, 1040—1043).—From the results of a large number of analyses, the author concludes that in genuine milk the relation between the proteids and the fat may be expressed by the equation $P = 2 + 0.35 F$.

If the proteids found by actual experiment do not reasonably agree with those obtained by calculation, the milk is either skimmed, watered, or affected both ways. Formulae are given to facilitate calculation. The question of watering may also be decided from the percentage of milk-sugar found; in fact, the process requires a complete and careful analysis.

L. DE K.

Effect of Milk Preservatives on Milk Fat. By BERNHARD SCHULZE (*Bied. Centr.*, 1899, 25, 858; from *Ber. Agri. Versuchs-Stat. Breslau*, 1896).—Small amounts of potassium chromate (0.1—0.2 per cent.) had no essential effect on the amount of milk-fat in 14 days. With more than 0.5 per cent. of chromate there was, however, a considerable reduction in the percentage of fat. Milk which is, perhaps, not

examined for a considerable time should therefore not be treated with uncontrolled quantities of chromate. Salicylic acid seems to be the best preservative.

N. H. J. M.

Estimation of Fatty Matter in Butter by Gerber's Process. By J. WERDER (*Chem. Zeit.*, 1899, 23, 1028).—Gerber's acid-butyrometric process gives unsatisfactory results, as a well-defined layer of liquid fat is rarely obtained, but by a slight modification of the method, satisfactory results may be obtained.

1 gram of the sample of butter is treated in the "Gerber butyrometer" (old pattern) with 18 c.c. of sulphuric acid of sp. gr. 1.5 and 1 c.c. of amyl alcohol, and the result multiplied by 1.094; the percentage of fat so found practically agrees with the results obtained by Soxhlet's process.

L. DE K.

Bechi and Halphen's Colour Reactions for the Identification of Cotton-seed Oil. By P. N. RAIKOW and N. TSCHERWENIWANOW (*Chem. Zeit.*, 1899, 23, 1025—1028).—The authors, after a lengthy investigation, conclude that the Bechi silver test is quite satisfactory if conducted according to the directions of the Italian Scientific Committee (in which a solution of colza oil in amyl alcohol is used).

The Halphen test, in its original form (heating the sample with sulphur, carbon disulphide, and amyl alcohol), is also an excellent test for the presence of cotton-seed oil in olive and similar oils.

L. DE K.

Macassar Oil. By J. J. A. WIJS (*Zeit. physikal. Chem.*, 1899, 31, 255—257).—The author has determined a number of physical and chemical constants for this oil, and gives a table comparing his values with those of other observers.

J. C. P.

Detection of Phytosterol and Cholesterol in Fats. By HANS KREIS and ERNST RUDIN (*Chem. Zeit.*, 1899, 23, 986).—The process recommended by Kreis and Wolf (*Abstr.*, 1898, ii, 343) not being found to be quite satisfactory, has now been modified by the authors as follows: 50 grams of the fat are saponified, as usual, with 125 c.c. of strong alcohol and 25 c.c. of 40 per cent. aqueous caustic potash. When the alcohol has evaporated, the soap is dissolved in 500 c.c. of boiling water, and decomposed by adding 120 c.c. of a 10 per cent. solution of calcium chloride. When cold, the precipitate is collected on a cotton cloth, and the lime-soap pressed dry, powdered, and covered in a closed flask with 100 c.c. of a mixture of equal parts of alcohol and ether. After an hour, the liquid is filtered, and the residue washed with another 50 c.c. of the ethereal mixture; the filtrate is then mixed with 3 c.c. of the aqueous potash and 20 grams of quartz-sand, and evaporated to complete dryness on the water-bath. The residue is extracted with ether in a Soxhlet's apparatus, the solvent evaporated, and the phytosterol, or cholesterol, recrystallised from alcohol.

L. DE K. 16

General and Physical Chemistry.

Rotatory Power of Active Valeric Acid. By PHILIPPE A. GUYE and EMILY ASTON (*Compt. rend.*, 1900, 130, 585—588).—The authors have determined the specific rotatory power of active valeric acid at various temperatures, with the following results:

1st specimen: $[\alpha]_D +11.27$ at 11° , $+10.84$ at 59.5° , $+9.0$ at 188° (vapourised).

2nd specimen: $[\alpha]_D +9.07$ at 16° , $+7.54$ at 99° , $+7.3$ at 188° (vapourised).

In dilute aqueous solution, the acid may be regarded as existing in the form of simple molecules; in a 1.2 per cent. solution, $[\alpha]_D +14.4$ at 18° , and in a 3.9 per cent. solution, $[\alpha]_D +14.6$ at 18° , the rotatory power of the liquid acid being $+12.02$ at 15° . When dissolved in ethylene dibromide, the acid is most probably polymerised; in a 1.27 per cent. solution, $[\alpha]_D +7.8$, in a 2.1 per cent. solution, $[\alpha]_D 9.65$, in an 11.91 per cent. solution, $[\alpha]_D +10.12$, the rotatory power of the liquid acid being $+11.27$ at the same temperature (18°).

The influence of temperature on the specific rotatory power of active valeric acid is not abnormal, and the difference between the acid and the alcohol in this respect is doubtless due to the relatively much smaller effect of temperature in dissociating the acid into simple molecules. It is evident that under ordinary conditions the acid is partially polymerised.

C. H. B.

Silver Germ or Subhaloid Theory. By RICHARD ABEGG (*Chem. Centr.*, 1900, i, 439—440; from *Arch. wiss. Phot.*, 1, 268—272).—An answer to Mercator's objections (*Arch. wiss. Phot.*, 1, 199) to the silver germ theory of the latent photographic image (*ibid.*, 15). Eder's observation (*Phot. Korresp.*, 1899, 233, 276), that collodion plates, even after treating with a very strong nitric acid sensitising bath, still exhibit a faint image on development, shows that a portion of the latent image is destroyed by the acid, and must therefore be due to silver germs. It is still doubtful, however, whether the layer of acid adhering to the plate is sufficient to destroy all the silver germs of the latent image, or whether the image obtained is not due to unattacked germs.

E. W. W.

The Nature of the Latent Image and the so-called Eder Test. By ROBERT LUTHER (*Chem. Centr.*, 1900, i, 440; from *Arch. wiss. Phot.*, 1, 272—274).—When silver powder is repeatedly shaken with fresh quantities of chlorine water, each portion of which contains 1/10th the amount of the chlorine required to convert the silver into chloride, the oxidation potential of the residual chlorine remains constant until just 50 per cent. of the chlorine equivalent to the silver is combined, whilst after this point the oxidation potential increases until the whole of the silver has been converted into chloride. Silver and bromine give similar results, hence the subhaloids, Ag_2Cl and

Ag_2Br , exist, and their formation marks a distinct phase in the action of the halogen on the metal. The oxidation potentials for the conversion of the subchloride and subbromide into the ordinary haloids are 1.15 and 1.45 respectively. When the latent image of a silver bromide plate is treated with a solution of potassium chromate containing hydrogen bromide sufficient to give an oxidation potential of 1.1, the latent image is not attacked, but it is completely destroyed by a solution of oxidation potential 1.2. The oxidation potential of the compound formed by the action of light must therefore be about 1.15, or identical with that of silver subbromide. Similar results were obtained in the case of silver chloride plates, hence, at least in the absence of gelatin, the latent image consists of subhaloids. When silver is placed on a dry plate without pressure, Eder's test fails, and no image is formed on development, but if silver powder, quartz, and silver subbromide are rubbed into a silver bromide gelatin plate, the plate, when developed, shows no change below the quartz, but is black below the silver, and is found to be still more strongly affected under the bromide.

E. W. W.

Electric Charge of the Deviable Rays of Radium. By P. CURIE and SKŁODOWSKA CURIE (*Compt. rend.*, 1900, 130, 647—650).—Those rays emitted by radium which are deviated by a magnetic field are charged with negative electricity, but to a less degree than cathode rays. Hence it may be concluded that the radiation of radium is due to the emission of particles of electrified matter. Röntgen rays are extremely feebly, if at all, charged.

N. L.

[Validity of Maxwell's Equations.] By P. S. WEDELL WEDELLSBORG (*Zeit. physikal. Chem.*, 1899, 29, 494) and ANTON SCHEYE (*ibid.*, 1900, 32, 145—149).—A continuation of the controversy regarding the validity of Maxwell's equations (see Abstr., 1898, ii, 61, 419.)

L. M. J.

Inversion of Hepta- and Hexa-hydrates of Zinc Sulphate in the Clark Cell. By H. T. BARNES (*J. Physical Chem.*, 1900, 4, 1—20).—The paper contains a more detailed account of the experiments made by the author in conjunction with Callendar on the change of E.M.F. of the Clark cell at a temperature about 39°. The E.M.F. of the cell was determined at various temperatures above 30° by comparison with another maintained at 15°; the experimental details are explained, and curves and tables are given showing the difference between the E.M.F. found and that calculated from the temperature coefficient between 15° and 30°. It is seen that, with ascending temperatures, the change took place at about 42°, and with descending temperatures at about 30°, the curves for the two branches cutting a little below 39°. The variations of E.M.F. with temperature between 0° and 30° in millivolts are given by the expression $E_t - E_{15} = -1.200(t - 15) - 0.0062(t - 15)^2$, and expressions for the two branches above 30° are given, the actual transition point being at 38.78°. The inversion point, as determined by solubility experiments, is 39.95°, but in the Clark cell this temperature must necessarily be lowered by the presence of the mercurous sulphate. The author also considers

that secondary change, due to decomposition of mercurous sulphate, takes place above 35° , as by maintaining a cell at 46° a further change in the E.M.F. was found to occur (Abstr., 1898, ii, 276).

L. M. J.

Potential of the Iodine Electrode. By FRIEDRICH W. KÜSTER and F. CROGINO (*Zeit. anorg. Chem.*, 1900, 23, 87—88).—The potential differences between a platinum electrode and various solutions of potassium iodide saturated with iodine have been determined. Solutions have also been used containing different quantities of iodine in a $1/8$ th normal solution of potassium iodide. The results are analogous to those obtained with metal electrodes.

J. C. P.

Potential of Silver in Solutions of its Mixed Halogen Salts. By FRIEDRICH W. KÜSTER and A. THIEL (*Zeit. anorg. Chem.*, 1900, 23, 25—27).—A preliminary note of work arising out of a previous research (Abstr., 1899, ii, 205). The potential between a silver electrode and a normal mixed solution of potassium chloride and bromide, the latter being in equilibrium with a mixed precipitate of silver chloride and bromide, changes gradually from -0.51 volt when there is no silver bromide in the precipitate and no potassium bromide in the solution, to -0.36 volt when there is no silver chloride in the precipitate and no potassium chloride in the solution.

J. C. P.

Three Additions to the Kohlrausch-Ostwald Conductivity Method. By J. LIVINGSTON R. MORGAN (*J. Amer. Chem. Soc.*, 1900, 22, 1—5, 26—28).—Owing to magnetisation of the spring of the contact breaker, the interruptor deteriorates, and the clear note of the telephone is lost. The author describes a form of contact breaker in which this is avoided, the wire conveying the current being attracted by an electro-magnet excited by a separate strong current, this attraction of the wire causing the interruption of the current. Resistances equal to 4, 9, or 19 times that of the metre bridge are so arranged that no readings may be necessary near the end of the bridge; and a double contact key is described, by which two points, about a centimetre apart, are readily obtained, for which the sound intensity is equal, the mid-point giving the zero.

L. M. J.

Influence of Temperature on the Electrical Conductivity of Dilute Amalgams, and the Solubility of Metals in Mercury. By ABSALON LARSEN (*Ann. Phys.*, 1900, [iv], 1, 123—131).—The relative conductivity L_t of liquid amalgams of lead, zinc, cadmium, tin, and bismuth, that is, the conductivity compared with that of mercury at the same temperature, increases proportionally with the temperature, the absolute increase depending on the concentration of the particular amalgam; if $L_t = 1 + \delta_t$, then $\delta_t = \delta_{20}[1 + \alpha(t - 20)]$, the coefficient α varying from 0.0004 for cadmium and zinc amalgams to 0.002 for bismuth amalgams. It appears that in dilute liquid amalgams the dissolved metal is dissociated, and that the degree of dissociation increases both with falling concentration and with rising temperature.

The curve connecting relative conductivity and concentration of the

amalgam shows a break where the limit of solubility is reached. The relative conductivity, and therefore the concentration, of amalgams saturated at various temperatures increases nearly proportionally with the temperature. J. C. P.

Stannic Chloride in Aqueous Solution. By WL. VON KOWALEWSKY (*Zeit. anorg. Chem.*, 1900, 23, 1—24).—The hydrolysis of stannic chloride solutions, according to the equation $\text{SnCl}_4 + 4\text{H}_2\text{O} = \text{Sn}(\text{OH})_4 + 4\text{HCl}$, has been traced by determinations of their conductivity, which increases as time goes on. A point of equilibrium is ultimately reached before hydrolysis is complete, and the effect of a rise of temperature on the equilibrium is to diminish the extent of hydrolysis: the equilibrium in question can further be reached from both sides. Excess

of Cl^- ions hinders the hydrolysis, and the conductivity of a mixed solution of stannic chloride and hydrochloric acid may be less than that of the hydrochloric acid solution alone, owing, doubtless, to the formation of a complex salt. Investigation of the freezing points of the solutions, and their influence on the hydrolysis of methyl acetate, leads to the conclusion that the non-electrolytes present interfere considerably with the dissociation of the hydrochloric acid. The author has been unable to determine definitely the concentrations of the various molecules present in solution at the point of equilibrium.

When a solution of stannic chloride is added to a saturated solution of sodium chloride, and the mixed solution is diluted with water, the specific conductivity is found to increase to a certain point with the dilution. J. C. P.

Electrochemical Properties of Silver Fluoride and of Fluorine. By RICHARD ABEGG and CL. IMMERWAHR (*Zeit. physikal. Chem.*, 1900, 32, 142—144).—The conductivity of solutions of silver fluoride at dilutions of from about $N/1$ to $N/200$ was determined, and from the values the dissociation was calculated; at the higher concentrations, this is approximately equal to that of silver nitrate. In the more dilute solutions, high values for the conductivity indicate partial hydrolysis of the salt. The decomposition tension of fluorine exceeds that of chlorine by about 0.45 volt, and it is noticeable that an approximately equal difference separates the other halogens. An increase of solubility of silver oxide is occasioned by addition of silver fluoride, this being probably due to the formation of complex ions. L. M. J.

Electrochemical Equivalent of Copper and Silver. By THEODORE W. RICHARDS, EDWARD COLLINS, and GEORGE W. HEIMROD (*Zeit. physikal. Chem.*, 1900, 32, 321—347).—An examination of the irregularities of the copper voltameter leads in general to results agreeing with those of Foerster and Seidel (compare Abstr., 1897, ii, 241; 1898, ii, 10). Copper plates become lighter in acidified copper sulphate solutions, owing to the solution of the copper and the simultaneous formation of cuprous sulphate: this action increases as the temperature rises. Copper plates in neutral copper sulphate solutions become heavier by the deposition of cuprous oxide, formed by the hydrolysis of cuprous sulphate. With regard to the copper

voltameter, the authors point out that (1) the solution must be as cold as possible; (2) the solution must be acid to prevent hydrolysis; (3) the solution must be as dilute as possible, whilst the liberation of hydrogen is avoided; (4) air must be carefully excluded. Foerster and Seidel's plan of saturating the solution from the beginning with cuprous ions is criticised as giving too heavy a deposit of copper: this view is borne out by experiment. Comparison of the copper deficit in the copper voltameter with the current density at the cathode shows: (1) that a high current density gives far too low a deposit of copper, owing doubtless to the separation of hydrogen; (2) that the loss of copper due to solution in the copper sulphate is approximately proportional to the extent of the electrode surface. By taking then the actual weight of copper deposited in any given case, and extrapolating to the electrode surface zero, a value is obtained which will correspond closely with the amount of electricity that has passed through the cell. A series of experiments, treated in this way and based on a comparison of the copper voltameter with the ordinary silver voltameter, gave the mean value 63.563 for the atomic weight of copper, distinctly less than the value 63.604, obtained by purely chemical methods.

As regards the silver voltameter, it appears from the work of numerous observers that some substance, connected with or proceeding from, the anode, causes too large a deposit of silver at the cathode. Experiment having shown that the cathode deposit was not contaminated by mother liquor, the authors adopted the device of inserting a porous cell between the anode and the cathode. This arrangement of the silver voltameter gives, under similar conditions, a smaller deposit of silver than any other of the forms used. The quantity of silver deposit is less affected by change of temperature in this porous cell form of the voltameter than in Lord Rayleigh's form, and the authors consider their results the more correct. When the necessary correction is made on the ordinary silver voltameter, the atomic weight of copper, deduced from the experiments described above, now lies between 63.598 and 63.615. The electrochemical equivalent of silver is corrected to 0.0011172 gram per amp. sec., and that of copper to 0.0003292 gram per amp. sec.

J. C. P.

Electrochemical Equivalent of Carbon. By H. C. PEASE (*J. Physical Chem.*, 1900, 38—40).—The electrochemical equivalent of carbon was found by determining the loss of weight of a carbon anode in fused caustic potash, iron being used for the cathode. The results obtained were 3.15, 3.66, 3.40, 3.23 and 3.14, which, when a slight loss due to disintegration is allowed for, indicated the electrochemical equivalent of 3 (Abstr., 1893, ii, 14).

L. M. J.

The Electrical Reduction of Non-electrolytes. By FRITZ HABER (*Zeit. physikal. Chem.*, 1900, 32, 193—270).—For the electrolytic reduction of nitrobenzene in alkaline solution, the equation is deduced: $\epsilon = 0.0436 \log(I/C_{NO_2}) - \text{const.}$, where ϵ is the fall of potential at the cathode, I the current strength, and C_{NO_2} the concentration of the nitrobenzene in the cathode solution. This equation, which holds for ordinary temperatures, is based on Nernst's formula for the fall of

potential at an electrode, on the law of mass action, and on the conception of the cathode as a solid solution of the reducing agent. In three series of experiments, where the fall of potential, the concentration of the nitrobenzene, and the current strength respectively were kept constant, the equation just given was found to agree with the results of observation. A plain platinum cathode was used in almost all cases. The equation $\epsilon = 0.0436 \log(10/C_{NO_2}) - \text{const.}$, represents the results satisfactorily both with a platinised platinum cathode in alkaline solution and with a plain platinum cathode in acid solution.

J. C. P.

Recent Researches on Magnetic Susceptibility. By JOH. KÖNIGSBERGER (*Ann. Phys.*, 1900, [iv], 1, 175—177).—A criticism of some of Meyer's results and conclusions (this vol., ii, 7). The author holds that compounds of twodiamagnetic elements may be paramagnetic. In the case of certain compounds for which Meyer observed no influence of the field strength, such an influence has been detected.

J. C. P.

Thermochemical Law of Maximum Work. By ALBERT REYCHLER (*Chem. Centr.*, 1900, i, 162; from *Rev. Univ. Bruxelles*, 1899, 5, 5—16).—The author shows that, under certain conditions, Berthelot's law of maximum work can be looked on as a consequence of the fundamental laws of thermodynamics. Superheated systems are those which are in equilibrium at a lower temperature, supercooled those which were in equilibrium at a higher temperature; the former are endothermic, the latter exothermic. Non-reversible reactions take place in supercooled systems, and are always exothermic; reversible reactions are only exothermic when the temperature is below that of equilibrium. Berthelot's law should be interpreted as meaning that heat is developed by all spontaneous changes in systems which are below their temperature of equilibrium. Supercooled systems may be due to the fact that during the process of cooling, external causes prevented equilibrium being established at each temperature; thus sulphur and free oxygen exist together on the earth. Exothermic, and therefore supercooled, systems may also arise through access of energy by radiation, although the temperature of equilibrium did not prevail at the point of formation.

J. C. P.

Tubular Furnace giving Fixed Temperatures, adjustable at Will. By ARMAND GAUTIER (*Compt. rend.*, 1900, 130, 628—633).—A detailed description of a form of gas furnace by means of which any desired temperature between 150° and 1300° may be maintained constant within a few degrees for several hours. The apparatus consists essentially of an iron tube containing the glass or porcelain tube to be heated and enclosed in a fire-clay casing, between which and the iron tube pass the flames of two rows of Bunsen burners supplied with gas at a carefully regulated pressure.

N. L.

Measurement of Low Temperatures. II. By ALBERT LADENBURG and C. KRÜGEL (*Ber.*, 1900, 33, 637—638. Compare Abstr., 1899, ii, 545).—More careful measurements than those already carried out (*loc. cit.*) lead to the following revised data. *Boiling points:*

Oxygen, -182.2° (745.0 mm.); nitric oxide, -142.8° (757.2 mm.); hydrogen chloride, -83.1° (755.4 mm.); hydrogen bromide, -68.1° (755.4 mm.); hydrogen iodide, -36.7° (751.7 mm.); hydrogen sulphide, -60.4° (755.2 mm.); methane, -162° (751.0 mm.); ethane, -84.1° (749.0 mm.); propylene, -48.2° (749.0 mm.); trimethylene, about -34° (749.0 mm.); acetylene, -82.4° .

Melting points: Nitric oxide, -150.5° ; ammonia, -75.5° ; hydrogen chloride, -111.3° ; hydrogen bromide, -86.13° ; hydrogen iodide, -51.3° ; hydrogen sulphide, -82.9° ; ethane, -172.1° ; trimethylene, -126.6° ; toluene, -93.2° ; ethylbenzene, -93.2° ; mesitylene about -57.5° ; cymene, -73.5° ; methyl chloride, -102.9° ; ethyl bromide, -115.8° ; ethyl iodide, -110.6° to -113.1° ; methyl alcohol, -93.9° ; ethyl alcohol, -111.8° ; ethyl ether, -113.1° ; acetaldehyde, -120.6° ; acetone, -93.9° ; ethylene glycol, -15.6° ; methyl formate, -100.4° ; ethyl acetate, -82.4° ; ethylamine, -83.8° . T. H. P.

Specific Heat of Metals at Low Temperatures. By U. BEHN (*Ann. Phys. Chem.*, 1898, [ii], 66, 237—244).—Small cylinders of aluminium, iron, nickel, copper, lead, palladium, iridium, and platinum, contained in test-tubes, were cooled in a bath of liquid air or a mixture of solid carbon dioxide and alcohol; they were then introduced into a quantity of water in a calorimeter, and the specific heat calculated in the usual way. In all cases examined, the specific heat diminishes as the temperature falls, the decrease being greatest for the metals with large specific heat. The mean atomic heats of copper, nickel, iron, and aluminium, in the interval -79° to -186° , lie between the values 4.0 and 4.5. J. C. P.

Specific Heat of Metals, Graphite, and a few Alloys at Low Temperatures. By U. BEHN (*Ann. Phys.*, 1900, [iv], 1, 257—269).—The specific heats of antimony, tin, cadmium, silver, zinc, magnesium, and graphite have been determined by the method and at the temperatures formerly employed (see preceding abstract). In these, as in the earlier cases, the specific heat diminishes with falling temperature; the smaller the atomic weight of the metal, and the lower the temperature reached, the greater is the decrease of the specific heat. The mean atomic heat of graphite for the interval -79° to -186° is only 0.9.

From the mean specific heats obtained by experiment, the true specific heat c at any particular temperature t may be calculated, with the help of the relation $c = A + Bt + Ct^2$, where A , B , and C are constants. The atomic heat of graphite at -186° is thus calculated to be 0.486. Of the curves showing the relation between true specific heat and temperature, those for lead, antimony, tin, and graphite are nearly straight lines. The variation of specific heat with temperature is seen from these curves to be greatest in the case of elements with a small atomic weight and a small atomic volume.

For brass and a few alloys of lead and tin, the specific heat has approximately the same value as that calculated from the specific heats of the component metals. J. C. P.

Method for the Determination of the Melting Point. By MITSURU KUHARA and MASUMI CHIKASHIGÉ (*Chem. News*, 1899, 80, 270—271).—Instead of being placed in a capillary tube, a thin layer of the substance is held between two pieces of thin glass (microscope cover glasses) and suspended by a platinum foil support in a test-tube, which is placed in the sulphuric acid bath. D. A. L.

Regularities in Melting Points. By THEODOR SALZER (*J. pr. Chem.*, 1900, [ii], 61, 165—168).—The regular fall of melting point in the series of alkylsuccinic acids has been confirmed by Bone and Sprankling's determination of the melting point of methylsuccinic acid (*Trans.*, 1899, 75, 839).

In the malonic acid series, a similar regularity cannot be observed, since the decomposition points are very low. Thus malonic acid and methylethylmalonic acid were found to decompose at the melting point, and isopropylmalonic acid at 120°, but dimethylmalonic acid is stable at the melting point.

Further regularities occur in the melting points of the following series: (1) Acetanilide (112°), propionylanilide (105°), butyrylanilide (90°); (2) methyl, ethyl, and propyl *p*-hydroxybenzoates (131°, 112·5° or 116°, and 96°); (3) the aurichlorides of morpholine, methylmorpholine, and ethylmorpholine (240°, 183°, and 125°); (4) α -methylpiperidine, α -ethylpiperidine, and α -propylpiperidine (167°, 121°, and 85°); (5) β -methylpiperidine, β -ethylpiperidine, and β -propylpiperidine (139°, 112° or 108°, and 98° or 93°). T. M. L.

Heat of Sublimation of Carbon Dioxide, and Heat of Vaporisation of Air. By U. BEHN (*Ann. Phys.*, 1900, [iv], 1, 270—274).—The mean specific heat of a metal being known for the interval 18° to -183° (see preceding page), it is possible, by dropping a cylinder of the metal into liquid air and measuring the quantity of vapour formed, to calculate the heat of vaporisation of air; the value actually found as a mean of two experiments was 50·8 Cal. An analogous process for solid carbon dioxide in absolute alcohol gave for the heat of sublimation of carbon dioxide the value 142·4 Cal., the two separate experimental results being 142·0 and 142·8 Cal.

When these values for r , the heat of sublimation or vaporisation, are introduced in the equation $Jr = T.s.dP/dT$, where J is the mechanical equivalent of heat, T the absolute temperature, s the specific volume of the vapour, and dP/dT the temperature coefficient of the vapour pressure, the specific volume of gaseous air at -183° is calculated to be 358, and that of gaseous carbon dioxide at -79° to be 423. J. C. P.

Heat of Neutralisation and Electrolytic Dissociation. By A. THIEL (*J. pr. Chem.*, 1900, [ii], 61, 141—150).—A criticism of Vaubel's conclusions as to the significance of the thermochemical data for the heat of neutralisation of acids and bases (*Abstr.*, 1899, ii, 727). T. M. L.

Thermochemistry of Normal Adipic Acid. By GUSTAVE MASSOL (*Bull. Soc. Chim.*, 1900, [iii], 23, 100—101).—Anhydrous

normal adipic acid melts at 146.5° (Arppe gives 148° , and Bromeis 145°); its solubility in water (1 per cent. at 15°) is too small to allow its heat of dissolution to be determined. Normal potassium adipate becomes anhydrous at 100° , and dissolves in water with the development of 2.67 Cal. From the heats of neutralisation,

it is calculated that the heat of formation of normal potassium adipate is 45.45 Cal., all the substances concerned being in the solid state. Adipic acid is therefore perfectly comparable with its homologues, succinic, glutaric, and suberic acids, for which the corresponding figures are 46.50 Cal., 44.23 Cal., and 44.76 Cal. respectively (Abstr., 1899, ii, 80).

N. L.

Isomerism of Thiocyanic Derivatives. By MARCELLIN P. E. BERTHELOT (*Compt. rend.*, 1900, 130, 441—447).—A thermochemical study of the isomeric thiocyanates and thiocarbimides. The following constants are recorded :

	Heats of combustion.		Heat of formation.	Heat of transformation of normal-into iso-salt.
	Constant volume.	Constant pressure.		
Methyl thiocyanate.....	452.1 Cal.	453.1 Cal.	-19.9 Cal.	8 to 9 Cal.
Methylthiocarbimide (solid)	441.6 "	442.6 "	-9.4 "	—
Ethyl thiocyanate.....	612.5 "	613.8 "	-17.25 "	9.6 "
Ethylthiocarbimide	602.8 "	604.1 "	-7.6 "	—
Phenylthiocarbimide	1019.0 "	1020.3 "	-46.5 "	—
Allylthiocarbimide.....	731.2 "	732.6 "	-41.8 "	—
Thiosinamine.....	790.4 "	781.8 "	-6.48 "	—

G. T. M.

Meconin, Opianic and Hemipinic Acids. By ÉMILE LEROY (*Compt. rend.*, 1900, 130, 508—510).—The heat of combustion of meconin at constant volume is 1136.2 Cal., and, at constant pressure, 1136.5 Cal., its heat of formation being 151.6 Cal.; this substance, considered as a dimethoxyphthalide, is comparable with phthalide; their heats of combustion differ by 251.1 Cal., and a similar difference exists between those of benzene and its methoxy-derivatives. When meconin is oxidised to opianic acid, the heat developed is 46.1 Cal., the mean value for the heat of oxidation of an alcohol to an aldehyde is greater than 50 Cal.; the discrepancy is probably due to the slight thermal change which accompanies the dehydration of the hydroxy-acid, of which meconin is the inner anhydride. The heats of combustion, formation, and dissolution of opianic acid are 1090.4, 197.7, and -6.8 Cal. respectively; the heat of neutralisation of the dissolved acid by a solution of potassium hydroxide is 15.53 Cal. Opianic acid almost completely displaces acetic acid, the heat developed being 2.0 Cal., the value calculated for complete displacement being 2.2 Cal. The heat of dissolution of crystallised potassium opianate, $\text{C}_{10}\text{H}_9\text{KO}_5 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, is -4.88 Cal., whilst that of the salt dehydrated at low temperatures is 4.30 Cal.; when dried at higher temperatures, the heat developed is only 1.20 Cal.; the heat of formation of the solid salt is 18.44 Cal. The two isomeric methyl opianates have

practically the same heats of combustion and formation, the mean values of these constants being 1262 Cal. and -189.7 Cal. respectively. The heat of combustion of hemipinic acid is 1024.7 Cal., and its heat of formation 263.5 Cal.

The difference between the heats of combustion of hemipinic and phthalic acids is 253 Cal., and corresponds with the thermal change produced by the introduction of two methoxyl groups into the molecule of the latter compound; this supports the view that the former acid is a dimethoxyphthalic acid.

The heat of oxidation of opianic acid to hemipinic acid agrees closely with the normal value of the thermal change produced by the oxidation of an aldehyde to an acid. The heat of oxidation of meconin to hemipinic acid is 111.0 Cal., whilst that of phthalide to phthalic acid is 113.8 Cal. G. T. M.

Freezing Point Method in Dilute Solutions, and the Theory of Solutions. By MEYER WILDERMANN (*Zeit. physikal. Chem.*, 1900, 32, 288—302).—A review of recent work on this subject, and a criticism in particular of Dieterici's views and results (*Abstr.*, 1898, ii, 207; 1899, ii, 403). J. C. P.

Abnormal Depressions of the Freezing Point produced by Chlorides and Bromides of the Alkaline Earths. By HARRY C. JONES and VICTOR J. CHAMBERS (*Amer. Chem. J.*, 1900, 23, 89—105).—The depression of the freezing point produced by the chlorides and bromides of calcium, strontium, barium, and magnesium in aqueous solutions of various concentrations has been measured; unlike the alkali halogen salts, which produce a continually increasing molecular depression with increase of dilution, the salts of the alkaline earths give rise initially to a *decrease* of the depression, which falls to a minimum at a concentration between $N/10$ and $N/5$, but subsequently increases in the ordinary manner with increasing dilution. With cadmium chloride or bromide, however, normal results are obtained, the molecular depression increasing regularly with increase of dilution. A comparison of the electrical conductivities of the salts named, in solutions of varying concentration, shows no irregularity in the region where the molecular depression is a minimum. Since the halogen salts of the alkaline earths are very hygroscopic, it is suggested tentatively, as a possible explanation of their abnormal behaviour, that in concentrated solutions they combine with a portion of the water used as solvent, forming complex hydrates, which undergo dissociation on increasing the dilution. The conductivity results, which show that marked dissociation occurs in the concentrated solutions, cannot, however, be readily reconciled with this view unless it is assumed that a certain number of the molecules are ionised by the water in combination with them just as salts are probably dissociated by their water of crystallisation. W. A. D.

Cryoscopic Observations. By KARL AUWERS [and, in part, W. BAERTSCH, F. H. BETTERIDGE, MAX DOHRN, and H. M. SMITH]. (*Zeit. physikal. Chem.*, 1900, 32, 39—62).—Various derivatives of *p*-cresol which are *o*-hydroxy-ketones were found to be cryoscopically

normal in naphthalene solution; *p*-nitrobenzoyl-*p*-cresol, however, yields a curve which falls with increasing concentration, no explanation of this anomaly being assigned. *p*-Hydroxy-ketones of the type of *p*-hydroxyacetophenone were found to yield abnormal curves, the abnormality increasing with molecular weight, a result which differs from that usually obtained in such cases. Methyl *p*-hydroxybenzoate is abnormal, but the halogen derivatives ($\text{OH} : \text{Cl} = 1 : 2$) are all almost normal, the halogens having approximately equal normalising influence. A number of derivatives of *p*-hydroxybenzaldehyde were found to be abnormal, but to a less extent than the parent substance. Amongst the diphenols and their monomethoxy-derivatives, resorcinol was found to be abnormal, guaiacol normal, and the remainder slightly abnormal. Dimethyl oxalate was also employed as a solvent, and it was found that compounds cryoscopically abnormal in naphthalene give almost normal results, so that the solvent is only weakly abnormalising. *p*-Azoxyanisole was also used as a solvent, all the compounds investigated giving normal curves; the cryoscopic constant of this solvent is, however, somewhat uncertain; Schenck adopted the value 750, whilst the author obtains a mean value of 545, with, however, very wide limits, so that before the compound is useful cryoscopically, this uncertainty must be removed (Abstr., 1899, ii, 637). L. M. J.

Corresponding States. By KIRSTINE MEYER née BJERRUM (*Zeit. physikal. Chem.*, 1900, 32, 1—38).—Although van der Waals's expression can be only regarded as an approximation, nevertheless the important law of corresponding states may be valid, and the paper contains an elaborate investigation of known data in order to determine whether this is the case or not. If a law of corresponding states holds, then, assuming the critical states as corresponding for any pair of compounds, at corresponding temperatures T and T' the expression $\log.(T_c - T) - \log.(T'_c - T')$ is constant and independent of pressure, whilst a similar expression $\log.(P_c - P) - \log.(P'_c - P')$ is independent of temperature. Curves for $\log.(T_c - T)$ against $\log.(P_c - P)$ for the two compounds should therefore be mere displacement be superposable, and this is found to be the case, whilst, further, since $\log.(P_c - P) - \log.(P'_c - P') = \log.P_c - \log.P'_c$, it follows that equal fractions of the critical pressure are corresponding pressures. This, however, does not hold for temperature, that is corresponding temperatures, at which the vapour pressures are equal fractions of the critical pressure, are not always equal fractions of the critical temperatures, and for comparison temperatures must be measured from different zero values, usually a few degrees above 273° . This is also the case for volumes, the ratio of corresponding volumes not being that of the critical volumes, but equal to a ratio q/q' , where q' is usually slightly greater than the critical volume. The law of corresponding states hence does actually obtain, but temperatures and volumes must be measured from different null points. The validity of the deductions is also proved by the comparison of the found and calculated isothermals of isopentane, hexane, ether, and carbon dioxide. Water and the alcohols form exceptions to these deductions, and this is probably to be ascribed to molecular association. L. M. J.

Absolute Molecular Volumes. By CATO M. GULDBERG (*Zeit. physikal. Chem.*, 1900, 32, 116—126).—By extreme compression of a liquid, a value may be assumed to be finally reached which is the absolute volume of the molecules, and is independent of temperature; whilst, similarly, the same value, independent of pressure, is reached by cooling to the absolute zero. Assuming the validity of the expression $p/RT = 1/(v - v_0) - \alpha$, then the value for v_0/v may be obtained by comparison of the volumes at either two temperatures or two pressures. These, however, involve the unknown constant, α , but by neglecting the term in which it occurs, the ratios are in one case too great, and in the other too small, and the values, which do not greatly differ, are given for a number of different compounds, the compressibility data being obtained from Amagat's results. The author has also given an empirical expansion law, which may be expressed as $a = a_0/\sqrt{1-t}$, where t is the ratio of the absolute temperature to a certain temperature T , which varies for different liquids, but is for many equal to the critical temperature. De Heen has also given the expression $a = a_0/(1 - \frac{2}{3}a_0T)$, and from each of these expressions v_0/v is calculable. From these, the values v_0 are derived, and it is seen that the numbers agree well with the previous values. The absolute molecular volumes and densities are so calculated and given for about 80 liquids. The mean value of the ratio of the critical volume to the absolute molecular volume is found to be 3.75. This absolute molecular volume is, however, not the sum of the atomic volumes, being dependent on structure; thus carbon, which has in the diamond an atomic volume of 3.4, has in organic liquids an atomic volume of 7.2. The molecular volumes so obtained may be approximately expressed by assuming C = O = N = 1; H = $\frac{1}{2}$; Cl = P = As = S = Si = 2.5; Br = 3; I = 3.75, the unit varying in different classes of compound between 7.1 and 7.9, and being greatest for unsaturated compounds. L. M. J.

Development and Application of a General Equation for Free Energy and Physico-chemical Equilibrium. By GILBERT NEWTON LEWIS (*Zeit. physikal. Chem.*, 1900, 32, 364—400).—A theoretical paper not suitable for abstraction. J. C. P.

Chemical Affinity. By WILHELM VAUBEL (*Chem. Zeit.*, 1900, 24, 35—36).—The author regards chemical affinity as made up of two components—gravito-affinity and electro-affinity. The part played by each of these factors is illustrated by several numerical examples, based on the author's previous papers (*Abstr.*, 1898, ii, 206 and 503; 1899, ii, 727). J. C. P.

Diazotisation and the Affinity Constants of Nitrous Acid. By M. SCHÜMMANN (*Ber.*, 1900, 33, 527—533).—The author has studied the velocity of the change represented by the equation $R \cdot NH_2Cl + HNO_2 \rightarrow R \cdot N_2Cl + 2H_2O$, by observing the fall of electrical conductivity in aqueous solution due to the transformation of the original dissociated acid system into the neutral, non-dissociating diazonium chloride; this method is possible, because all diazonium chlorides show practically the same conductivity in solution, and is superior to that employed by Hantzsch and Schümann (*Abstr.*, 1899, ii, 549), in that its rapidity

enables the first phases of the process to be accurately observed. The conclusion finally arrived at is that, in presence of an excess of acid, and in absence of secondary decomposition, "all aromatic amines are diazotised at approximately the same speed."

The experiments were carried out at 20°, by adding an *N*/500 solution of sodium nitrite to an *N*/500 solution of the hydrochloride of the base containing 1 mol. of hydrochloric acid. With *p*-anisidine and *p*-toluidine, the conductivity falls regularly, until a constant final value is reached after 2 hours; with aniline, *o*-toluidine, and ψ -cumidine, however, the minimum value, which is reached after about 2 hours, does not remain constant, but subsequently increases, owing to the secondary change, $R \cdot N_2Cl + H_2O = R \cdot OH + HCl + N_2$, occurring. In some cases, the formation of a diazoamino-compound introduces a similar disturbing influence; with *p*-bromoaniline, this factor produces little effect (compare Hantzsch and Schümann, *loc. cit.*), but with α - and β -naphthylamine, considerable quantities of diazoamino-compounds are formed in the first few minutes.

The author has also determined the affinity-constant of nitrous acid by measuring the conductivity of aqueous solutions of carefully purified sodium nitrite; for $NaNO_2$ at 25°, $\mu_\infty = 115.5$, and hence for HNO_2 at 25°, $\mu_\infty = 391.5$, and therefore $K = 0.045$. This value indicates that in the diazotisation process a considerable repression of the hydrolytic dissociation of the salt of the aromatic base must be caused by the nitrous acid; hence it is impossible to calculate the conductivity of the system additively from that of its components. W. A. D.

Chemical Equilibrium in a System of Four Gases. By H. PÉLABON (*Compt. rend.*, 1900, 130, 576—579).—The action of hydrogen on mercury selenide above 500° provides a case of four gaseous substances which, at a given temperature, are in chemical equilibrium; and the author shows that through a fairly wide range of pressure, and even in presence of excess of mercury, the partial pressures observed agree with those deduced from mechanical and thermochemical principles. C. H. B.

Relations between Ammonia and Salts in Aqueous Solution. By DMITRI P. KONOWALOFF (*J. Russ. Phys. Chem. Soc.*, 1899, 31, 910—927).—The relations between the strength of an aqueous ammonia solution and the pressure exerted by the ammonia in the solution have been determined at 59.96°. In the following table, n represents the number of gram-mols. of ammonia per litre, and P the partial pressure in mm. of mercury, due to the ammonia dissolved:

n	3.098	1.549	1.239	1.033	0.7745	0.6196
P_1	202.0	94.01	74.42	61.4	45.66	36.39
P_1/n	65.3	60.7	60.0	59.4	58.9	58.7

The presence of dissolved salts causes a diminution in the value of P_1 and for solutions containing less than about 1.5 gram-mols. of ammonia per litre (for which Henry's law is approximately true), this diminution is expressed by the following formula: $P = P_1(n - k.m)$, where P_1 represents the pressure of the ammonia in pure aqueous solution, P the pressure of the dissolved salt, n and m the number of

gram-mols. of ammonia and salt respectively in a litre of the solution, and k a constant. For silver nitrate, $k=2$, whilst for cadmium nitrate, zinc nitrate, nickel chloride, copper nitrate, copper chloride, coppersulphate, and copper acetate, k approximates more or less closely to the value 4. The more stable a solution is towards water, so much the more nearly do the values of k approach 4, the deviations from this number being greatest for those solutions which most readily give a precipitate on the addition of water. These facts are explained as due to the formation in solution of compounds $MX_2 \cdot 2NH_3$ (in the case of silver nitrate), or $MX_2 \cdot 4NH_3$ (for the salts of dibasic acids). Support is given to this hypothesis by the fact that increasing quantities of copper sulphate, when dissolved in aqueous ammonia, cause increasing elevations of the freezing-point, the magnitudes of the elevations being the same as would be produced if the compound $CuSO_4 \cdot 4NH_3$ were formed in the solution.

The colour of aqueous salt solutions is regarded as due to the existence of definite hydrates in the solutions, the different colours obtained in the presence of ammonia being caused by the formation of compounds of the salt with ammonia analogous to the hydrates. The change in electrical conductivity of a solution of ammonia on adding copper salts and that produced in a nickel sulphate solution by the addition of ammonia, are also explained by the formation of such compounds.

When ammonia combines with a salt, it causes a large increase in its electrical conductivity, whilst the replacement of the combined ammonia by water is accompanied by comparatively small changes in the conductivity. Thus luteocobaltic bromide, $CoBr_3 \cdot 6NH_3$, at a dilution of 500 litres, has the molecular conductivity, 401.6; $CoBr_3 \cdot 5NH_3 \cdot H_2O$ gives the value 390.3; $CoBr_3 \cdot 4NH_3 \cdot 2H_2O$, 379.8; $CoBr_3 \cdot 5NH_3$, 244.7; and $CoBr_3 \cdot 4NH_3$, about 190.6. T. H. P.

Equilibrium in Systems containing an Alkali Salt, Water, and Alcohol. By B. R. DE BRUYN (*Zeit. physikal. Chem.*, 1900, 32, 63—115).—The following systems were examined, water, ethyl alcohol, and (1) ammonium sulphate, (2) potassium carbonate, (3) sodium sulphate, and water, methyl alcohol, potassium carbonate. These differ from the systems examined by Schreinemakers, inasmuch as no pair forms two liquid phases. The systems containing the sulphates were most fully investigated, and for these spacial diagrams are given. In the system, ammonium sulphate—alcohol—water, a lower critical point occurs, about 8° , below which no separation into liquid phases can occur. Increase of temperature causes an increase of solubility in dilute alcohol, and the binodal curve indicates that for a high percentage of alcohol, cooling of a homogeneous solution causes a separation into two layers, whilst for solutions of low percentage the reverse obtains. The system, potassium carbonate—water—ethyl alcohol, gave no critical point between 75° and -18° ; as in the previous case, in systems of small alcohol content, warming causes a separation into two layers, and at certain compositions further increase of temperature again produces homogeneity. At all temperatures, potassium carbonate has a much greater effect than ammonium

sulphate in this respect. The hydrates were found to have the composition $K_2CO_3 \cdot 3H_2O$ and $K_2CO_3 \cdot 2H_2O$ respectively. In the system with methyl alcohol, a lower critical point of -35° was found, and at all temperatures in the presence of the solid hydrated carbonate, methyl alcohol and water are more miscible than water and ethyl alcohol. In systems of sodium sulphate—water—ethyl alcohol, above 32.5° , the anhydrous is the only solid phase; below this temperature, either the anhydrous salt or the decahydrate may occur; solutions in equilibrium with the heptahydrate are not stable. The solubility of the hydrates in dilute alcohol increases with temperature, that of the anhydrous salt decreases. Systems with two layers were obtained, but are unstable below 32.5° , and at 25° speedily deposit crystals of the hydrate with the formation of but one liquid phase. In this system, the complete spacial diagram between 0° and 45° is given.

L. M. J.

A Case of Chemical Equilibrium suitable for Demonstration. By PAUL DUDEN (*Ber.*, 1900, 33, 483—484).—Benzenesulphoncamphylamide is suspended in an excess of 10 per cent. sodium hydroxide solution, and, in the course of half a minute, is converted almost completely into the insoluble sodium salt; on adding ether, almost the whole of the sulphonamide is regenerated. In this way, it is easy to demonstrate the fact that in the equation

the equilibrium passes over almost completely to the right or to the left when the sodium salt or the acid is removed from the liquid phase in which interaction takes place. Benzenesulphoncamphenamide can also be used with a 6—7 per cent. solution of sodium hydroxide.

T. M. L.

Solubility of Carbon Dioxide in Alcohol between -67° and $+45^\circ$. Invasion and Evasion Coefficients at 0° . By CHRISTIAN BOHR (*Ann. Phys.*, 1900, [iv], 1, 244—256. Compare *Abstr.*, 1898, ii, 211, and 1899, ii, 641).—Two methods have been employed, one consisting in saturating the alcohol with carbon dioxide, and subsequently determining the quantity of gas absorbed, the other being an ordinary absorption method, and used at temperatures below 0° . The formula $\alpha(T-n) = K$ (*Abstr.*, 1898, ii, 211) is found applicable, the variation of n between -12° and 36° being very small. The values of α obtained at ordinary temperatures agree well with those of Carius; at 0° , α has the value 4.3, and as the temperature falls, it increases to about 44 at -67° . At the lowest temperatures, however, the absorption of gas causes considerable alteration of volume, and there is a little uncertainty about the extent of the correction to be applied.

The quantity δ , given by the equation $\delta = (\log x_0 - \log x) / t \cdot \log e$ (*Abstr.*, 1899, ii, 641), is satisfactorily constant, and the evasion coefficient at 0° is thence calculated to be 0.524. From the relation $\gamma = \alpha\beta$, where α is the absorption coefficient, β the evasion coefficient, and γ the invasion coefficient, γ is calculated to have the value 2.375

at 0°; direct experiment gave the value 2.459. The following table gives the various coefficients for water and alcohol:

	β	γ	α
Water	0.077	0.132	1.713
Alcohol	0.524	2.375	4.532

J. C. P.

Relation between the Dissociation Constant of Weak Acids and the Hydrolysis of their Alkaline Salts. By JAMES WALKER (*Zeit. physikal. Chem.*, 1900, 32, 137—141).—The author has recently determined the dissociation constants of a number of weak inorganic acids (Walker and Cormack, *Trans.*, 1900, 77, 5). From these results, the values of the hydrolysis of the sodium salts may be calculated by the expression $x^2/(1-x)v = k^2/c$, where x is the quantity of salt hydrolysed, and k and c are respectively the dissociation constants of water and the acid. By the reverse calculation, van Laar obtained values for the dissociation of hydrocyanic acid and phenol considerably higher than the experimental determinations of the author, but this was due to the use of an erroneous high value for the dissociation of water (*Abstr.*, 1894, ii, 132). The following values are obtained for the percentage hydrolysis of the sodium salts in $N/10$ solutions: Acetate, 0.008; bicarbonate, 0.06; hydrosulphide, 0.14; metaborate, 0.84; cyanide, 0.96; phenoxide, 3.0; these agree satisfactorily with the direct determinations of Shields (*Abstr.*, 1893, ii, 418), acetate, 0.008; borax, 0.5; cyanide, 1.1; phenoxide, 3.0. The hydrolysis of sodium phenoxide calculated by the author is also in accord with the direct determinations of Hantzsch, although the determinations of the conductivity made by the latter do not agree with the author's results (*this vol.*, i, 94).

L. M. J.

Hydrolysis of Salt Solutions. By LUDWIK BRUNER (*Zeit. physikal. Chem.*, 1900, 32, 133—136).—Results are communicated of work on the same lines as that of Ley (*this vol.*, ii, 67) on the hydrolytic dissociation of salts. The method of sugar inversion was employed for the measurement of the dissociation, and the following results were obtained. The chlorides of quadrivalent elements are considerably hydrolysed, stannic chloride at $v=8$ being almost completely decomposed and zirconium chloride being hydrolysed to the extent of 35 per cent. at $v=64$. In other salts examined, the hydrolysis was in the following order: ferric chloride, uranyl chloride, uranyl nitrate, uranyl sulphate, aluminium chloride, aluminium nitrate, aluminium sulphate, beryllium chloride, beryllium nitrate, beryllium sulphate, and the percentage hydrolysis at three dilutions is given. The hydrolysis is not noticeable, or is too small for measurement in solutions of ammonium, potassium, lithium, manganese, cobalt, cerium, erbium, barium, strontium, calcium, and magnesium chlorides, and in silver, manganese and cobalt nitrates. In general, the chlorides appear to be hydrolysed to the greatest extent, then the nitrates, and the sulphates least. The results are in good accord with those of Ley and the temperature coefficient of the hydrolysis may in some cases be estimated from the two sets of determinations.

L. M. J.

Catalysis with Normal Salts. By HANS EULER (*Zeit. physikal. Chem.*, 1900, 32, 348—359).—The inversion of sugar and the catalysis of esters by acids are both accelerated in the presence of normal salts. In the former case, the influence of a small quantity of a normal salt is nearly independent of the sugar concentration, whilst the acceleration due to the normal salt is the more marked the more dilute the acid is. On the supposition that all chemical compounds are electrolytes, and that every catalytic action consists in a change of concentration of the ions involved, the author considers that the accelerating action of normal salts is due to an increased osmotic pressure of the sugar and ester ions, or to an increased reactive capacity on the part of the water. Normal salts may increase the dissociating power of the solvent, and thus increase the osmotic pressure of the sugar and ester, whilst on the other hand the normal salt may increase the number of hydrogen and hydroxyl ions formed from the water.

J. C. P.

Colloidal Solutions. By GEORG BREDIG and A. COEHN (*Zeit. physikal. Chem.*, 1900, 32, 129—132).—Stoeckl and Vanino (this vol., ii, 11) add nothing new regarding colloidal solutions, the evidence recorded having been previously stated by Linder and Picton (*Trans.*, 1892, 61, 137, 148, 1895, 67, 63) and by Barus and Schneider (*Abstr.*, 1891, 1412). Stark's view that precipitation is due to the separation of dissolved air (*Abstr.*, 1899, ii, 644) is untenable, as colloidal solutions under reduced pressure evolve air without precipitation and may afterwards be precipitated by dilute sulphuric acid and other electrolytes.

L. M. J.

Stereoisomerides and Racemic Compounds. By HERMAN C. COOPER (*Amer. Chem. J.*, 1900, 23, 255—261).—The solubility curves for sodium hydrogen dextro- and lævo-tartrates in aqueous solutions of dextrose are coincident. The same holds for the two optically active sodium ammonium tartrates.

In a discussion on partial racemism, the possibility of obtaining a racemic compound the active components of which are not chemically equivalent is suggested.

T. H. P.

Recognition of Racemic Compounds. By GIUSEPPE BRUNI (*Gazzetta*, 1900, 30, i, 35—39).—The method given by Roozeboom (*Abstr.*, 1899, ii, 276 and 401) for the recognition of racemic compounds, pseudoracemic mixtures, and inactive conglomerates by means of their melting point curves has a complete analogue in the author's method, in which the solubility is examined; in place, however, of the ordinary curves of solubility, in which the latter is considered as a function of the temperature, solubility curves are made use of, which only consider the relative quantities of the two enantiomorphous isomerides present and take no account of the solvent. The various types of such solubility curves, which are similar to the melting point curves of Roozeboom (*loc. cit.*), are as follows. For a racemic compound, the curve consists of three distinct parts and has two minima and a maximum, which may, however, be less than or greater than

the solubility of either of the components; for an inactive conglomerate, the curve is composed of two parts with one minimum, whilst the curve corresponding with a pseudoracemic mixture is continuous,

T. H. P.

Water of Crystallisation. II. By THEODOR SALZER (*J. pr. Chem.*, 1900, [ii], 61, 157—165. Compare Abstr., 1895, ii, 488, and 1898, i, 315).—Calcium malonate and methylmalonate are held to be trimolecular, since when air dried they have the composition $\text{CaC}_3\text{H}_2\text{O}_4 + 1\frac{1}{2}\text{H}_2\text{O}$ and $\text{CaC}_4\text{H}_4\text{O}_4 + 1\frac{1}{2}\text{H}_2\text{O}$; the salts $\text{CaC}_3\text{H}_2\text{O}_4 + 4\text{H}_2\text{O}$ and $\text{CaC}_3\text{H}_2\text{O}_4 + 2\text{H}_2\text{O}$ are also found to be less soluble than the anhydrous salt. Calcium propylmalonate has the composition $\text{CaC}_6\text{H}_8\text{O}_4 + 2\text{H}_2\text{O}$; the butylmalonate, $\text{CaC}_7\text{H}_{10}\text{O}_4 + 2\text{H}_2\text{O}$, loses all its water of crystallisation at 110° ; the dimethylmalonate forms readily soluble needles, $\text{CaC}_6\text{H}_6\text{O}_4 + 3\text{H}_2\text{O}$, loses its water of crystallisation at 110° , and begins to decompose at 162° , whilst the acid first melts at 192° ; the methylmalonate crystallises with $3\text{H}_2\text{O}$. The author withdraws his earlier conclusions with regard to the water of crystallisation of calcium malonate and its homologues.

Other examples of salts which are to be regarded as trimolecular are Fittig's barium propylitaconate, $\text{BaC}_8\text{H}_{10}\text{O}_4 + 1\frac{1}{2}\text{H}_2\text{O}$, and calcium dimethylfumarate, which loses two-thirds of its water of crystallisation when heated.

On repeating the work of Rahlis (*Annalen*, 1879, 198, 106), it is found that calcium *o*-bromobenzoate crystallises with only $2\text{H}_2\text{O}$ and is therefore in agreement with Rule VIII (Abstr., 1898, i, 315). Calcium *p*-bromobenzoate, when prepared from calcium chloride and the ammonium salt at the ordinary temperature, crystallises in minute needles containing $3\text{H}_2\text{O}$, in agreement with Rule VIII, but when the solution is evaporated on a water-bath, separates in tablets with $1\text{H}_2\text{O}$.

T. M. L.

Relation of the Taste of Acid Salts to their Degree of Dissociation. By LOUIS KAHLBERG (*J. Physical Chem.*, 1900, 4, 33—37).—Experiments on the taste of acids have indicated that the sour taste is ascribable to the hydrogen ions (Richards, Abstr., 1898, ii, 209). Experiments with acid sodium salts of a number of slightly dissociated acids prove, however, that the sour taste is obtained at concentrations of the hydrogen ion far below the limit for acids which had been previously found, and that the sour taste of these acid sodium salts cannot be ascribed to the hydrogen ions present. It hence appears that it must be due to the acid ion, and owing to the discrepancy between these results and those of Richards, the author considers the explanation of the sour taste from the standpoint of the dissociation theory to be unsatisfactory (see also Höber and Kiesow, Abstr., 1899, ii, 206).

L. M. J.

Laboratory Apparatus for Roasting Large Quantities of Material. By G. PAUL DROSSBACH (*Ber.*, 1900, 33, 486).—The apparatus consists of a horizontal metal tube, open at one end and provided with a gas delivery tube at the other; it carries a hopper on its upper

surface, and is fitted with a worm worked by a grooved wheel and cord. The whole may be heated in a furnace; the worm fits loosely into the tube, so that no lubricant is required. J. J. S.

Inorganic Chemistry.

Volumetric Composition of Hydrogen Fluoride. By HENRI MOISSAN (*Compt. rend.*, 1900, 130, 544—548).—The volumetric composition of hydrogen fluoride was determined (1) by electrolysing aqueous hydrogen fluoride, collecting and measuring the liberated hydrogen, and the oxygen formed by the fluorine acting on the water, and (2) by allowing a measured volume of fluorine to act on water, the liberated oxygen being measured, and the quantity of hydrofluoric acid formed being estimated by titration. In all cases, the ozone in the oxygen was either decomposed by heating or estimated by titration. The results show that hydrogen fluoride is formed by the union of equal volumes of hydrogen and fluorine.

C. H. B.

Vapour Density of Sulphur. By CARL SCHALL (*Ber.*, 1900, 33, 484—485).—A reply to adverse criticisms by Bleier and Cohn (this vol., ii, 203). Further determinations of the vapour density of sulphur at low pressures (to 42·7 mm.) give densities varying from 7·15 to 7·5 compared with oxygen.

J. J. S.

Products of the Action of Sulphur Dioxide on Ammonia. By HANS SCHUMANN (*Zeit. anorg. Chem.*, 1900, 23, 43—66. Compare Divers and Ogawa, *Trans.*, 1900, 77, 327).—The action of dry sulphur dioxide on dry ammonia results in the formation of the compound $\text{SO}_2\cdot\text{NH}_3$ in the presence of excess of sulphur dioxide, and in the formation of the compound $\text{SO}_2\cdot 2\text{NH}_3$ in the presence of excess of ammonia. The condensation is effected in a flask cooled at 0° , one of the gases being passed through mercury, the other gas entering above the mercury. It is essential that the gases should be carefully dried.

The compound $\text{SO}_2\cdot\text{NH}_3$ is a yellow, crystalline powder, very hygroscopic, and at once decomposed by water, yielding a faintly acid solution, which, on the addition of acids, evolves sulphur dioxide without the immediate precipitation of sulphur; the freshly prepared solution contains ammonium salts and sulphuric, sulphurous, thiosulphuric, trithionic, and pentathionic acids.

The compound $\text{SO}_2\cdot 2\text{NH}_3$, prepared in a flask cooled at -5 to -7° , forms red fragments, and nodular, seemingly crystalline conglomerates, is not so hygroscopic as the preceding compound, and remains undecomposed for some time on exposure to the air, but gradually changes into a white powder. It dissolves in water, with evolution of ammonia; the solution gives a transitory carmine coloration on the addition of

acids, and when freshly prepared, contains the same acids as that of the preceding compound.

The compound $\text{SO}_2\cdot\text{NH}_3$, when heated under dry carbon disulphide in a reflux apparatus, decomposes with evolution of ammonia, and forms a dark red, crystalline sublimate of the composition $3\text{SO}_2\cdot 4\text{NH}_3$, which is very hygroscopic, and yields a solution in water similar to that of the compound $\text{SO}_2\cdot 2\text{NH}_3$.

Potassamide, when heated in sulphur dioxide at 200° , undergoes a violent reaction, with evolution of light and heat; the products are a mixture of the compounds $\text{SO}_2\cdot\text{NH}_3$ and $\text{SO}_2\cdot 2\text{NH}_3$, and a residue containing potassamide, potassium, sulphur dioxide, and small quantities of ammonia.

Similar compounds are obtained by the action of sulphur dioxide on the anhydrous fatty amines, when brought into direct contact without the presence of a solvent at about -6° . Ethylamine yields the compound $\text{SO}_2\cdot\text{NH}_2\text{Et}$, which crystallises in yellow scales and yields a colourless solution in water containing the amine and sulphuric, sulphurous, thiosulphuric, trithionic, and pentathionic acids. The compound $\text{SO}_2\cdot\text{NHMe}_2$, obtained from dimethylamine, is a yellow, crystalline mass, and with water gives a faintly acid solution which contains the amine and sulphuric, sulphurous, and thiosulphuric acids only.

E. C. R.

Reduction of Selenium Dioxide by Sodium Thiosulphate. By JAMES F. NORRIS and HENRY FAY (*Amer. Chem. J.*, 1900, 23, 119—125).—The interaction between selenium dioxide and sodium thiosulphate (*Abstr.*, 1897, ii, 70) probably takes place thus: $\text{SeO}_2 + 4\text{Na}_2\text{S}_2\text{O}_3 = 2\text{Na}_2\text{S}_4\text{O}_6 + \text{Se} + 2\text{Na}_2\text{O}$; in concentrated solutions, selenium is precipitated, and the solution becomes alkaline, but in dilute solution no selenium is precipitated, and the reaction is not complete according to this equation, owing to the sodium hydroxide formed neutralising part of the selenious acid, which, therefore, does not enter into reaction. In presence of hydrochloric acid, the action occurs according to the equation: $\text{SeO}_2 + 4\text{Na}_2\text{S}_2\text{O}_3 + 4\text{HCl} = \text{Na}_2\text{S}_4\text{SeO}_6 + \text{Na}_2\text{S}_4\text{O}_6 + 4\text{NaCl} + 2\text{H}_2\text{O}$. No selenium is precipitated, but sodium selenotetrathionate is formed, which, although it cannot be isolated, gives Debus's tests for pentathionates (*Trans.*, 1888, 53, 278), with the difference that selenium, not sulphur, is precipitated; a dilute solution of the salt can be boiled without change, but stannous chloride precipitates selenium in a few minutes; sodium thiosulphate effects the same result, but more slowly. The sodium tetrathionate, formed according to the equation, was isolated and identified.

An acid solution of tellurium dioxide yields, with sodium thiosulphate, a solution apparently containing a compound analogous to a selenotetrathionate; this is remarkable, since no compounds of tellurium analogous to the thionates are known.

Incidentally, the authors point out that in presence of dilute acids the starch reaction for iodine is about 0.2 per cent. more sensitive at 3° than at the ordinary temperature.

W. A. D.

Preparation of Pure Tellurium. By JAMES F. NORRIS, HENRY FAY, and D. W. EDGERLY (*Amer. Chem. J.*, 1900, 23, 105—119).—The

basic tellurium nitrate obtained by dissolving tellurium in nitric acid is not hygroscopic, and appears to have the composition $4\text{TeO}_2 \cdot \text{N}_2\text{O}_5 + \text{H}_2\text{O}$, rather than $4\text{TeO}_2 \cdot \text{N}_2\text{O}_5 + 1\frac{1}{2}\text{H}_2\text{O}$ (Klein and Morel, *Abstr.*, 1884, 1256, and 1885, 16); since water is not given off on heating the salt until about 190° , when decomposition begins, it is probably present combined according to the formula $\text{Te}_2\text{O}_5(\text{OH})(\text{NO}_3)$. The tellurium obtained by dissolving the oxide prepared from the pure nitrate in pure hydrochloric acid, precipitating with sulphur dioxide, and distilling the metal so obtained, on careful examination does not show the presence of any other element.

The double bromide of tellurium and potassium, prepared from tellurium dioxide, hydrobromic acid, and potassium bromide, was fractionally crystallised by a process involving over 200 crystallisations; since the last fractions, when converted into the nitrate, gave practically the same loss of weight on ignition as the earlier ones, no evidence could be obtained by this process in favour of Brauner's view (*Trans.*, 1889, 55, 382; 1895, 67, 549) that tellurium is a mixture of "true tellurium" with an atomic weight of about 125 and another element with a higher atomic weight. The abnormal position of tellurium in the eighth group of the periodic classification of the elements still awaits explanation.

W. A. D.

Specific Gravity and Electrical Resistance of Tellurium. By VICTOR LENHER and J. LIVINGSTON R. MORGAN (*J. Amer. Chem. Soc.*, 1900, 22, 28—31).—The specific gravity of powdered tellurium, obtained by reduction of the alkaline solution of the oxide by sugar, was determined by the pycnometer method. The values obtained varied from 6.194 to 6.204, with a mean of 6.1993. For the determination of the electrical resistance, the molten metal was allowed to solidify in glass tubes of narrow bore jacketed by outer tubes also containing melted tellurium. Great difficulty was found, however, in obtaining uniform results, the values for the specific resistance varying from 279 to 1152; the mean is about 500, but the authors consider that the lower results are probably the more correct. The value obtained by Matthieson was about 2000, so that the structure has an enormous influence on the conductivity. It was observed that the metal expands slightly immediately after solidification, all the tubes cracking at this point, no matter how slowly they were cooled.

L. M. J.

Surface-tensions of Mixtures of Sulphuric Acid and Water, and the Molecular Mass of Sulphuric Acid. By CHARLES E. LINEBARGER (*J. Amer. Chem. Soc.*, 1900, 22, 5—11).—By the aid of the apparatus previously described by the author (*Abstr.*, 1897, ii, 247), measurements were made of the surface tension of aqueous sulphuric acid at concentrations varying from 2.65 to 95 per cent., and at temperatures varying from 0° to 70° . It was found the surface tension of both acid and water is raised by addition of the other component, the composition of the mixture possessing the highest surface tension being about 60 per cent., but varying slightly with temperature. For the higher concentrations, the influence of temperature is very slight, and this should indicate a high degree of polymerisation, so that the molecule of sulphuric acid is probably very complex, and this

complexity may account for many of the extraordinary properties of mixtures of sulphuric acid and water. According to the views of Brühl (Abstr., 1896, ii, 163), it should be a compound of high dissociative power, and the maximum conductivity of solutions of water in sulphuric acid at a concentration of 10 per cent. are probably to be ascribed to the dissociation of the water, the fall with increased concentration being due to the increased viscosity.

L. M. J.

A New Nitrogen Iodide, N_3I . By ARTHUR HANTZSCH (*Ber.*, 1900, 33, 522—527).—On adding an ethereal solution of iodine to silver azoimide suspended in water at 0° , extracting with ether, and allowing the latter to evaporate below 0° , a nearly colourless solid is obtained, which, from a determination of the ratio of nitrogen to iodine in a freshly prepared aqueous solution, appears to have the composition N_3I ; the dry substance often decomposes spontaneously with great violence, giving rise to nitrogen and iodine, whilst the same products are formed when slow decomposition occurs in benzene or chloroform solution. An aqueous solution of the iodide is at first neutral to litmus, and produces no coloration with starch solution, but decomposition occurs somewhat rapidly to azoimide and hypoiodous acid, which is then further resolved into iodine and iodic acid. Aqueous silver nitrate gives rise, similarly, to silver azoimide, iodine, and iodic acid, a reaction which furnishes the means of determining the ratio of iodine to nitrogen present in the compound.

All attempts to prepare the condensation product N_6 were unsuccessful.

W. A. D.

Nitrogen Iodide. By C. HUGOT (*Compt. rend.*, 1900, 130, 505—508. Compare Chattaway, *Trans.*, 1896, 69, 1572; *Proc.*, 1899, 15, 17).—When ammonia gas is passed into a cooled vessel containing iodine, a dark brown liquid is first produced; this becomes red, and finally assumes a faint yellow colour, whilst the compound, $NI_3 \cdot 3NH_3$, separates in dark green needles. The yellow liquid contains the ammonio-ammonium iodide, $NH_4I \cdot 3NH_3$, dissolved in liquid ammonia, together with small quantities of free iodine, and the compound $NI_3 \cdot 3NH_3$. The reaction appears to take the following course: $16NH_3 + 6I = 3(NH_4I \cdot 3NH_3) + NI_3 \cdot 3NH_3$.

The ammonio-nitrogen iodide, $NI_3 \cdot 3NH_3$, when maintained at a temperature of -30° in a vacuum, loses one-third of its ammonia, and a well-defined, crystalline, yellow compound, $NI_3 \cdot 2NH_3$, is produced; at 0° in a vacuum, the latter substance parts with half its ammonia, yielding violet needles of the compound $NI_3 \cdot NH_3$. It is not possible to eliminate the last mol. of ammonia, since the third compound is decomposed on warming, and at about 50° a violent detonation is produced.

G. T. M.

The Molecule of Carbon and the Supposed Negative Heat of Formation of various Carbon Compounds. By WILHELM VAUBEL (*Zeit. angew. Chem.*, 1900, 60—63).—Calculations based on the difference between the heats of combustion of carbon and carbon monoxide lead the author to the conclusion that the molecule of

carbon at its boiling point contains 24 atoms. The heat of dissociation of this complex carbon molecule is taken as 32300 cal., and hence it is deduced that acetylene, carbon disulphide, and other compounds which have commonly negative heats of formation assigned to them, have really positive heats of formation. The author proposes to recalculate on this new basis the heats of formation of organic compounds.

J. C. P.

Preparation of Amorphous Silicon, Silicon Sulphide, Silicon Chloride, and Thiosilicates. By WALTHER HEMPEL and VON HAASY (*Zeit. anorg. Chem.*, 1900, 23, 32—42).—Amorphous silicon is prepared easily and in considerable quantities by heating sodium in an atmosphere of silicon fluoride. The apparatus, which is figured in the original paper, consists of a generator of silicon fluoride and a special iron retort so arranged that when heated and filled with silicon fluoride, sodium can be expeditiously introduced in successive small portions. The product consists of silicon, sodium fluoride, and sodium silicofluoride; it is powdered and heated with sufficient sodium to decompose the silicofluoride and with sufficient aluminium to form an alloy containing not more than 16 per cent. of silicon. When cold, the alloy is separated mechanically from the fused mass, and the aluminium dissolved in hydrochloric acid. The amorphous silicon is lead-grey, amounts to 90—95 per cent. of the theoretical yield, and contains 3—4 per cent. of silica; this is extracted with hydrofluoric acid, and brown, amorphous silicon, amounting to 60—62 per cent. of the theoretical yield, is obtained in a very active form, which, when gently heated in the air, burns to silica. By melting aluminium with silicon, alloys containing up to 22·5 per cent. of silicon can be prepared, but the silicon separated from these is very inert. Silicon from an alloy containing 16·5 per cent. burns in chlorine at 280°, that from an alloy containing 22·5 per cent. at 340—350°.

Silicon sulphide is obtained by melting amorphous silicon with three times its weight of sulphur, and then throwing the fused mass into a red-hot crucible in successive small portions. The product contains 92—95 per cent. of silicon sulphide mixed with silicon and silica, and is purified by sublimation under diminished pressure. It crystallises in beautiful, long, white needles. Silicon chloride is easily prepared by heating the amorphous silicon in a current of chlorine.

Sodium metathiosilicate, Na_2SiS_3 , obtained by melting pure sodium sulphide with silicon sulphide, is a brownish-black mass which evolves hydrogen sulphide when treated with water, yielding a solution which does not evolve more hydrogen sulphide when treated with acids; when treated with chlorine, it yields sulphur chloride and silicon chloride with development of much heat. The authors have applied this last reaction to detect the presence of thiosilicates in some complex silicates, and obtained the following results: ultramarine, 0·174 per cent. SiS_2 ; blast furnace slags, 0·043, 0·009, and 0·104 per cent. SiS_2 ; lava from Vesuvius, 0·007 per cent. SiS_2 . They also point out that the sulphur present in many of the sulphur springs may be due to the decomposition of thiosilicates.

E. C. R.

Preparation of Arsenides, Antimonides, and Alloys of the Alkali Metals. By PAUL LEBEAU (*Compt. rend.*, 1900, 130, 502—505).—Impure arsenides containing excess of the metal or arsenic are produced when the latter or its hydride, either in the gaseous or liquid state, reacts with an alkali metal. Liquefied hydrogen arsenide has no solvent action on the alkali metals, and, unlike liquid ammonia, does not form compounds with these elements.

Pure sodium arsenide, Na_3As , is prepared by heating to redness in a closed iron vessel a mixture of arsenic and sodium; an excess of the latter is employed and the uncombined metal is removed from the cooled product by means of liquid ammonia; the arsenide remains undissolved and is obtained in the form of small, black crystals. Sodium antimonide, bismuthide, and stannide, and the corresponding lithium and potassium compounds, have been produced in a similar manner.

G. T. M.

Electrolytic Formation of Potassium Chlorate. By ANDRÉ BROCHET (*Compt. rend.*, 1900, 130, 718—721. Compare this vol., ii, 205).—When a cold and almost neutral solution of potassium chloride is electrolysed, the whole of the electric energy is spent in producing hypochlorite; the greater portion of this substance, however, is at once transformed into chlorate, the transformation being accompanied by an evolution of oxygen; under certain conditions, the addition of potassium chromate prevents the decomposition of the hypochlorite. This transformation is made manifest on electrolysing a solution of potassium chloride containing potassium dichromate; this salt liberates hypochlorous acid, becoming itself converted into the neutral chromate, and the colour of the solution changes from orange to yellow; the change is reversed when the solution is left for twelve hours owing to the production of chloric acid, this acid partially displacing chromic acid and regenerating the dichromate.

The auto-oxidation of hypochlorous acid takes place even more rapidly in hot or alkaline solutions, the yield of available chlorine being correspondingly diminished.

G. T. M.

Presence of Potassium Nitrite in Brown Powder Residue when the Powder is Burnt in Air under Ordinary Pressure. By A. M. SETON and K. L. STEVENSON (*Chem. News*, 1899, 80, 221).—Brown powder burns more slowly than black powder, and leaves more residue, which is generally white or greyish-white, hygroscopic, and partly soluble in water. A complete analysis gave the following results: K_2CO_3 , 61.96; K_2SO_4 , 26.18; KNO_3 , 6.17; insoluble, 5.8 per cent.

D. A. L.

Isomeric Potassium Sodium Sulphites. By GEORGE S. FRAPS (*Amer. Chem. J.*, 1900, 23, 202—214).—The existence of two isomeric potassium sodium sulphites has been indicated by the work of Röhrig (Abstr., 1888, 649), Schwickler (Abstr., 1889, 942), and Barth (Abstr., 1892, 564). The author prepares the double sulphite, firstly, by dissolving sodium carbonate in a solution of potassium hydrogen sulphite, and, secondly, by the interaction of potassium carbonate and sodium hydrogen sulphite; from a number of experiments on the action of

ethyl iodide on these two products, it is concluded that there is no evidence of the existence of two isomeric double sulphites.

T. H. P.

Compounds of Metals among themselves. By NICOLAI S. KURNAKOFF (*J. Russ. Phys. Chem. Soc.*, 1899, 31, 927—948).—The relations between melting point and composition are given for the following mixtures: mercury and sodium, mercury and potassium, cadmium and sodium, lead and sodium, bismuth and sodium.

The melting point curve for sodium and mercury shows five transition points, at which the ratio of the number of atoms of sodium to the number of mercury atoms has the values: 5·690 : 1 (at 21·25°); 2·559 : 1 (at 67·0°); 1·020 : 1 (at 209·7°); 1 : 1·101 (at 218°); 1 : 4·571 (at 155°). The maximum melting point corresponds with the compound NaHg_2 . From the eutectic mixture ($\text{Na} : \text{Hg} = 5·690 : 1$), beautiful, hexagonal plates of indefinite composition separate. The compound Na_3Hg , described by Maey (Abstr., 1899, ii, 547), has probably the composition Na_nHg , where n is not greater than 2·559. For potassium-mercury, the curve has three transition points, namely, 195·0°, 129·0°, and 70·3°, the corresponding values for the ratio $\text{K} : \text{Hg}$ being 1 : 3·283, 1 : 6·350, and 1 : 10·556 respectively. The maximum melting point mixture has the composition KHg_2 . The compound KHg_{12} , described by several writers, is probably KHg_n , n being not greater than 10·556; Maey (*loc. cit.*) found that n does not exceed 11. From the researches of the author and others, definite compounds of sodium and mercury of the composition NaHg_n are shown to exist, as follows: (1) n less than 2·5 (NaHg_2); (2) NaHg ; (3) n between 1 and 2; (4) NaHg_2 ; (5) n between 2 and 5 (NaHg_3); (6) NaHg_5 or NaHg_6 . The definite mercury potassium compounds, having the formula KHg_n , are: (1) KHg ; (2) KHg_2 ; (3) n between 2 and 3·28 (KHg_3); (4) n between 3·28 and 6·3 (KHg_5 or KHg_6); (5) n between 6·3 and 10·5 (KHg_{10}).

The maximum points of the other curves correspond with compounds having the formulæ NaCd_2 , NaPb , and Na_3Bi . NaCd_2 separates in glistening octahedra.

T. H. P.

Persulphates of Rubidium, Cæsium, and Thallium. By HUGH MARSHALL (*J. Amer. Chem. Soc.*, 1900, 22, 48. Compare Abstr., 1899, ii, 747).—Rubidium and cæsium persulphates, obtained by double decomposition from ammonium persulphate, are isomorphous with the ammonium salt, whereas mixtures of these salts with the potassium salt crystallise in monoclinic crystals. Mixtures of the thallous and ammonium salts also crystallise in the monoclinic system, and are isomorphous with the preceding mixtures.

J. J. S.

Melting Point of Lithium. By GEORG W. A. KAHLBAUM (*Zeit. anorg. Chem.*, 1900, 23, 220—221).—The sample of lithium was prepared by A. Guntz by the electrolysis of a mixture of equal parts of lithium and potassium chlorides. The melting point was determined in a bath of dry paraffin, and found to be 186° (Bunsen and Matthiessen give 180°).

E. C. R.

Action of Hydrogen Peroxide on Barium Hydroxide. By ROBERT DE FORCRAND (*Compt. rend.*, 1900, 130, 716—718).—When

baryta water containing 1 mol. of barium hydroxide is treated with $\frac{1}{2}$ mol. of hydrogen peroxide, a precipitate is formed in 3 minutes, even in dilute solutions; the heat evolved during the first 2 minutes is 3.121 Cal., and this represents the heat of the reaction before the formation of any insoluble compound; when twice this quantity of the peroxide is employed, the heat generated is somewhat greater, namely, 4.350 Cal., and the immediate addition of 2 mols. of hydrochloric acid produces a further thermal change of 23.474 Cal. The addition of 2 and 3 mols. of the peroxide to two solutions, each containing 1 mol. of the barium compound, is accompanied by the development of 7.801 and 8.552 Cal. respectively, the corresponding heats of neutralisation by hydrochloric acid (2 mols.) being 19.958 and 18.984 Cal. The heat developed on adding 10 mols. of the peroxide to the solution of barium hydroxide is 12.261 Cal., and the heat of neutralisation by hydrochloric acid is 15.345 Cal.; when a larger excess of the peroxide (30 mols.) is employed, the thermal effect is 13.586 Cal. Two compounds appear to be successively produced, one, containing a large proportion of hydrogen peroxide, which has not been isolated, the other being the substance $\text{BaO}_2 \cdot \text{H}_2\text{O}_2$ studied by Schoene and Berthelot; the latter may be regarded as having the constitution $\text{Ba}(\text{O}\cdot\text{OH})_2$. The heat of neutralisation of this compound by barium hydroxide is 0.899 Cal., or 0.45 Cal. for each hydroxyl group; it appears, therefore, that the compound is slightly acidic. The formula $\text{Ba} \begin{array}{c} \diagup \text{O} \diagdown \\ \diagdown \text{O} \diagup \end{array} \text{Ba}$ is ascribed to the salt produced.

G. T. M.

Action of Metallic Magnesium on Water. By EDWARD G. BRYANT (*Chem. News*, 1899, 80, 211—212).—Magnesium of commerce, containing 1.77 per cent. of iron and 0.3 of calcium, but no detectable carbon, was found to evolve hydrogen when placed in water, the action continuing for many hours with decreasing energy, and finally ceasing. 0.1 gram of the powdered metal, placed in 100 c.c. of water, yielded 2—3 c.c. of hydrogen; this quantity could be increased by the addition of normal sodium sulphate, which dissolves magnesium oxide; heating the water did not cause a greater, but only a more rapid, evolution of hydrogen. The metal itself became tarnished, and, if polished, regained its activity. There was no question of a couple forming, and the gases in water were shown to have no effect on the action, which is a direct action of magnesium on water. One part of magnesium oxide dissolves in 225,000 parts of water. D. A. L.

Colloidal Cadmium. By GEORG BREDIG (*Zeit. physikal. Chem.*, 1900, 32, 127—8. Compare this vol., ii, 213).—Colloidal metallic solutions have been proved to consist of minute suspended particles of metals, and it hence follows that colloidal solutions of metals with a lower potential than hydrogen, such as cadmium or zinc, would be unstable and difficult to obtain. By means of an E.M.F. of 30—40 volts and a current of 5—10 ampères, an arc may be obtained between cadmium electrodes immersed in pure, air-free water, the cadmium being dispersed with the formation of a deep brown colloidal solution which changes to a blue-green, and coagulates on the addition of

electrolytes. By exposure to air, the solution speedily oxidises, but by exclusion of air, especially if the liquid be thickened by gelatin, it may be kept for a considerable time. L. M. J.

Action of Hydrogen Sulphide on Lead Peroxide. By LUDWIG VANINO and OTTO HAUSER (*Ber.*, 1900, 33, 625).—When hydrogen sulphide is passed over either moist or dry lead peroxide, the whole mass glows, and the gas burns with the characteristic lead flame. The reaction can be used, not merely as a lecture experiment, but may also be employed for starting an explosion, even with guncotton saturated with moisture. The reaction works best when the peroxide is collected in small heaps and not spread over a flat surface. Bismuth and silver peroxides give the same reaction, but lead oxide, manganese peroxide, cobaltic hydroxide, or cupric oxide do not. J. J. S.

A New Type of Ammonio-copper Chromate. By M. C. SCHUYTEN (*Chem. Centr.*, 1900, i, 399—400; from *Bull. Acad. roy. Belg.*, [iii], 37, 649—656).—By treating an aqueous solution of copper sulphate and potassium dichromate with ammonia, or by adding potassium dichromate to an ammoniacal solution of cupric hydroxide from which the excess of ammonia has been removed by exposure to the air, a compound, $4\text{CuCrO}_4 \cdot 3\text{NH}_3 \cdot 5\text{H}_2\text{O}$, separates as a brown, amorphous powder; when heated, it evolves ammonia, water, and a small quantity of nitrous fumes, but the whole of the ammonia and water cannot be expelled even by heating for a long time at a high temperature. It dissolves in hydrochloric acid or ammonia, forming a yellow or a green solution respectively; it is also easily soluble in a solution of silver nitrate, but insoluble in organic solvents. Alcohol is not oxidised to aldehyde by boiling with the hydrochloric acid solution of this compound. E. W. W.

Mercury Derivatives of Nitrogen Compounds. By KARL A. HOFMANN and EDUARD C. MARBURG (*Zeit. anorg. Chem.*, 1900, 23, 126—134. Compare *Abstr.*, 1899, i, 486).—In answer to Pesci's criticisms (*Abstr.*, 1899, ii, 750), the authors maintain the correctness of their formulæ for the fusible and infusible precipitates obtained from mercuric chloride and ammonia in the presence of ammonium chloride. They point out that these compounds, HgNH_2Cl and $\text{Hg}(\text{NH}_2)_2\text{Cl}_2$, correspond with the ethylamine derivatives, HgNH_2EtCl , $\text{HgNH}_2\text{EtCl}_2$, and $\text{Hg}(\text{NH}_2\text{Et})_2\text{Cl}_2$, whereas ethylamine derivatives corresponding with compounds of the formulæ Hg_2NCl , NH_4Cl and $\text{Hg}_2\text{NCl} \cdot 3\text{NH}_4\text{Cl}$, could not be formed from an ethylated ammonia. The decomposition of the fusible and infusible precipitates by dilute alkalis naturally results in the formation of the theoretical quantity of mercuriammonium chloride, the first products of decomposition being alkali chloride, mercuric oxide and oxychloride, and ammonia; the mercuric oxide and ammonia, in the presence of halogen, then form the chloride of Millon's base and from 2 mercury atoms 1 mol. of mercuriammonium chloride is formed, 1 mol. of ammonia retained, and the excess of ammonia evolved.

Pesci's formulæ for Millon's base, $\text{Hg}_2\text{N} \cdot \text{OH} \cdot 2\text{H}_2\text{O}$, and the mercuriammonium salts, Hg_2NX , do not explain the behaviour of these

compounds on dehydration. Millon's base becomes dark brown on dehydration and the resulting compound, Hg_2NOH , is explosive and does not combine with hydrogen chloride to form salts. The salts of Millon's base are represented by the formula $(\text{HgOH})_2\text{NH}_2\text{X}$ and cannot be dehydrated without decomposition. The only exception is the nitrate, HgN_2NO_3 , which, when prepared from Millon's base, is not pure and on heating yields a small quantity of water. E. C. R.

Anhydrous Dimercuriammonium Iodide, Amorphous and Crystalline. By MAURICE FRANÇOIS (*Compt. rend.*, 1900, 130, 571—573).—Dimercuriammonium iodide, contrary to the usual statements, contains neither hydrogen nor oxygen, but is anhydrous and is a very stable substance. It is obtained in an amorphous state by the action of a large excess of concentrated ammonia solution on mercuric iodide or mercuridiammonium iodide, or, better, by the prolonged and repeated action of a 25 per cent. solution of sodium hydroxide on mercuridiammonium iodide. The crystallised compound is prepared by mixing a saturated solution of mercuridiammonium iodide in concentrated ammonia solution with twice its volume of the same concentrated ammonia solution. The crystals form slowly and are very dark purple by reflected light, but dark red brown by transmitted light. C. H. B.

Preparation and Properties of a Manganese Perfluoride. By HENRI MOISSAN (*Compt. rend.*, 1900, 130, 622—627).—Metallic manganese is attacked by fluorine at the ordinary temperature, but the reaction is limited by the formation of a layer of fluoride on the surface of the metal. If the manganese is finely powdered, the reaction takes place with incandescence, but the fluoride formed is partly volatilised and decomposed, so that the product is not of constant composition. Manganous fluoride is also attacked by fluorine, but the reaction is never complete, whilst with manganous chloride it is difficult to expel the whole of the chlorine. With manganous iodide, however, the reaction is much more regular, and manganese trifluoride, Mn_2F_6 , is obtained in crystals which preserve the form of those of the iodide from which it was derived, and have a sp. gr. 3.54. When heated, it decomposes with the production of manganous fluoride and fluorine, whilst it is reduced by hydrogen below a red heat, hydrogen fluoride and manganous fluoride being formed. At the ordinary temperature, chlorine, bromine, and iodine are without action on manganese trifluoride, but on heating, ternary compounds are formed, that with iodine being of a red colour. When the trifluoride is heated in glass, the latter is violently attacked, silicon fluoride being liberated, whilst a mixture of fluoride and oxyfluoride of manganese remains. Manganese trifluoride is decomposed by oxygen at a red heat with the formation of black, crystalline oxide of manganese. With sulphur at its boiling point, sulphur fluoride and manganous fluoride are formed; with phosphorus at a slightly elevated temperature, phosphorus trifluoride and pentafluoride are produced; and with arsenic, the trifluoride is obtained. Silicon, boron, and carbon are converted into fluorides by the action of manganese trifluoride. When heated in an atmosphere of hydrogen chloride, manganous

chloride, hydrogen fluoride, and free chlorine are formed. Sulphuric, nitric, and hydrochloric acids dissolve manganese trifluoride, forming dark brown solutions which are decomposed by excess of water. The action of water alone results in the formation of manganous fluoride, hydrofluoric acid, and a hydrated oxide of manganese, the relative proportions of these products depending on the amount of water employed. Manganese trifluoride readily reacts with hydrogen sulphide, sulphur chloride, and sulphuryl chloride, whilst with phosphorus trichloride it yields phosphorus fluorochloride, PF_2Cl_2 , and with phosphorus pentachloride the pentafluoride. With carbon tetrachloride, the products obtained are a white manganese fluoride, chlorine, and carbon fluoride. Organic substances, such as benzene, turpentine, chloroform, alcohol, and ether are without action on manganese trifluoride, even at 100° .

N. L.

Ferric Oxide Solution obtained by Dialysis. By WILLY WOBBE (*Chem. Centr.*, 1900, i, 165; from *Pharm. Centr.-H.*, 40, 793—796).—A solution of ferric oxide may be obtained by dialysing a solution of ferric oxychloride prepared by adding ammonia to a solution of ferric chloride in small portions at a time, so that after each addition the ferric hydroxide is completely dissolved on stirring. The clear, dark brown solution so obtained scarcely tastes of iron. It is evaporated until it contains 3.5 per cent. of iron, and has a sp. gr. 1.05. The last traces of chlorine cannot be removed by dialysis, and the product still contains 0.75 per cent. of ferric chloride, but it is free from ammonium salts. Attempts to completely remove the chloride by a process of hot dialysis appear to promise success. The solutions of ferric oxychloride and of ferric oxide may be boiled for some time without decomposing. The possibility of concentrating a solution of ferric oxychloride by heat renders unnecessary the pressing of the ferric hydroxide in the preparation of the solution for pharmaceutical purposes. After removing the supernatant liquid, the precipitate is added in small portions to the hydrochloric acid, and the solution then evaporated to the required density.

E. W. W.

Preparation of the Phosphides of Iron, Nickel, Cobalt, and Chromium. By GEORGES MARONNEAU (*Compt. rend.*, 1900, 130, 656—658).—A number of metallic phosphides were obtained in a well crystallised state by heating a mixture of the finely divided metal with copper phosphide in the electric furnace, the product of the reaction being treated with nitric acid to remove the copper. Iron phosphide, Fe_2P , was thus obtained in the form of whitish-grey, brilliant needles having a sp. gr. 6.57. Nickel phosphide, Ni_2P , crystallises in transparent, grey needles of sp. gr. 6.3, whilst cobalt phosphide, Co_2P , of similar appearance, has a sp. gr. 6.4. Chromium phosphide, CrP , forms dull grey crystals of a sp. gr. 5.71. The phosphides of iron, nickel, and chromium are insoluble in all acids except a mixture of nitric and hydrofluoric acids; cobalt phosphide is dissolved by concentrated nitric acid, and is slowly attacked by hydrochloric and sulphuric acids.

N. L.

Alloys of Platinum and Palladium with Cadmium, Zinc, and Magnesium. By W. R. EATON HODGKINSON, R. WABING, and A. P. H. DESBOROUGH (*Chem. News*, 1899, 80, 185).—A weighed quantity of platinum or palladium foil contained in a porcelain boat was placed close to a porcelain boat containing a large excess of the volatile metal and heated above the boiling point of the latter in refractory glass tubing; during the experiment, either a current of dry hydrogen was passed over the volatile metal towards the platinum or a vacuum was induced by means of a Sprengel pump at the platinum end of the tube. At the close of the experiment, the platinum or palladium in the boat was weighed and examined. With platinum, cadmium formed an alloy, PtCd_2 , which was white, crystalline, and brittle, and from which cadmium does not volatilise at full redness; when treated with nitric acid, some platinum dissolved as well as the cadmium. With zinc, the results were less definite, but if heated to a point where the glass tube collapsed, a brittle, crystalline alloy was obtained similar in character to the cadmium alloy, but of the composition PtZn . Magnesium proved still more troublesome, as its vapour was absorbed by the glass, but by lining the tube with magnesium oxide, a friable, crystalline alloy was produced of the composition PtMg_2 .

Experiments with palladium and with nickel have yielded only negative results.

D. A. L.

Complex Palladium Salts. By ARTHUR ROSENHEIM and HERMANN ITZIG (*Zeit. anorg. Chem.*, 1900, 23, 28—31).—*Potassium palladous iodonitrite*, $\text{K}_2\text{PdI}_2(\text{NO}_2)_2 + 3\text{H}_2\text{O}$, obtained by saturating a concentrated solution of potassium nitrite with palladous iodide and allowing the mixture to crystallise over sulphuric acid, crystallises in purplish-red, prismatic needles, effloresces on exposure to the air, and decomposes when dissolved in water or treated with dilute acids, with precipitation of palladous iodide.

Potassium palladous oxalonitrite, $\text{K}_2\text{Pd}(\text{NO}_2)_2\text{C}_2\text{O}_4$, obtained by warming the preceding salt with a molecular proportion of oxalic acid, crystallises in beautiful, yellow needles sparingly soluble in cold, but easily so in hot, water.

Ammonium palladous trichlorosulphite, $(\text{NH}_4)_3\text{PdCl}_3\text{SO}_3 + \text{H}_2\text{O}$, obtained by saturating a concentrated solution of ammonium sulphite with ammonium palladochloride, crystallises in bright red, hexagonal crystals [$\alpha : c = 1 : 0.8923$].

E. C. R.

Mineralogical Chemistry.

Roumanian Petroleums. By ALFONS O. SALIGNY (*Chem. Centr.*, 1900, 60; from *Bul. Roumanie*, 8, 351—365).—In the original paper, the physical and chemical properties of 12 kinds of Roumanian

petroleum are described and tabulated. The flash points of the various fractions are given, and their suitability for use as burning oils is also discussed. These petroleums contain very variable amounts of volatile oils, and ethylisobutane and isopropane were found in the fractions boiling below 70°.

E. W. W.

Melonite from South Australia. By ALFRED J. HIGGIN (*Trans. Roy. Soc. South Australia*, 1899, 23, 211—212).—This mineral, previously only known from California, has now been found with quartz and calcite at Worturpa, South Australia. The thin lamellæ have a brilliant metallic lustre; the cleavage planes are silver-white to reddish-brown. $H=1.5$; sp. gr., 7.6. Analyses I and II agree with the formula Ni_2Te_8 (compare this vol., ii, 22).

	Te.	Ni.	Au.	Insol.	Total.
I.	74.49	22.99	0.329	2.091	99.90
II.	71.500	21.274	0.018	7.319	100.11

Traces of bismuth and lead are present. On dissolving the mineral in nitric acid, the gold is left as bright spangles.

L. J. S.

Titaniferous Magnetites. By JAMES F. KEMP (*School of Mines Quart.*, 1899, 20, 323—356; 21, 56—65).—Titaniferous magnetites, with the exception of the occurrences in sands, are almost invariably found associated with rocks of the gabbro type, and have originated by a process of segregation from the magma. The mineral, as a rule, contains vanadium, chromium, nickel and cobalt, which together may amount to several per cent. (compare Abstr., 1899, ii, 109). Phosphorus and sulphur are low, or entirely absent. A description is given of the occurrence of titaniferous magnetites in each country of the world. Numerous references and analyses are quoted. Although abundant in certain regions, the mineral is not at present worked as an ore.

L. J. S.

Manganese Nodules from New South Wales. By WILLIAM M. DOHERTY (*Rept. Australian Assoc. Adv. Sci.*, 1898, 7, 339).—In the scrub-land near Onybygambah, on the Tweed river, are scattered about numerous spherical nodules which are dark and shining, with the appearance of seeds, or dull black; they are soft, and of the size of a pea to that of a Barcelona nut. Analyses gave:

MnO ₂	Fe ₂ O ₃ , Al ₂ O ₃	MgCO ₃	Organic Matter.	Gangue.
24.70	11.20	2.00	12.00	49.60
25.00	8.70	2.60	12.80	50.20
40.60	14.00	3.10	10.00	32.10

L. J. S.

Egyptian Soda Valleys. By G. SCHWEINFURTH and L. LEWIN (*Jahrb. Min.*, 1900, i, 236—237; from *Zeit. Ges. Erdkunde*, 1898, 33, 1—25).—The following analyses of the natural soda, as exported, are given. I. Dirty white nodular concretions. II and III. "Natrūn Sultani," which separates out on the floor of the lakes. IV. Hopper-shaped crystals of salt on the surface of the lakes.

	I.	II.	III.	IV.	V.
$\text{Na}_2\text{CO}_3 + \text{NaHCO}_3 \dots$	85.86	80.56	87.98	0.212	66.80
$\text{NaCl} \dots \dots \dots$	7.00	10.40	4.00	98.00	18.44
$\text{Na}_2\text{SO}_4 \dots \dots \dots$	1.20	3.72	0.59	0.506	11.40

Analysis V is of material found in a tomb near Thebes, dating from 1500—1600 B.C. The lakes are probably supplied by Nile water, and it is suggested that the soda is formed by the interaction of calcium hydrogen carbonate and sodium sulphate, the latter being derived by the interaction of sodium chloride and gypsum. L. J. S.

Formation of Oceanic Salt Deposits, particularly of the Stassfurt Beds. XV. Formation of Glauberite at 25°. By JACOBUS H. VAN'T HOFF and D. CHIARAVIGLIO (*Chem. Centr.*, 1900, i, 59—60; from *Sitzungsber. Akad. Wiss. Berlin*, 1899, 810—818. Compare this vol., ii, 76).—At Leopoldshall, glauberite is found in isolated masses in the older rock salt 30 metres below the potassium chloride stratum, and under the kieserite region. The mineral also occurs in the upper layers of the kainite zone, and single crystals are found in the lower portions of the kieserite bed. When a solution of calcium chloride is mixed with a solution of sodium sulphate, and the mixture stirred and evaporated at 100°, the separation of gypsum is followed by the formation of needles of the compound, $\text{Na}_2\text{Ca}(\text{SO}_4)_2 + 2\text{H}_2\text{O}$, which are then, however, rapidly replaced by rhombohedra of glauberite, the latter change being complete when the liquid has been concentrated. The mother liquor was removed by means of alcohol. Calculations from experimental data and graphical representation of results show that glauberite is formed, together with the following minerals, at 25°: rock salt, epsomite, $\text{MgSO}_4 + 7\text{H}_2\text{O}$; picromerite, $\text{MgK}_2(\text{SO}_4)_2 + 6\text{H}_2\text{O}$; blöditte, $\text{MgK}_2(\text{SO}_4)_2 + 4\text{H}_2\text{O}$; thenardite, Na_2SO_4 ; and aphthitalite, $\text{K}_2\text{Na}(\text{SO}_4)_2$, and also that glauberite is not formed when sea water is evaporated at 25°. When crystals of glauberite are left in contact with sea water which is beginning to deposit sodium chloride or magnesium sulphate at 25°, they gradually disappear and gypsum is formed. E. W. W.

Formation of Oceanic Salt Deposits, particularly of the Stassfurt Beds. XVI. Hydrate of Magnesium Potassium Sulphate, $\text{Mg}_4\text{K}_2(\text{SO}_4)_5 + 5\text{H}_2\text{O}$. By JACOBUS H. VAN'T HOFF and N. KASSATKIN (*Chem. Centr.*, 1900, i, 368; from *Sitzungsber. Akad. Wiss. Berlin*, 52, 951—953).—In order to ascertain the conditions of the formation of langbeinite, $\text{Mg}_2\text{K}_2(\text{SO}_4)_3$, obtained by removing water from a mixture of magnesium and potassium sulphates, the progress of dehydration of a system, $\text{MgSO}_4 \cdot 6\text{H}_2\text{O} + \text{MgK}_2(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$, prepared by concentrating at 47.2° was followed. A hydrate of magnesium potassium sulphate, $\text{Mg}_4\text{K}_2(\text{SO}_4)_5 + 5\text{H}_2\text{O}$, was formed; it is a double salt of the hydrate, $\text{MgSO}_4 + \frac{1}{2}\text{H}_2\text{O}$ (*Abstr.*, 1899, ii, 759). It is also formed when a mixture of hexahydrated magnesium sulphate and leonite are heated at 72.5°. Its formation is easily recognised by means of the dilatometer or the thermometer, and depends on the mutual action of the salts, for solutions of these salts, when heated alone, do not show any such change. When a solution containing

magnesium sulphate (4 mols.) and potassium sulphate (1 mol.) is evaporated, leonite first separates, then the new compound in well formed needles, and finally the leonite disappears and the whole mass solidifies.

E. W. W.

Formation of Oceanic Salt Deposits, particularly of the Stassfurt Beds. XVII. A Relationship between the Composition of Solutions of Sodium Chloride and Potassium Chloride saturated at 25°. By HAROLD A. WILSON (*Chem. Centr.*, 1900, i, 368—369; from *Sitzungsber. Akad. Wiss. Berlin*, 52, 954—955).—In the diagram representing the relations of solubilities in the case of saturation with potassium chloride in presence of chlorides and sulphates of magnesium and potassium (*Sitzungsber. Akad. Wiss. Berlin*, 1898, 820), it is seen that, in the plane which indicates saturation with sodium chloride and potassium chloride, the data have a very simple relationship. If the composition is expressed in molecules of Na_2Cl_2 (a), K_2Cl_2 (b), MgCl_2 (c) and MgSO_4 (d) per 1000 molecules of water, then $b + c/5$ is a constant, that is, by the entry of each double molecule of potassium chloride, 1/5th of a molecule of magnesium chloride is expelled.

The following data are quoted :

	Saturation with		
	K_2Cl_2	MgCl_2	$\text{K}_2\text{Cl}_2 + \frac{\text{MgCl}_2}{5}$
NaCl and KCl.....	19.5	0	19.5
NaCl, KCl and apththalite	20	0	20
NaCl, KCl and carnallite	5.5	70.5	19.6
„ „ glaserite and picromerite.....	16	18.5	19.7

„ „ $\text{MgSO}_4 + 5\text{H}_2\text{O}$ and carnallite.....	6	68	19.6
„ „ and $\text{MgSO}_4 + 6\text{H}_2\text{O}$	7.8	55.8	19
„ „ picromerite and $\text{MgSO}_4 + 6\text{H}_2\text{O}$...	9.5	42.5	18
„ „ in 20 per cent. MgCl_2	9.5	47.5	19

E. W. W.

Constitution and Classification of Silicates. By VASILE C. BUTUREANU (*Jahrb. Min.*, 1900, i, Ref. 184—186; from *Bul. Soc. Sci. Fis. Bucuresti*, 1896, 60—73, 129—139, 254—279).—The following is the classification given :

I. Neutral silicates.

a. Orthosilicates. General formula, $(\text{SiO}_4)_n(\text{M}'_4)_n$.

(1). Simple.

(2). Condensed.

b. Metasilicates. General formula, $(\text{SiO}_3)_n(\text{M}'_2)_n$.

(1). Simple.

(2). Condensed.

c. Polysilicates. Derived from meta- or ortho-silicic acid : general formulæ $\text{Si}_n\text{O}_{3n+1}\text{M}'_{2n+2}$, $\text{Si}_n\text{O}_{3n}\text{M}'_{2n}$, $\text{Si}_n\text{O}_{3n-1}\text{M}'_{2n-2}$ &c.

II. Basic silicates.

III. Acid silicates.

IV. Silicates with water of crystallisation.

V. Mixed silicates; for example, borosilicates, titanosilicates, &c.

Structural formulæ for each mineral species are given in the original. L. J. S.

Augite from Yoneyama, Japan. By C. IWASAKI (*Zeit. Kryst. Min.*, 1900, 32, 302; from ? [separate copy, 5 pp.]).—Augite crystals, up to 1 cm. across, occur in a weathered olivine-augite-andesite at Yoneyama, Prov. Echigo. A short, crystallographic description is given; sp. gr. 3.42. Analysis by Yoshida gave:

SiO ₂ .	Fe ₂ O ₃ .	Al ₂ O ₃ .	FeO.	CaO.	MgO.	K ₂ O.	Na ₂ O.	Total.
53.56	2.75	0.26	8.69	30.16	1.70	0.21	2.64	99.97.

L. J. S.

Westanite, Pyrophyllite and Kaolinite from Westana, Sweden. By MATS WEIBULL (*Jahrb. Min.*, 1900, i, Ref., 197—198; from *Geol. För. Förh.*, 1898, 20, 57—66).—A microscopical examination of Blomstrand's westanite shows it to consist of pyrophyllite derived by the alteration of andalusite. Pyrophyllite also occurs at Westana as colourless to yellow, six-sided crystals embedded in kaolinite. The optical properties of these crystals are given; sp. gr. 2.768. At about 600°, the material loses 5.11 per cent. of water, and none is lost below this temperature. The alteration of andalusite to pyrophyllite is expressed by the equation, $(\text{AlO})_2\text{SiO}_3 + 3\text{H}_2\text{SiO}_3 = 2(\text{AlH})(\text{SiO}_3)_2 + 2\text{H}_2\text{O}$.

The granular kaolinite, in which the pyrophyllite is embedded, gave the following results on analysis, agreeing with the usual formula $\text{H}_4\text{Al}_2\text{Si}_2\text{O}_9$,

SiO ₂ .	Al ₂ O ₃ .	MgO.	K ₂ O, Na ₂ O.	H ₂ O.	Total.	Sp. gr.

L. J. S.

[Minerals in] the Pegmatites of the Upper Veltlin. By GOTTLOB ED. LINCK (*Jenaische Zeit. Naturwiss.*, 1899, 33, 345—360).—The crystalline schists between Sondalo and Bormio are penetrated by pegmatite masses containing quartz, plagioclase, muscovite, biotite and garnet with apatite, tourmaline, dumortierite, chrysoberyl, prehnite, zoisite, epidote and chlorite; descriptions are given of each of these minerals, and analyses of the following. Plagioclase is white and cloudy: I, from Val Lenasco, corresponds with $\text{Ab}_{81}\text{An}_{19}$; II, from Val Donbastone, with $\text{Ab}_{13}\text{An}_{87}$; optical determinations are also given. Garnet occurs as light coffee-brown crystals of the form $n\{211\}$; analysis by W. Schimpff of material from Val Donbastone gave III, showing the mineral to be almandine with the formula

the slight excess of silica and alumina is due to alteration. Dumortierite occurs at Val Donbastone as columnar crystals 5 cm. in length; it is pistachio-green or rarely bluish-green, and resembles epidote in appearance. The prism angle is $110^\circ 54'$, and there is a prismatic

cleavage. $H=7$. It is strongly pleochroic; optical determinations are given. Analysis by W. Schimpff gave IV; boron is also present.

L. J. S.

Ransätite. By MATS WEIBULL (*Jahrb. Min.*, 1900, i, Ref., 187; from *Geol. För. Förh.*, 1898, 20, 53).—A re-examination of the supposed new mineral ransätite (Abstr., 1897, ii, 268) shows it to be an impure manganese garnet enclosing quartz, pyrophyllite, chloritoid, kyanite and ore particles (hæmatite?).

L. J. S.

Tourmaline from Elba. By E. MANASSE (*Jahrb. Min.*, 1900, i, Ref., 192; from *Proc. Verb. Soc. Toscana Sci. Nat.*, 1898, 11, 104—107).—A finely crystalline, light ash-grey substance in a tourmaline-bearing granite from the Grotto d'Oggi, Elba, was found, on microscopical examination and chemical analysis, to be tourmaline. In the analysis, the loss on ignition represents water and silicon fluoride.

	SiO ₂	Al ₂ O ₃	FeO(MnO)	B ₂ O ₃	CaO	MgO	Na ₂ O	K ₂ O	Loss on ignition.	Total.

L. J. S.

Kieselguhr from County Antrim. By JAMES HOLMS POLLOK (*Sci. Proc. R. Dublin Soc.*, 1899, 9, N.S., 33—36).—Deposits of kieselguhr, resting on peat and covered only by vegetation, occur on both banks of the Lower Bann from Toome Bridge, where the river emerges from Lough Neagh, right down to Coleraine at the mouth. At Toome Bridge, the deposit is 4 feet thick. After cutting and drying in the sun, the material is pure white, porous and very light (sp. gr. of the mass, 0.5422). The material is probably now being deposited when the river overflows its banks, the diatoms, which are mostly cubical in shape, being brought down from Lough Neagh. Analyses gave:

	Soluble SiO ₂	Insol. SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	MgO	Alka. lia.	Organic matter, comb.	Moisture.	Total.

L. J. S.

Illinois Gulch Meteorite. By H. L. PRESTON (*Amer. J. Sci.*, 1900, [iv], 9, 201—202).—This iron was found in 1899, 4 feet below the surface, in Illinois Gulch, Deer Lodge County, Montana. It weighs about 2435 grams, and measures 63 × 104 × 105 cm. No distinct figures are brought out by etching. A little troilite and

possibly some rhabdite are present. Analysis by Mariner and Hoskins gave:

Fa.	Ni.	Co.	Si.	P.	C.	Total.
92.51	6.70	0.16	trace	0.62	0.01	100.00

L. J. S.

Composition and Properties of the Mineral Waters of Australasia. By ARCHIBALD LIVERSIDGE, WILLIAM SKEEY, and G. GREY (*Rept. Australian Assoc. Adv. Sci.*, 1898, 7, 87—108).—A collection of all the available analyses that have been made.

L. J. S.

Physiological Chemistry.

Action of the Blood-gases on Breathing. By W. PLAVEC (*Pflüger's Archiv*, 1900, 79, 195—210).—The difference between the action of deficiency of oxygen and increase of carbon dioxide in the blood is greater than has been supposed. With small carbon dioxide tension in the blood, such as is obtained by breathing air containing 5 per cent. of the gas, there is only an action on the respiratory movements, but with greater tension the respiratory centre is greatly stimulated. The theory of Hermann, that the deficiency of oxygen raises the irritability of the centre to carbon dioxide, has no foundation; in fact, there is a progressive lessening of its excitability. The terminal inspirations of acute asphyxia are caused by the accumulation of carbon dioxide in the blood. The breathing in of this gas causes an increased rate of respiration, and its presence in the blood is the normal stimulus to produce breathing.

W. D. H.

Respiration in the Frog. By J. ATHANASIU (*Pflüger's Archiv*, 1900, 79, 400—422).—The respiratory metabolism in the frog varies greatly with the time of year. The respiratory quotient is in the mean 0.77 in summer, and 0.95 in winter, but in the winter it may exceed unity. The high respiratory quotient apparently depends on reserve of oxygen in the tissues.

W. D. H.

Nitrogenous Metabolism after Splenectomy. By LAFAYETTE B. MENDEL and HOLMES C. JACKSON (*Proc. Amer. Physiol. Soc.*, Dec., 1899; *Amer. J. Physiol.*, 1900, 3, iii—iv).—In view of the part supposed to be played by the spleen in uric acid formation, it was found that, in cats and dogs, removal of this organ does not lessen the normal output of uric acid, after diets of different kinds. The ability of the organism to form allantoin after ingestion of thymus or pancreatic tissue is in no way diminished.

W. D. H.

Nutritive Value of Alcohol. By WIEBUR O. ATWATER (*Proc. Amer. Physiol. Soc.*, Dec., 1899; *Amer. J. Physiol.*, 1900, 3, xiii—xiv).—Experiments on men show that alcohol serves the body as fuel, as

do fats and carbohydrates. 98 per cent. of the alcohol given was oxidised in the body, and the alcohol supplied about one-fifth of the total energy during rest, and about one-seventh during work.

W. D. H.

Digestion of Carbohydrates by Aplysia. By FRANZ RÜHMANN (*Chem. Centr.*, 1900, i, 50; from *Centr. Physiol.*, 13, 455).—The *Aplysia*, like the *Geophila*, live on the green portions of plants, and those found in the Bay of Naples principally consume the algæ, *Ulva lactuca*, which contains starch, and a pentosan which is soluble in water. By the action of an enzyme in the intestines, the starch is converted into dextrose. Although glycogen was not found in the intestines, the presence of a pentosan identical with that of the algæ was detected.

E. W. W.

Some Comparative Analyses of, and Digestion Experiments with, White and Whole-meal Breads. By OTTO ROSENHEIM and PHILIP SCHIDROWITZ (*Analyst*, 1899, 24, 227—234).—Analyses are recorded of ordinary white bread, ordinary whole-meal bread, and patent whole-meal bread; the figures relating to the two brown breads reveal no striking differences, and although the white bread was somewhat poorer in mineral phosphatic matter and total soluble constituents, its nitrogenous matter, or total, pure, and soluble albumin was about equal to that of the brown samples.

Digestion experiments (salivary, gastric+pancreatic, and pancreatic), conducted *in vitro*, did not accord with the popular belief in the superiority of the brown breads; in fact, white bread is superior as far as digestibility pure and simple is concerned.

L. DE K.

Plasmon. By HEINRICH PODA and WILHELM PRAUSNITZ (*Zeit. Biol.*, 1900, 39, 279—312).—Plasmon is a new preparation from the proteids of milk. The experiments here recorded, which were carried out on human beings, show that it is easily digestible and assimilable, and that its nutritive value is equal to that of meat.

W. D. H.

Assimilation of Iron. By EMIL ARDERHALDEN (*Zeit. Biol.*, 1900, 39, 193—270).—The numerous experiments here recorded on various animals relate principally to the estimation of hæmoglobin. They support the author's previous contention that the iron of inorganic compounds, of hæmoglobin, and of hæmatin in the food, is absorbed and utilised in the manufacture of hæmoglobin.

W. D. H.

Absorption in the Small Intestine. By OTTO COHNHEIM (*Zeit. Biol.*, 1900, 39, 167—172).—The main contention of the argument from the experiments recorded, which consisted chiefly in destroying the epithelium of the small intestine with hot water, is that the living cells play an important selective part in absorption. Höber's contention that the act of absorption is the same in principle in living and dead animals is contested.

W. D. H.

Reduction of Cholesterol to Coprosterol in the Human Intestine. By PAUL MÜLLER (*Zeit. physiol. Chem.*, 1900, 29, 129—135).—Whether the reduction of cholesterol into coprosterol which Bondzynski showed occurred in the intestine is due to putre-

factive organisms or to the normal action of the digestive juices is a matter of doubt. By a pure milk diet, the putrefactive processes in the intestine are reduced to a minimum; under these circumstances, cholesterol is found unchanged in the fæces. The fact that cholesterol is found in meconium, the contents of the foetal intestine (Flint), also points to the bacterial origin of coprosterol.

W. D. H.

Chemical Changes in the Developing Egg. By P. A. LEVENE (*Proc. Amer. Physiol. Soc.*, Dec., 1899; *Amer. J. Physiol.*, 1900, 3, xii—xiii).—The quantity of xanthine bases and nuclein compounds increases with the growth of the egg embryo. The importance of mineral salts increases also. The following table summarises the facts with regard to nitrogen; the numbers given are percentages:

Nitrogen.	Unfertilised	Eggs after fertilisation,		
	eggs.	24 hours.	10 days.	19 days.
In mono-amino-compounds	21.10	21.37	22.72	0
In bases	12.07	25.10	12.48	28.25
In proteids	66.00	53.57	64.79	71.84

W. D. H.

Composition of Hen's Egg. By ADOLF JUCKENACK (*Chem. Centr.*, 1900, i, 304; from *Zeit. Unters. Nahr. Genussmittel.*, 1899, 905—913).—The quantity of phosphorus contained in the ash of yolk of egg does not represent much more than half the amount before incineration, for, owing to insufficiency of bases, a portion of the phosphoric acid is reduced during combustion; it is necessary, therefore, to add sodium carbonate and potassium nitrate before incinerating. An egg contains 0.455 per cent. of phosphorus, the white containing 0.031 and the yolk 1.279 per cent. Of the latter, 0.478 is present as distearyllecithin (5.42 per cent.), 0.345 as the compound of vitellin and distearyllecithin (3.93 per cent.), 0.178 as nucleins, and 0.278 as insoluble phosphates, glycerophosphoric acid or derivatives. The yolk contains 0.91 per cent. of cholesterol.

E. W. W.

Chemical Composition of New-born Children. By WILLIAM CAMERER, jun., and FRIEDRICH SÖLDNER (*Zeit. Biol.*, 1900, 39, 173—192).—The total composition of three new-born children is given, and contrasted with that of human milk.

W. D. H.

Chemico-physical Relations of Animal Juices and Tissues. By MAX OKER-BLOM (*Pflüger's Archiv*, 1900, 79, 111—145).—The electrical conductivity reckoned for a unit column of 1 c.c. offering a resistance of 1 ohm is, at 25°, for defibrinated ox blood, 52.5 to 70.9; for ox-serum, 114.4 to 131.1; for defibrinated pig's blood, 44.5 to 51.5; and for pig's serum, 119.3 to 126.8; for a 0.7 per cent. solution of sodium chloride, it is 124.1, a number approximately equal to that of serum. By diluting blood or serum with distilled water, the conductivity increases much more quickly than that of a 0.7 per cent. solution of sodium chloride with the same amount of dilution. The degree of dissociation of the serum electrolytes is 0.65 to 0.76, and of the blood 0.34 to 0.45. Between 20° and 40°, the conductivity in-

creases with the temperature. No difference was found between arterial and venous blood. The conductivity depends partly on the electrolytes of the corpuscles. W. D. H.

Influence of Iodine, Sodium Iodide, and Iodothyron on the Circulation. By A. G. BARBERA (*Pflüger's Archiv*, 1900, 79, 312—318).—Largely polemical. Laudenbach has found that iodothyron has not the action on the circulation described by von Cyon. He, however, used Notkin's preparation, which appears to be very toxic, whilst von Cyon used Baumann's iodothyron. The latter lowers the blood pressure and the heart rate, whilst Notkin's preparation acts in the opposite way. Iodine and sodium iodide act like Notkin's preparation, stimulating the cardiac accelerators and vaso-constrictors, and depressing the inhibitory nerves of the heart and blood-vessels. W. D. H.

Infusion after Severe Hæmorrhage. By PERCY M. DAWSON (*Proc. Amer. Physiol. Soc.*, Dec., 1899; *Amer. J. Physiol.*, 1900, 3, xxviii).—After removal of large quantities of blood in dogs, infusion with isotonic solutions (normal saline with and without milk, Ringer's solution) was performed. A post-hæmorrhagic fall of red corpuscles continues for from four to eight days. This is not due to osmotic changes in the plasma, but to the low resistance of the remaining corpuscles. With regard to the post-hæmorrhagic leucocytosis which were noted, there is no evidence that the polymorpho-nuclears are formed from the lymphocytes, at any rate in the circulating blood. W. D. H.

Influence of Protoplasmic Poisons on Lymph Formation. By WILLIAM J. GIES and LEON ASHER (*Proc. Amer. Physiol. Soc.*, Dec., 1899; *Amer. J. Physiol.*, 1900, 3, xix—xx).—Experiments were made on dogs with quinine and arsenic. Quinine does not interfere with the usual influence of dextrose, but suppresses the action of leech extract. The action of dextrose as a lymphagogue therefore depends on physical factors, and of leech extract on physiological factors. The effect of sugar is not merely due to increased capillary pressure, for in a dog, after quinine and dextrose, the lymph flow continued for three hours after the animal's death. Arsenic increases the permeability of the vessel walls, but it hardly influences the flow of lymph. Starling's mechanical theory therefore fails. W. D. H.

Bile as a Solvent. By BENJAMIN MOORE (*Proc. Amer. Physiol. Soc.*, Dec., 1899; *Amer. J. Physiol.*, 1900, 3, xiv—xv).—Bile dissolves lecithin and cholesterol. It also dissolves soaps and free fatty acids. This power is due to the bile salts, and is increased by the presence of lecithin in solution. Cholesterol and soaps of calcium and magnesium are only slightly soluble in bile, but are more soluble when lecithin is present also. The sodium soaps are more soluble in bile than in water; the solution is less viscid when bile is present, and, on cooling, the soaps are precipitated in a granular form, not as a jelly. All these facts show the importance of bile in the digestion of fats. W. D. H.

Fat in Cartilage. By CESARE SACERDOTTI (*Virchow's Archiv*, 1900, 159, 152—173).—The fat in cartilage cells is constantly and

normally present. It increases in quantity with the physiological growth of, and diminishes with degenerative changes in, the cells, although in some cases of inanition the lessening of the cartilage fat is not perceptible.

W. D. H.

Hepatic Glycogen during Pregnancy. By ALBERT CHARRIN and A. GUILLEMONAT (*Compt. rend.*, 1900, 130, 673—675).—Experiments on guinea-pigs show that the hepatic glycogen increases during pregnancy, especially as full term approaches. This increase is more marked if sugar is supplied to the animals. The sugar eliminated by the urine is more considerable in gravid as compared with normal animals. The need of the animals for sugar is thus less during pregnancy, and the accumulated carbohydrate is believed to be used up later for the needs of lactation.

W. D. H.

Does Cellulose occur in the Shield of Sepia? By FRIEDRICH N. SCHULZ (*Zeit. physiol. Chem.*, 1900, 29, 124—128).—Ambronn (*Mitt. zool. Station Neapel*, 1890, 9, 475) states that besides chitin, the so-called *Os sepia* contains cellulose. This is stated to be an error.

W. D. H.

The Catechol-like Substance of the Suprarenals. By OTTO VON FÜRTH (*Zeit. physiol. Chem.*, 1900, 29, 105—123. Compare Abstr., 1899, ii, 115).—The active substance in the suprarenal bodies which produces the typical rise of blood pressure is termed *suprarenine*. It is believed to be a hydro-derivative of dihydroxy-pyridine of the composition $C_6H_7O_2N$ or $C_6H_6O_2N$. It may be readily separated as an iron compound, 0.000017 gram of which produces a rise of blood pressure. It differs in its reactions and composition entirely from Abel's epinephrine, which is stated to produce no effect on blood pressure. The suprarenals contain 0.01 per cent. of epinephrine, and from 0.1 to 0.17 per cent. of suprarenine. A very small contamination of the former with the latter would produce a rise of blood pressure.

W. D. H.

Deposits of Uric Acid Artificially Produced in Birds. By E. SCHREIBER and ZAUDY (*Pflüger's Archiv*, 1900, 79, 53—98).—In the course of Ebstein's investigations of the aetiology of gout, he succeeded with hens in producing deposits of urates artificially in the organs and tissues after ligature of the ureters, or injury to the kidneys produced by injection of chromates. These experiments having been called in question, the present work, carried out under Ebstein's supervision, consisted in repeating and confirming them. The deposits, partly crystalline, partly amorphous, were found in the blood, lymph, and among the tissue elements in various organs. Although the view is supported that the uric acid is the source of the irritation in gout, the actual deposition of the urates is considered to occur *post-mortem*, or at earliest in the *ante-mortem* death agony.

W. D. H.

Coagulable Proteids of Connective Tissues. By WILLIAM J. GIES and A. N. RICHARDS (*Proc. Amer. Physiol. Soc.*, Dec., 1899; *Amer. J. Physiol.*, 1900, 3, v).—In aqueous and magnesium sulphate

extracts of tendon, there are two coagulable proteids; one separates at 54—57°, the other at 73°. Elastic ligaments contain more proteid than tendon, and fractional heat coagulation indicates the existence of as many as five proteids; they also contain a large quantity of creatine.

W. D. H.

Glucoproteids of White Fibrous Tissue. By WILLIAM J. GIES and WILLIAM D. CUTTER (*Proc. Amer. Physiol. Soc.*, Dec., 1899; *Amer. J. Physiol.*, 1900, 3, vi).—The amounts of nitrogen and sulphur in the mucin obtained in lime-water extracts from the tendo Achillis indicate that there are several members of the group present, and that these are different from those in the tendon sheath. The osazone obtained melts at 182°, but a pure crystalline product was not isolated. Some experiments appear to indicate the possibility of the presence of glucosamine. The differences between mucins, mucoids, and chondro-proteids appear to depend chiefly on the proportions of proteid and acid radicles in them.

W. D. H.

Organic Phosphorus Compounds in Infants' Urine. By ARTHUR KELLER (*Zeit. physiol. Chem.*, 1900, 29, 146—184).—Children fed on mother's milk excrete less phosphorus than those fed on cow's milk. This is not entirely dependent on the amount of phosphorus in the food. Full particulars are given of experiments on numerous infants, healthy and sick, the amount of phosphorus being determined both in organic and inorganic compounds in the urine. The amount of organically combined phosphorus in three healthy children corresponds with 0.00218 to 0.0167 gram of phosphoric oxide, which is more in proportion to body weight than in adults; in relation to total phosphorus, from 0.5 to 9.9 per cent. is in organic combination; in adults, the number is from 1.6 to 4.8 (Oertel). These numbers do not run parallel to the total phosphorus or total nitrogen in either food or excreta. They are, however, parallel to the amount of phosphorus retained in the body. The amount is not influenced by the administration of sodium phosphate, but the organic phosphorus does not come exclusively from the food, but from organs rich in nuclein.

W. D. H.

Elimination of Sodium Cacodylate in the Urine after Administration by the Stomach. By HENRI IMBERT and E. BADEL (*Compt. rend.*, 1900, 130, 581—583).—Sodium cacodylate, when administered by ingestion in quantity amounting to 0.2 gram, has a marked effect in reducing the volume of urine eliminated for three or four days, although this soon returns to its normal amount. The greater part of the cacodylate is eliminated in the urine during the first twenty-four hours, and after this approximately the same minute quantity (0.003 gram) is eliminated each day for about a month, the elimination being then complete.

C. H. B.

Oxidation of Urine. Phenols and Indican. By S. COTTON (*J. Pharm.*, 1900, [vi], 11, 59—61. Compare Abstr., 1899, ii, 780).—The oxidation product of indican, the formation of which is used as a test for this substance in urine, may be obtained from urine as follows: The urine is distilled with 1/20th of its weight of nitric acid until 40

per cent. has distilled over, the distillation being effected, as far as possible, out of contact with air. The solid carbonaceous residue in the flask is collected and treated with light petroleum to remove benzoic acid, &c., and then extracted with chloroform, which dissolves out the oxidation product of indican, and on evaporation yields it in the form of coloured, prismatic crystals.

The first portion of the distillate, obtained as above, contains benzoic acid, and the latter portions, a phenol derivative which forms a red crystalline potassium salt.

H. R. LE S.

Physiological Action of Tellurium Compounds. By WILLIAM J. GIES and L. D. MEAD (*Proc. Amer. Physiol. Soc.* Dec., 1899; *Amer. J. Physiol.*, 1900, 3, xx—xxi).—In dogs, small doses (0.1 gram daily) of tellurous oxide, sodium tellurite, and tellurium tartrate have no effect on metabolism. Tellurium is eliminated in the urine and faeces, and the odour of methyl telluride in the expired air is pronounced. Larger doses (0.2 to 0.5 gram) cause violent vomiting, disintegration of the gastric mucous membrane, interference with the secretion of hydrochloric acid, and regurgitation of bile. Under 1 per cent. of tellurium tartrate and sodium tellurite does not hinder artificial peptic or tryptic digestion. When tellurium compounds come in contact with tissue cells, reduction to the metallic state occurs, although tellurium itself is soluble in the body juices. Thus tellurium was recovered from liver, kidneys, bile, and brain, but most from the tissues about the point of injection.

W. D. H.

Behaviour of Chitosamine [Glucosamine] Hydrochloride in the Animal Organism. By THEODOR R. OFFER and SIGMUND FRÄNKEL (*Chem. Centr.*, 1900, i, 211; from *Centr. Physiol.*, 13, 489—491).—The urine of men or dogs fed with glucosamine hydrochloride showed distinct reducing properties and was dextrorotatory. By determining the rotatory power, it was found that when doses of 10—20 grams were administered to dogs *per os*, 20 per cent. of the glucosamine hydrochloride was excreted in the first seven hours, and that after this time the urine became optically inactive. Similar results were obtained by subcutaneous injection. Glucosamine may be separated from the urine as the benzoate.

E. W. W.

Study of the Relationship between the Chemical Constitution of Alkylated Alkaloids and their Physiological Action. By WLADIMIR ROSENSTEIN (*Compt. rend.*, 1900, 130, 752—755).—The following alkaloid salts, basic cinchonine hydrochloride, and the hydrochlorides of methylecinchonine, dimethylecinchonine, cinchotoxine and methylquinine, produce tetanic and epileptic convulsions, whereas the salts of the corresponding quaternary bases, namely, cinchonine and methylecinchonine methochlorides, dimethylecinchonine benzochloride, cinchonine dimethochloride, and quinine and methylquinine methiodides have a paralysing action; moreover, the toxic effect of the latter series is always much greater than that of the former.

No definite relationship can be traced as to effect of alkylation on the physiological action of the alkaloid; cinchotoxine and its

N-methyl derivative, methylcinchonine, have the same effect, whereas methylquinine differs from quinine in being a highly poisonous base. The curarising action of the second series of salts seems to be due to the molecular configuration peculiar to quaternary bases.

G. T. M.

Suprarenal Extracts. By BENJAMIN MOORE and C. PURINTON (*Proc. Amer. Physiol. Soc.*, Dec. 1899; *Amer. J. Physiol.*, 1900, 3, xv, xvi—xvii).—In the dog, injection of extracts of suprarenal medulla in doses varying from 0.24 to 24 millionths of a gram per kilo. of body weight produces marked results. The minutest doses produce a fall instead of a rise of blood pressure. This is considered to be due to the action of the same active substance, not to admixture with a second material. The results show that any activity possessed by the substances hitherto isolated from the suprarenal may be explained by slight contamination with the unaltered active principle. In separating the active substance, the use of alkali should be avoided. The presence of the chromogen must not be taken alone to indicate the presence of active material. A new colour reaction of the chromogen is described, namely, dilute ferric chloride after excess of zinc acetate gives an evanescent, deep violet colour, which, in strong solutions, leaves a violet precipitate.

W. D. H.

A Depressor Substance in the Suprarenal Gland. By R. HUNT (*Proc. Amer. Physiol. Soc.*, Dec., 1899; *Amer. J. Physiol.*, 1900, 3, xviii—xix).—After epinephrine has been removed from an aqueous extract of suprarenal by means of benzoyl chloride, a substance remains which produces a fall of blood pressure. By both chemical and physiological properties, this substance is found to be choline. Extracts of sympathetic ganglia and brain contain choline also.

W. D. H.

Mucin. By I. LEVIN (*Proc. Amer. Physiol. Soc.*, Dec., 1899; *Amer. J. Physiol.*, 1900, 3, xxix—xxx).—Thyroidectomy causes auto-intoxication from the accumulation of mucin in the blood. Injection of mucin in sodium carbonate has no effect on healthy rabbits, but is fatal to those without a thyroid. In dogs, it causes a fall of blood pressure due to its action on the vasomotor centre.

W. D. H.

Metabolism in Pernicious Anæmia. By WAŁAW VON MORAWIEWSKI (*Virchow's Archiv*, 1900, 159, 221—247).—Observations were made on four patients suffering from pernicious anæmia. In the simple anæmia, a noteworthy feature of the metabolism is a retention of chlorine. From the cases now recorded, the characters of the metabolism are so marked as to assist diagnosis. They are, a relatively large excretion of chlorine, an absolute loss of calcium, and a small excretion of both nitrogen and phosphorus.

W. D. H.

Multiple Amyloid Tumours in the upper Air Passages. By PAUL MANASSE (*Virchow's Archiv*, 1900, 159, 117—136).—Some cases of multiple tumours in the upper air passages are recorded, with full clinical and microscopical details. The substance of the tumours, which, in an early stage, appeared to be sarcomatous, was later found, from

its microscopic appearance and reaction with iodine, to be amyloid, or lardacein. From the history of the cases, and the examination after death, it is regarded as probable that the amyloid substance is formed within the lymphatic vessels and canaliculi, and that the infiltration of the connective tissue is secondary to this.

W. D. H.

Occurrence of Lactic Acid in the Animal Organism in Reference to Arsenical Poisoning. By KURATA MORISHIMA (*Chem. Centr.*, 1900, i, 45; from *Arch. exp. Path. Pharm.*, 43, 217—244).—Sarcrolactic acid occurs in the liver of all animals, and is also found in the kidneys, the coat of the stomach, and the blood. After death, the quantity of lactic acid in the liver increases as the glycogen decreases, fermentation lactic acid, however, being mainly formed. In cases of poisoning by arsenious oxide, the consequent rapid disappearance of glycogen in the liver is accompanied by the formation of a large quantity of paralactic acid in this organ, and also in the blood. Arsenical poisoning also causes an even larger increase of lactic acid in the kidneys than in the liver.

E. W. W.

Toxicology of Potassium Chlorate. By S. J. MELTZER (*Proc. Amer. Physiol. Soc.*, Dec., 1899; *Amer. J. Physiol.*, 1900, 3, ix—x).—Potassium chlorate does not cause death by changes in the blood. Death often supervenes before the blood is altered, and the formation of methæmoglobin within the vessels is comparatively harmless. Death results from paralysis of inspiratory muscles. Intracerebral injection shows it is a poison to nerve-cells, first exciting, then paralyzing them.

W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

Fermentation of Yeast. By CARL J. LINTNER (*Chem. Centr.*, 1900, ii, 54; from *Centr. Bakt. Parasit.*, 5, ii, 793—800).—Chlorides check the fermentation of yeast, whilst the action of sulphates depends on the base. Zinc, magnesium, and ferrous sulphates, and potassium hydrogen phosphate promote the fermentation, whilst copper, and, still more, manganese sulphate, disodium phosphate, ammonium salts, and perhaps nitrates retard it. Saturated, and in some cases super-saturated, solutions were employed.

The fermentation of yeast diminishes gradually, as the reserve substances are consumed. By adding sodium sulphate, which induces vigorous fermentation, to yeast, it would be possible to ascertain whether the yeast is fresh, or whether it has been kept for some time; but this is not thought to be of practical importance.

The effect of salts may be due to abstraction of water, by which the plasma would be stimulated; excessive abstraction of water (by chlorides) would act deleteriously.

N. H. J. M.

Formation of Alcohol in the Putrefaction of Proteids free from Carbohydrates. By DIOSCORIDE VITALI (*Chem. Centr.*, 1900, i, 141—142; from *Boll. Chim. Farm.*, 38, 729—734).—Alcohol was found amongst the products formed by allowing horse muscle, from which the fat and sugar had been completely removed, to putrefy in presence of water at 28—32° from July to December. Blumenthal and Mayer (*Abstr.*, 1899, i, 968) have observed the formation of a hexose from albumin, and the glucoproteids or compounds of the simpler proteids, such as albumin or globulin with carbohydrates, also yield sugars which may be fermented. According to Gautier and Étard (*Abstr.*, 1882, 1115), the putrefaction and fermentation of muscular tissue takes place in two periods, an acid reaction obtaining in the first period, and an alkaline reaction in the second; the formation of alcohol takes place in the latter period. The bacteria which cause putrefaction are also capable of producing alcoholic fermentation. Experiments have been made with mucin, a glucoproteid found in considerable quantities in snails; the fresh aqueous extract was neutral, but on keeping became, first, acid, then, after a time, again neutral, and finally, in 2—3 months, acquired a faint alkaline reaction. True putrefaction had not, however, commenced, and consequently alcohol had not been formed. E. W. W.

Acetic Bacteria. By W. HENNEBERG (*Bied. Centr.*, 1900, 29, 66—67; from *Centr. Bakt. Parasit.*, 4, ii, 14, 67, and 138).—In addition to the two new varieties previously described (*Bied. Centr.*, 28, 647), a third (*Bacterium acetigenum*) has been found.

As regards temperature, it was found that in the case of five varieties (excluding *B. acetigenum*), the production of acetic acid is very slight at 33°, but is considerable at 26—29°, and (with the exception of *B. acetosum*) at 15° again very slight.

The degree of acidity produced, under conditions as favourable as possible, by the different varieties was as follows: *Bacterium oxydans*, 2; *B. acetigenum*, 2.72; *B. acetosum*, *B. aceti*, and *B. Kützingerianum*, 6.6; and *B. Pasteurianum*, 6.2 per cent.

The highest percentage of alcohol in which acetic acid can be produced varies a good deal. The limit is lowest in the case of *B. acetigenum* (less than 5 per cent.); with *B. oxydans*, it is 7; with *B. Kützingerianum*, and *B. Pasteurianum*, 9.5; and with *B. acetosum* and *B. aceti*, 11 per cent. None of the six varieties develops in beer to which 3—6 per cent. of acetic acid has been added.

N. H. J. M.

Effect of different Substances on the Curdling of Milk. By THOMAS BOKORNY (*Bied. Centr.*, 1900, 29, 62—65; from *Milchzeit.*, 1898, No. 49, 769).—Certain poisons, such as 0.01 per cent. solutions of hydroxylamine hydrochloride, formaldehyde, and menthol, which act strongly on putrefying bacteria, have no, or very little, effect on the lactic acid bacillus. A number of experiments were made in which various substances were added to milk, which was then kept at the temperature most favourable to curdling (26—27°). Milk alone curdled in 24 hours. In the following summary of results, the time required for curdling is given after each substance. Oil of turpentine

(1:75000), 48 hours; menthol (0.01 per cent.), 48 hours; eugenol (0.005 per cent.), 24 hours; cinnamaldehyde (0.005 per cent.), 24 hours; *p*- and *o*-hydroxybenzaldehydes (0.05 per cent.), after 48 hours; *p*- and *o*-hydroxybenzoic acids (neutralised, 0.05 per cent.), within 48 hours; *p*- and *o*-cresols (0.05 per cent.), 48 hours; paraldehyde (0.1 per cent.), 24 hours; salicylaldehyde (0.1 per cent.), 48 hours; carvol (0.05) and cuminaldehyde (0.005 per cent.), 24 hours; salicylic acid (0.2 per cent.), 3 days; heliotropin (0.1 per cent.), 24 hours; formaldehyde (0.002 per cent.), 24 hours; (0.01 per cent.), 3 days; (0.1 per cent.), no curdling in 6 days.

Silver nitrate (0.001 per cent.), 48 hours; (0.01—0.1 per cent.), 4 days; (0.2 per cent.), no curdling in 6 days; hydroxylamine hydrochloride (0.1 per cent.), 48 hours; boric acid (0.1—0.2 per cent.) has scarcely any appreciable effect according to Lazarus. Sodium carbonate (0.3 per cent.), no effect (Lazarus in *König's Nahrungsmittel*, 2, 244). Calcium hydroxide (0.15 per cent.) has no effect, and borax (0.4 per cent.) very little effect on bacteria (Lazarus). Hydrogen peroxide (0.1 and 1.0 per cent.), 3 days.

N. H. J. M.

Denitrification and Fermentation. By KURT WOLFF (*Chem. Centr.*, 1900, i, 52—53; from *Hygien. Rundsch.*, 9, 1169—1172. Compare this vol., ii, 98).—The bacteria employed in these experiments were four of the typhus-like bacilli (including *B. coli commune*, and Löffler's mouse typhus bacillus), and two hay bacilli (one apparently *B. Fitzianus*, from ginger root, the other from meal). All the bacilli reduced nitrates to nitrites in 1 per cent. dextrose broth containing 0.05—0.23 per cent. of potassium nitrate; but the extent of the reduction varied very much with the different bacilli; the coli-like bacilli reducing least, the hay bacilli the most, nitrate. Only one of the latter (of all six bacilli) can be compared with the real denitrifying organisms. The strength of the sugar solution was without influence, but the amount of nitrate present had a decided effect; an excess of nitrate checks fermentation, without, however, otherwise disturbing the functions of the bacilli; and complete disappearance of nitric nitrogen can only take place simultaneously with fermentation.

It is concluded that denitrification is not due to the direct action of the microbes, but that the products of fermentation reduce nitrates to nitrites and eventually convert them into carbonates.

Any fermentation of sugar, by whatever microbes it is caused, will, it is believed, destroy nitrates when present, and denitrification can only take place in presence of substances which yield denitrifying products of metabolism.

N. H. J. M.

Inoculation with Nitragin. By BERNHARD FRANK (*Landw. Versuchs.-Stat.*, 1899, 51, 441—445).—At the suggestion of the Prussian Agricultural Department, pot and field experiments with nitragin were made in 1896—1897, at twelve Experiment Stations. Positive results were only obtained at four of the twelve. The negative results are attributed to there being sufficient abundance of leguminous nodule bacteria already in the soil.

It is, however, pointed out that negative results were obtained on uncultivated land where the application of inoculating soil had proved to be at once effective. In such cases, the failure of nitragin is thought to be due to the cultivations being weak, and it is suggested that if the gelatin of nitragin were to be replaced by some substance more similar to the natural media of the nodule bacteria, better results might be obtained.

N. H. J. M.

How can the Action of Nitragin be Increased? By FRIEDRICH NOBBE and LORENZ HILTNER (*Landw. Versuchs.-Stat.*, 1899, 51, 447—462).—A reply to Frank (preceding abstract). It is stated, in the first place, that subsequent experiments made at the Prussian Experiment Stations in 1897—1898 have given more satisfactory results than the previous ones.

As regards the employment of gelatin, reference is made to earlier experiments, the results of which showed that gelatin cultivations were extremely vigorous. In some cases, inoculation of seedlings growing in absence of combined nitrogen, resulted in injury to the plant, owing to the vigour of the cultures; in presence of a little combined nitrogen, the gelatin cultures proved to be better than direct inoculation from nodules, production of active nodules being much quicker.

As regards the application of nitragin, dilution with distilled water may completely kill the bacteria, and even well-water may be injurious. It is thought that the extract of glycyrrhiza roots, known as "Lakritzen," might be advantageously employed. This could not, of course, be utilised in cultivating the bacteria, as they would all gradually become converted into the glycyrrhiza modification.

When seeds are inoculated, they should be allowed to swell before being sown. In the case of soil inoculation, the material may be added to a mixture of soil and finely cut leguminous hay; the mixture is sown over the land, not with the seed, but some weeks later, if possible in rainy weather.

N. H. J. M.

Action of Moulds on Arsenic and its Compounds. Biological Proof of the Presence of Arsenic. By RUDOLF ABEL and PAUL BUTTENBERG (*Chem. Centr.*, 1900, i, 428—429; from *Zeit. Hyg.*, 32, 449—490).—In the original paper, the part played by moulds in reference to arsenical poisoning caused by wall papers containing arsenic is discussed. Of the various microbes, the development of the moulds is least retarded by the presence of arsenious acid, and of 40 kinds which were examined, 10 were found to be capable of decomposing this acid and forming arsenical vapours. *Penicillium brevicarule* gave the best results (compare Gosio, *Abstr.*, 1897, ii, 381). The presence of 0.01, and often even of 0.001 mg. of arsenic may be detected by the arsenical odour produced by raising a strong culture of the mould in the presence of a soluble or insoluble substance containing arsenic. The conditions necessary, and the use of this method, in comparison with the ordinary chemical methods, are discussed in the original paper.

E. W. W.

Influence of the Temperature of Liquid Hydrogen on the Germinative Power of Seeds. By SIR W. THISELTON-DYER (*Proc. Roy. Soc.*, 1899, 65, 361—368. Compare BROWN and ESCOMBE, *ibid.*, 62, 161).—Various seeds which had been cooled to -250° , in one case in a vacuum, in another case by immersion in liquid hydrogen, showed no alteration in appearance, and germinated well. The question whether the temperature of the seeds actually reached that of the liquid hydrogen is discussed; in the case of the seeds immersed for more than six hours, there would seem to be no room for doubt.

N. H. J. M.

Changes in the Organic Constituents of the Seed during Germination. By GUSTAVE ANDRÉ (*Compt. rend.*, 1900, 130, 728—730. Compare this vol., ii, 159).—The amount of total nitrogen present in the seedling of *Phaseolus multiflorus* from the commencement of germination to the period at which the dry weight of the young plant is again equal to that of the seed is fairly constant.

On extracting the seedling with dilute acetic acid, the asparagine passes into solution as ammonium aspartate; the extract is rendered alkaline and distilled, the ammonia evolved being a measure of the asparagine present in the seedling; acetic acid also dissolves other amides which are not affected by the alkali. The amounts of asparagine and soluble amides attain their maxima when the dry weight of the seedling reaches its minimum; from this stage onwards, it appears that the soluble amides are utilised in the production of the insoluble proteid material of the young plant.

The soluble carbohydrates are extracted with warm 60 per cent. alcohol, hydrolysed by dilute acid, and estimated as reducing sugar; the amount of these substances is greatest in the seed and decreases continuously during germination.

The quantity of starch and hydrolysable cellulose diminishes rapidly during germination; on the other hand, the proportion of non-hydrolysable cellulose increases greatly, and when the seedling has regained its original weight, the increase is twofold. At the close of the period under examination, the amounts of cellulose and mineral constituents increase very rapidly, and there seems to be an intimate relation between the development of cellulose and the absorption of lime and silica. The analytical results are exhibited in tabular form.

G. T. M.

Digestion of the Reserves in Seeds during Germination and their Assimilation by the Seedlings. By PIERRE MAZÉ (*Compt. rend.*, 1900, 130, 424—427. Compare Abstr., 1899, ii, 607).—The production of alcohol and carbon dioxide in germination indicates that the weight of a plant just after germination, from an amylaceous seed, should represent about half the loss in the cotyledons. As germination proceeds, the relation should diminish, since there is also a loss due to construction in addition to the increasing loss due to maintenance. In accordance with this view, it was found that in the germination of peas and haricots, the relation of the weight lost by

the cotyledons to the weight of the seedlings was about 2 after 5—6 days, and increased to 2·3—2·4 at the end of 15—20 days.

Oleaginous seeds, or seeds with mixed reserves, give totally different results. The amount of carbon dioxide given off in 8 days was, however, about the same for *Arachis*, maize (which contain respectively 53·7 and 4·8 per cent. of ether extract), and haricots. It is thought that the conversion of fatty acids into sugar does not depend on the nature of the acid (compare Maquenne, Abstr., 1899, ii, 171); in the case of some oleaginous seeds, the sugar is utilised in constructing or maintaining the cells as soon as it is formed. The digestion of the oil in *Arachis* is thus comparable with that of starch in haricots or peas. *Ricinus*, on the other hand, accumulates sugar, and thus resembles the *Gramineæ*.

The transformation in oily seeds of the group CH_2 into $\text{CH}\cdot\text{OH}$ seems to be as general as the degradation of starch; it is shown to be due to a diastase.

N. H. J. M.

Accumulation of Asparagine in Leguminous Plants cultivated with Insufficient Light. By ÉMILE BRÉAL (*Ann. agron.*, 1900, 26, 5—19. Compare Prianischnikoff, Abstr., 1899, ii, 787).—It was found that when lupins were grown with insufficient light there was an accumulation of asparagine during the last months of the year, the dry matter of the stems and roots (when the plants were 25 cm. high) containing as much as 50 per cent. of asparagine. The nitrogen of the dry matter was 8 per cent., 6 per cent. being in the form of asparagine.

At the time when the stems had reached the length of 20 cm., the plants were still green. The dry matter of the plants weighed less than that of the seeds, and the loss amounted to 36 per cent.

Blue lupins were grown in nutritive solutions containing minerals alone and minerals with potassium humate. By the time the stems were 15 cm. long, the plants without humate had lost 31 per cent. of the dry matter of the seed, whilst those with humate lost 27 per cent.

Subsequent experiments with blue lupins grown in better light showed a gain in weight of dry matter, instead of a loss, and the percentage of asparagine was 4 to 15 in the dry matter.

Lentils, without the cotyledons, grown in solutions of starch, caused a loss of starch in the solutions, and the plants developed better when supplied with starch in addition to minerals than with minerals alone; white lupins were much benefited by potassium humate (compare this vol., ii, 35).

N. H. J. M.

Carbohydrates in the Reserve Material of Lucerne and Fenugreek Seeds. By ÉMILE BOURQUELOT and HENRI HÉRISSEY (*Compt. rend.*, 1900, 130, 731—733. Compare Abstr., 1899, i, 839 and 840).—The pulverised seeds of lucerne are macerated in a solution of lead acetate; after removing the excess of lead from the extract by oxalic acid, the carbohydrate present in the filtrate is precipitated by the addition of alcohol. The product is optically active; $[\alpha]_D +84\cdot26^\circ$ (compare Müntz, Abstr., 1882, 709); on hydrolysis with dilute sulphuric acid at 110° , it yields a mixture of mannose (Abstr., 1899, ii, 817) and galactose; the carbohydrate is accordingly

a mannogalactan. A similar substance is also obtainable from the seeds of fenugreek. The two carbohydrates differ somewhat in composition and properties, but are both hydrolysed by seminaase, with the production of reducing sugars.
G. T. M.

Presence of Dextrose and Lævulose in Beet Leaves. By LÉON LINDET (*Ann. agron.*, 1900, 26, 103—113. Compare Brown and Morris, *Trans.*, 1893, 63, 604; Maquenne, *Abstr.*, 1896, ii, 328; and Lobry de Bruyn and Alberda van Ekenstein, *ibid.*, i, 116).—The different parts of new leaves on beet developed in darkness, as well as in presence of light, were separated, the juice expressed, and the sucrose, dextrose, and lævulose determined. Determinations were also made in normal leaves from the beginning of July to the beginning of October, and in the large and new leaves at different dates from July 17—26.

In the case of etiolated leaves, sucrose is withdrawn from the roots and inverted. Respiration in the leaves is feeble, whilst the production of cellulose is active; in every case, the amount of lævulose is less than that of dextrose. Analogous results were obtained with roots from which the leaves had been removed, and which produced fresh leaves under the influence of light.

As regards the amounts of dextrose and lævulose in the different parts of the leaves, the results showed relatively less dextrose in the parts in which respiration is least active. Comparing the new and the old leaves on the same roots, the new leaves invariably contained relatively less lævulose to dextrose than the old ones; and the question arises whether the better utilisation of lævulose by the plant is not correlative with the production of vegetable tissue (compare Durin, *Ann. agron.*, 1876, 220). It would seem that the vegetable cell selects each sugar for a different function. Certain yeasts attack lævulose in preference to dextrose, others, dextrose rather than lævulose.
N. H. J. M.

Ash of a Coccoanut. By F. BACHOFEN (*Chem. Zeit.*, 1900, 24, 16).—The husk, inner shell, kernel, and milk yielded respectively 1.63, 0.29, 0.79, and 0.38 per cent. of ash.

Each of the ashes were fully analysed, and the results are communicated in tables. The ashes of the inner shell and kernel are richest in phosphoric acid and potassium.
L. DE K.

Plasmolysis. Determination of the Toxicity of Alcohols. By ALB. J. J. VANDEVELDE (*Chem. Centr.*, 1900, i, 481; from *Hand. v. III. Vlammsch Nat. Geneskskundig Congres. Antwerp*, 1899).—The poisonous effects of various alcohols have been measured by experiments on the cells of the red onion, which are rich in anthocyanin and readily exhibit plasmolysis. The poisonous nature of the monohydric alcohols increases with the molecular weight, thus amyl alcohol is about twice as poisonous as isobutyl alcohol, and much more poisonous than ethyl alcohol. Normal propyl alcohol is more poisonous than isopropyl alcohol. The aqueous solutions of the alcohols are usually about twice as poisonous as the alcohols themselves. The older cells withstand the action of the alcohols better than the younger.

E. W. W.

Toxic Action of a Series of Acids, and of their Sodium Salts on *Lupinus Albus*. By RODNEY H. TRUE (*Amer. J. Sci.*, 1900, [iv], 9, 183—192).—Toxic action may be due to the anions, the cations, or the undissociated molecules. In the case of hydrochloric, hydrobromic, nitric, and other inorganic acids, the anions are only slightly toxic compared with the H^+ ions; the toxic value of the sodium salts of these acids is low. In the case of organic acids, the undissociated molecules have considerable toxic action, often exceeding that due to the H^+ ions; in cinnamic acid solutions, for example, the undissociated molecules are credited with 77 per cent. of the total toxic action; the anions of organic acids have in general a low toxic value. J. C. P.

Cultivation of Wheat and Oats at Grignon. By PIERRE P. DEHÉRAIN (*Ann. agron.*, 1900, 26, 20—33. Compare Abstr., 1899, ii, 243).—The results of experiments with large and small wheat grain showed that the larger seeds gave a decidedly greater yield, but the difference was not so marked as might be expected from previous results. Of greater importance is the place of wheat in a rotation, and at Grignon a clover crop was found to be a bad preparation for wheat, perhaps owing to the abstraction by the clover of water from the subsoil.

As regards the best place for oats in a rotation, no very definite conclusion is drawn from the results of the experiments. The greatest yield was obtained after beet, but to grow oats after beet would put wheat after clover, which is undesirable. If potatoes are grown in the place of roots, it is better to grow oats after wheat than after barley, especially if the wheat is succeeded by vetches to be ploughed in. N. H. J. M.

Experiments on Meadows. By BRIGHETTI (*Bied. Centr.*, 1900, 29, 23—26; from *Stas. sper. agrar. ital.*, 1898, 31, 620).—Analyses were made of the herbage from 15 meadows on alluvial soil in Ferrara. The results of botanical separations into gramineous, leguminous, and miscellaneous herbage are also given.

The percentage of proteids is highest in hay containing the most leguminous and leafy plants. The *Leguminosae* predominated under the influence of phosphatic manures, whilst the unmanured land, and that which received compost, produced the most grass.

N. H. J. M.

Vegetation of some Fodder Plants. By MONVOISIN (*Ann. agron.*, 1900, 26, 77—103. Compare DehéRAIN and Bréal, Abstr., 1882, 419; DehéRAIN and Meyer, *ibid.*, 1883, 493; and Villard and Bœuf, *ibid.*, 1898, ii, 181).—Experiments were made with a number of plants to ascertain whether the laws found by DehéRAIN and Bréal in the case of annuals also hold good in the case of plants of longer life.

The amount of root is always high in relation to the stems; it is greatest at the beginning, and is always greater than is the case with annuals.

When the period of maturation has passed, there is a distinct loss

of dry matter. The roots contain more ash than the stems; the maximum amount of ash in the entire plant is not at the beginning of vegetation, or at the flowering period, but between the two. Plants of more than annual growth contain more ash than annuals.

The maximum amount of total nitrogen, like that of ash, was found towards the end of April; afterwards the amounts diminish regularly. Leguminous roots contain more nitrogen than those of the *Gramineæ*. Nitrogen as non-proteid is relatively most abundant at the beginning of vegetation.

N. H. J. M.

Analyses of Norwegian Hay. By FR. WEERENSKIOLD (*Bied. Centr.*, 1900, 29, 19—22; from *Tids. Norsk. Landbr.*, 1899, 6, 35—43 and 82—85. Compare Abstr. 1897, ii, 187).—Further analyses of hay from various parts of Norway. Hay from peat land in Vegusdal, where cattle suffer a good deal from weak bones, contained only 2.86—3.82 per cent. of ash; its injurious effect may, however, be partly due to the small amounts of digestible proteids (three samples out of five contained only 1.08—2.26 per cent.).

Analyses of a number of single plants from Nordland are given.

N. H. J. M.

[Experiments on Sugar-cane in Hawaii.] By WALTER MAXWELL (*Chem. Centr.*, 1900, ii, 357).—Phosphates had practically no effect in increasing the yield of sugar, whilst potash and nitrogen increased the yield by 14 per cent. when employed singly and still more when employed together.

Analyses of the soil and of different parts of the plants are given in the original paper (Honolulu, 1899).

N. H. J. M.

Cultivation of Blue Lupins. By PIERRE P. DEHÉRAIN and E. DEMOUSSY (*Compt. rend.*, 1900, 130, 465—469. Compare this vol., ii, 238).—Blue lupins cannot themselves utilise elementary nitrogen. They may, however, grow normally when their roots are free from nodules; in this case, nitrogen is fixed by bacteria in the soil, associated with algæ (*Phormium autumnale* and *Ulothrix flaccida* were found in about equal amounts). Lupins also grow normally both in acid and in alkaline soil when provided with root nodules containing microbes which fix free nitrogen; in some cases, the nodule bacteria act as parasites, causing the plants to fail.

Arable soils do not generally seem to contain nodule microbes suitable for blue lupins; the microbes are, however, common in heath soil. Arable soil, can no doubt, be made available for blue lupins by inoculation.

N. H. J. M.

Manurial Experiments with Potatoes. By B. SJOLLEMA (*Bied. Centr.*, 1900, 29, 13—14; from *J. Landw.*, 1899, 47, 103).—Field experiments have been made on peat land at Groningen from 1881—1897, on potatoes alternated with cereals (generally oats). The greatest yield of potatoes (31,600 kilos.) was obtained with farm-yard manure, but the percentage of starch (14.25) was lower than with complete minerals and nitrate (31,500 kilos. with 16.15 per cent. of starch). Sodium nitrate (with complete minerals) gave better results than ammonium salts, both as regards total yield and per-

centage of starch. Complete minerals alone gave the highest percentage of starch (16·45), whilst the yield of tubers was 27,800 kilos. ; with potash alone, the yield was 24,150 kilos., and the percentage of starch 16·2 ; with phosphoric acid alone, the yield was 9160 kilos., and the starch 15·5 per cent. Addition of nitrate and lime to phosphate and to potash respectively increased the yield of tubers considerably, but lowered the percentage of starch. With complete minerals, nitrate increased the production of tubers without very appreciably diminishing the amount of starch.

The unmanured plots gave 8900 kilos. of potatoes containing 14·8 per cent. of starch.

Farmyard manure continued to act for three years, whilst artificial manures acted as much as dung for at least one year.

N. H. J. M.

Influence of Chlorides and other Compounds present in the Crude Stassfurt Salts on the Composition and Yield of Potatoes. By B. SJOLLEMA (*Chem. Centr.*, 1900, ii, 360 ; from *J. Landw.*, 47, 305—307).—The injurious effect of Stassfurt salts on potatoes is attributed exclusively to the chlorides present. Potassium, sodium, and magnesium chlorides diminish about equally the percentage of starch, especially in varieties of potato rich in starch. The effect is very marked when 1250 kilos. of kainite are applied in the spring.

Potassium sulphate and “potash magnesia” applied to soils which require potash for potatoes are favourable rather than unfavourable to starch production. The tubers contain about the same amount of potash, whether applied as sulphate or as potassium salts containing chlorides.

The diminished production of starch under the influence of chlorides is partly due to the absorption of water being increased. The amount of potash in the dry matter of the tubers is then much higher than when potassium sulphate is employed, the excess of potash being in the form of chloride.

Soda, even when applied in large amounts, is not taken up by potatoes. Sodium and magnesium sulphates are not injurious, but seem to increase both the yield of tubers and the percentage of starch ; they also reduce the amount of potash in the tubers.

Spring manuring with potassium salts containing much chloride diminishes the yield of potatoes, and still more the percentage of starch, the favourable effect of potash being considerably more than counterbalanced by the injury due to chlorides.

N. H. J. M.

Injurious Effect of Sodium Nitrate on the Growth of Sugar Beet. By JULIUS STOKLASA (*Chem. Centr.*, 1900, ii, 360—361 ; from *Zeits. Zucker-Ind. Böhm.*, 24, 131—146. Compare Sjollema, *Abstr.*, 1897, ii, 585 ; and Zaharia, *Abstr.*, 1899, ii, 799).—The toxic equivalent (expressed as fractions of the mol. weight in grams per 100 c.c.) of potassium perchlorate was determined for different plants at different periods of growth. For sugar beet, potassium perchlorate is not such a strong poison as copper and zinc sulphates, and sodium nitrate containing 2 per cent. of perchlorate has no effect on seed-

lings of sugar beet when the concentration did not exceed 1/10000 of the mol. weight (grams) per 100 c.c. It is thought that 200—500 kilos. per hectare of sodium nitrate containing 2 per cent. of perchlorate could be applied without injury to beet.

The toxic equivalents for rye, oats, and barley (or wheat) were found to be 1/10000, 1.5/10000, and 2/10000 respectively. Assuming the upper 20 cm. of soil to contain as little as 5 per cent. of water (which would only be in dry, summer periods), 100 kilos. of sodium nitrate with 1 per cent. perchlorate would give a concentration of 0.001 per cent., an amount insufficient to injure rye. With more sodium nitrate, or with a higher percentage of perchlorate than 1, rye is distinctly affected. For oats and barley (or wheat), the nitrate may contain 1.5 and 2 per cent. of perchlorate when the amount applied is 100 kilos. per hectare.

N. H. J. M.

Effect of Rain and of the Nature of the Soil on the Production of Crops. By AIMÉ PAGNOUL (*Bied. Centr.*, 1900, 29, 16—19; from *Ann. agron.*, 1899, 25, 83).—Pot experiments are described in which *Festuca pratensis* and incarnate clover were grown in light soil, loam, and calcareous soil respectively. One set of pots received rather less water than would have been the case if exposed to rain, whilst the second set received twice the amount given to the first. From the results, the following conclusions are drawn:

Gramineæ yield about three times, clover almost four times, as much produce in wet as in dry weather. The effect of the greater amount of water was greatest with loam, and least with calcareous soil. Loamy soil gave the smallest yield both of grass and clover, whilst the light soil (which contained 11.85 per cent. of calcium carbonate and 0.462 per cent. of phosphoric acid) gave the best yields.

The plants which received the smaller amount of water contained the greater percentage of dry matter, although the total dry matter was less. The percentage of nitrogen in dry matter was lowest in the plants grown in loam; the total nitrogen was almost twice as high in the case of the plants which received much water as compared with those which had the smaller amount of water.

A second cutting of *Festuca* gave similar results. Subsequently, the same amounts of water were given to all the plots, with the result that the yields became much more alike; the effect of the differences in the previous watering was, however, still noticeable, especially in the case of the loamy soil.

N. H. J. M.

Utilisation by Plants of the Potash Dissolved in the Water in Soil. By TH. SCHLÖSSING, jun. (*Compt. rend.*, 1900, 130, 422—424. Compare Abstr., 1899, ii, 119).—The potash dissolved in soil has, like the phosphoric acid (*loc. cit.*) a considerable nutritive value for vegetation, notwithstanding its relatively small amount; the three or four million kilos. of soil, representing a hectare, contain 1, 2, or 5 kilos. of dissolved potash.

In experiments with maize grown in sand, it was found that a solution containing 7.5 parts of potash per million, in addition to

other minerals in suitable quantity, enabled the plants to grow normally, whilst with a solution containing the same amounts of other minerals, but only 1·8 per million of potash, very much less growth was obtained, and the plants produced no fruit. Maize plants can therefore thrive when they have to depend on solutions containing only some millionths of potash.

N. H. J. M.

Injury to Agricultural Land on the Coast of Essex by the Inundation of Sea-Water on November 29th, 1897. By THOMAS S. DYMOND and FRANK HUGHES (*Chem. News*, 1899, 80, 191—194).—A large area of land was rendered infertile by flooding with sea-water, which itself contained 2·7 per cent. of sodium chloride, or sufficient to cause plasmolysis; the soil which had been flooded contained, however, an amount of salt insufficient to produce that effect. The quantity varied with the character of the soil and period of flooding, but on an average amounted to 0·25 per cent. in the top soil, or 25 times more than the average amount in the soil from land not flooded; nevertheless, pot cultures showed that many plants could grow in the soil from the flooded land. Investigation showed that the infertility was due to the extermination of the earth-worm and to the clay having become more gelatinous, and the soil consequently rendered less pervious to water. This condition was attributable to an increase in the combined water of the clay which was accompanied by a reduction by $\frac{1}{4}$ th in the amount of lime, magnesia, potash, and soda. Although the total potash in the clay had been reduced from 1·12 to 0·84 per cent., the available potash had increased from 0·025 to 0·079 per cent.; the available phosphates had also increased in quantity. To restore the land, good cultivation, good draining to aid the washing out of the salt, manuring with lime, with nitrogenous manures, with long hay manure, and if phosphate is required, with basic slag, are recommended. Suitable plants for crops are mentioned.

D. A. L.

Field Experiments with Superphosphate and Basic Slag. By PAUL BAESSLER (*Bied. Centr.*, 1900, 29, 12—13; from *Ber. Agrik.-Chem. Versuchs-Stat. Köslin* for 1897, 113).—Barley and oats were manured with equal amounts of water and citrate-soluble phosphoric acid (as superphosphate and basic slag), in addition to kainite and nitrate. The soil was a humous, loamy, or slightly loamy, sandy soil containing 0·064—0·091 per cent. of phosphoric acid, of which 4 or 5 parts dissolved in 1 per cent. citric acid.

Owing to unfavourable weather, the results were very irregular. Taking all the results together, it is seen that 40 kilos. of phosphoric acid soluble in water increased the yield of grain by 223, and the yield of straw by 147, kilos. per hectare, whilst the same amount of phosphoric acid soluble in citric acid increased the yields by 183 and 278 kilos. respectively. With 60 kilos. of phosphoric acid per hectare, the increase of grain was 310 kilos. with water soluble, and 288 with citrate soluble phosphate, and the increase of straw 412 and 435 kilos.

The results do not confirm the opinion that basic slag must be applied in the autumn.

N. H. J. M.

Field Experiments with Potash-lime Manure and Fish Guano. By PAUL BAESSLER (*Bied. Centr.*, 1900, 29, 10—12; from *Ber. Agrik.-Chem. Versuchs-Stat. Köslin* for 1897, 120).—Experiments were made in which winter-rye and sugar-beet were grown in humous, sandy soil, manured with the same amounts of potash in the form of potash-lime manure* and kainite, in addition to superphosphate. There were also plots manured with superphosphate alone, and with fish guano. The effect of the two potash manures on rye was only slight, and was almost the same. The results of the superphosphate and fish guano showed that the effect of the latter depended mainly on the nitrogen it contained. In the case of sugar-beet, the potash manures had a decided effect on the leaf development and on the yield of roots, but the effect of the two manures was nearly the same.

The results of experiments on meadows, as well as those just described, showed that potash-lime manure is mainly of use as a potash manure.

N. H. J. M.

Importance of Poultry Manure. By R. ULRICH (*Bied. Centr.*, 1900, 29, 3; from *Fühling's Landw. Zeit.*, 1897, 627).—Pigeons, fowls, ducks, and geese produce yearly 2·5, 5·5, 8·5, and 11 kilos. of manure per head. The composition of the manure is as follows:

	Water.	Organic matter.	N.	P ₂ O ₅ .	Alkali salts.	Ash.
Pigeons	62	31—32	1·2—2·4	3·0—4·2	2·0—2·2	6—7
Fowls...	65	21—26	0·7—1·9	5·0	1·2—1·6	9—14
Ducks..	53	40	0·8	3·5	0·4	7
Geese...	82	14	0·6	0·9	3·1	4

The nutritive constituents are in a readily soluble and concentrated form, especially in the case of pigeon-dung, and must be employed with care. The manures should not be employed in dry weather, or on soil which is dried up; they should be mixed with water, and addition of sulphuric acid (30 lb. per cwt.) is recommended. They may be applied to roots and cabbages, &c., with advantage.

N. H. J. M.

Analytical Chemistry.

Perezone, a New Indicator for Alkalimetry. By MAURICE DUYK (*Chem. Centr.*, 1900, i, 60; from *Ann. chim. anal. appl.*, 1899, 4, 372).—Perezone (pipitzaholic acid), which exists to the extent of about 5 per cent. in the rhizomes of *Perezia adnata*, is an extremely sensitive alkalimetric indicator (compare Abstr., 1885, 805). A drop of a 5 per cent. alcoholic solution gives a feeble opalescence to

* This is a waste product from the manufacture of potash, and contains CaCO₃, 41·8; K₂SO₄, 7·7; CaO, 0·33; K₂O (as sulphate), 4·2 per cent., besides water (about 25 per cent.), Fe₂O₃, Al₂O₃, MgCl₂, NaCl, and SiO₂ (*Bied. Centr.*, 1898, 27, 306).

distilled water, and the liquid becomes rose-coloured with traces of alkalis. Ammonia, aniline, pyridine, and alkaloids, carbonates, hydrogen carbonates, borates, and acetates behave as alkalis. The red liquid becomes colourless on adding mineral or organic acids, or carbon dioxide. Boric acid has an alkaline reaction, but after adding glycerol behaves as an acid. M. J. S.

Retention of Moisture by Asbestos. By GEORGE AUCHY (*J. Amer. Chem. Soc.*, 1900, 22, 46—47).—Some kinds of asbestos retain moisture with great tenacity, even after drying at 100°; on heating again over a blast, a loss of several milligrams may occur. It is therefore advisable to ascertain once for all the amount of water retained in a sample which is intended for use in a Gooch crucible. L. DE K.

Estimation of Water in Syrups and similar Products. By OSKAR MOLENDÁ (*Chem. Centr.*, 1900, i, 71—72; from *Oesterr.-ung. Zeit. Zucker-Ind. und Landw.*, 28, 621).—The author makes use of the reaction between water and calcium carbide, and measures the acetylene evolved. Scheibler's calcimeter is convenient for the purpose. Solutions stronger than 30 per cent. cannot be employed; those of 20—27 saccharimetric degrees are the most suitable. The syrup must therefore be diluted with water, and the amount of water added is best estimated from polarimetric observations of the original substance and the dilute solution. About 0.1 gram of the dilute solution is taken, and the formula $0.612 A/\text{subs.}$ in grams, in which A represents the percentage of calcium carbonate given by the calcimeter table as corresponding with the volume of gas, gives the percentage of water. Pure water gave an average result of 98.83 per cent., and sugar solutions of known composition gave differences averaging 2.56 per cent. M. J. S.

Estimation of Sulphur in Ores, Mattes, &c. By P. TRUCHOT (*Chem. Centr.*, 1900, i, 62; from *Ann. chim. anal. appl.*, 4, 374).—A gram of the finely powdered substance is rapidly heated in a covered beaker with 25 c.c. of concentrated nitric acid so long as red fumes are evolved. The liquid is cooled, twice warmed gently for 5 minutes with 1 c.c. of bromine, then evaporated on the water-bath almost to dryness, boiled with 15 c.c. of hydrochloric acid, diluted with 250 c.c. of water, filtered, and precipitated while boiling with barium chloride. M. J. S.

Estimation of Sulphur in Pig Iron and Cast Iron. By ADOLF RIEMER (*Chem. Centr.*, 1900, i, 61—62; from *Stahl. und. Eisen*, 1899, 19, 1064).—Wiborgh's method (*Abstr.*, 1886, 743) is utterly untrustworthy, indicating only about half the sulphur present. A rapid and exact method is to dissolve the metal in concentrated hydrochloric acid, and pass the evolved gases (after first washing with water) through ammoniacal cadmium acetate. An excess of standard iodine solution is added, the mixture acidified with hydrochloric acid, and the excess of iodine then titrated with thiosulphate. In very exact analyses, the cadmium sulphide precipitate should be collected and washed. M. J. S.

Estimation of Sulphur in Pyrites. By OLE N. HEIDENREICH (*Chem. Zeit.*, 1900, 24, 15).—The author recently improved the estimation of sulphur in pyrites or burnt pyrites by reducing the ferric solution to the ferrous state by means of zinc before adding barium chloride (Abstr., 1899, ii, 517). Thiel has stated that the supposed accuracy of the results is only due to a fortunate compensation of errors (this vol., ii, 242). In reply, the author points out that Meineke has independently investigated the method and finds the results to be trustworthy (Abstr., 1899, ii, 518, 693).

L. DE K.

Estimation of Sulphur in Bitumens. By A. C. LANGMUIR (*J. Amer. Chem. Soc.*, 1900, 22, 99—102).—The author criticises the process recommended by S. F. and H. E. Peckham (this vol., ii, 44), and points out several sources of error. No precautions are taken to prevent absorption of sulphur compounds during the fusion with alkali nitrate and the subsequent slow evaporation of the dissolved mass with hydrochloric acid. The most serious objection is, that on precipitating the iron and aluminium by means of ammonia and expelling the excess of the latter by boiling, a portion of the sulphuric acid recombines with the iron. Finally, if the sulphuric acid is precipitated after removing the calcium with ammonium oxalate, there is a danger of obtaining a very impure barium sulphate, which is rendered still more probable by the presence of a large quantity of alkali chlorides.

Eschka's process, as described by Heath, is admittedly the best process for the estimation of sulphur in bituminous coals.

L. DE K.

Estimation of Alkali Persulphates and of Hydrogen Peroxide. By BRUNO GRÜTZNER (*Arch. Pharm.*, 1899, 237, 705—706).—About 0.3 gram of the *persulphate* is heated to boiling with 50 c.c. *N*/10 arsenious acid, and a few grams of aqueous potassium or sodium hydroxide, the whole digested for a little while, cooled, made faintly acid with sulphuric acid, treated with a large excess of sodium hydrogen carbonate, mixed with starch solution, and titrated with *N*/10 iodine solution. 1 c.c. *N*/10 $\text{As}_2\text{O}_3 = 0.0135$ gram $\text{K}_2(\text{SO}_4)_2$, 0.0119 $\text{Na}_2(\text{SO}_4)_2$, or 0.0114 $(\text{NH}_4)_2(\text{SO}_4)_2$. The error in the analyses quoted does not exceed ± 0.2 per cent.

Of a commercial sample of *hydrogen peroxide*, 10 c.c. are diluted to 100 c.c., and 10 c.c. of the dilute solution treated as is the persulphate in the method just described; 1 c.c. *N*/10 $\text{As}_2\text{O}_3 = 0.0017$ gram of hydrogen peroxide. A result was obtained 0.04 per cent. higher than by titration with permanganate. Sodium peroxide cannot be analysed in this way.

C. F. B.

Estimation of Ammonia and of Nitrogen. By ANTOINE VILLIERS and E. DUMESNIL (*Compt. rend.*, 1900, 130, 573—576).—The estimation of ammonia by titration is often inaccurate, because of the effect of ammonium salts on the indicator used, and better results are obtained by weighing the ammonia in the form of ammonium chloride. The ammonia is absorbed in an excess of dilute hydro-

chloric acid which has previously been found to leave no residue on evaporation, and the solution is concentrated in a porcelain dish over a small flame which heats only the bottom and not the sides of the vessel. When the liquid is reduced in volume to about 25 c.c., it is transferred to a small weighed conical flask, in which the evaporation is completed, the residue being dried at 105°. C. H. B.

The Phosphometer, an Apparatus for the Clinical Estimation of Phosphorus in Blood. By ADOLF JOLLES (*Chem. Centr.*, 1900, i, 486—487; from *Wien. Med. Woch.*, 1899, Nos. 46, 47).—The estimation is a colorimetric one, in which the yellow coloration produced by potassium molybdate in solutions of phosphates is used as a measure of the phosphate present. The intensity of the colour varies with the temperature, reaching its maximum at 80°. The comparison tubes are therefore observed in a cylindrical vessel surrounded by a water jacket, and are so arranged that three tubes (one of which contains the substance and the other two standards) can be simultaneously seen by light thrown upward from an oblique mirror below the cylinder. The substance is prepared by evaporating a measured quantity of the blood (0.1 c.c.) in a platinum crucible, fusing the residue with a mixture of sodium carbonate and potassium nitrate (3:1), and dissolving the fused mass in dilute nitric acid. The comparison solutions are prepared by dissolving 18.7324 grams of sodium pyrophosphate in 50 c.c. of nitric acid of sp. gr. 1.2 and diluting to a litre; from this solution, others are prepared containing 2, 0.2, and 0.02 milligrams of P_2O_5 per c.c. The potassium molybdate solution contains 8 grams of the salt in 50 c.c. of water and 50 c.c. of nitric acid of sp. gr. 1.2; for use, 1 c.c. of this solution is diluted to 20 c.c. M. J. S.

Simplified Method of Estimating Phosphoric Acid by Molybdate. By JOSEPH HANAMANN (*Chem. Centr.*, 1900, i, 488—489; from *Zeit. landw. Vers.-Wes. Oesterr.*, 3, 53).—By employing a molybdate solution containing more nitrates than the usual one, and precipitating at 40°, the precipitation of the phosphoric acid is complete in ten minutes, and the precipitate is of constant composition after gentle ignition, containing 3.94495 per cent. of phosphoric oxide. The molybdate solution is made by dissolving 100 grams each of ammonium molybdate and ammonium nitrate in 150 c.c. of ammonia of sp. gr. 0.91 and pouring the solution into a litre of nitric acid of sp. gr. 1.2. After boiling the solution, it is filtered into bottles of brown glass, and kept in a cool place. M. J. S.

Wagner's New Reagent for Estimating Soluble Phosphoric Acid in Basic Slag. By ADOLFO CASALI (*Chem. Centr.*, 1900, i, 62; from *Staz. sper. agrar. ital.*, 32, 486).—The use of citric acid for extracting the soluble phosphate from basic slag gives a much higher result than that obtained with the ammonium citrate more usually employed. In reporting the results of analyses, it should always be stated which reagent has been used. M. J. S.

Detection of Adulterations in Bone Superphosphate. By HENRI LASNE (*Chem. Centr.*, 1900, i, 72—73; from *Ann. chim. anal. appl.*, 4, 361).—The results of the estimations made should be

expressed in the form of ratios to 100 parts of phosphoric oxide present. The total phosphoric oxide and calcium oxide are first estimated. In normal bone, this ratio is 100:129—134. A higher ratio of calcium oxide points to the addition of either gypsum or mineral phosphate. Gypsum is sought for by the microscope. A deficiency of calcium oxide indicates addition of precipitated phosphate. Calcium chloride is also estimated. A ratio of 0.15 is compatible with purity; 0.3 points to the addition of gypsum, and a higher ratio is characteristic of precipitated phosphate. Addition of mineral phosphate raises the ratio of aluminium and insoluble matter (containing titanium) and also that of calcium fluoride (of which only traces are normally present), or, in the case of certain phosphates which are poor in fluorine, introduces manganese. Bone ash is best detected by partially precipitating with ammonia, collecting the precipitate, and treating it with dilute hydrochloric acid, when fragments of bone can be seen. The part of a normal bone-superphosphate insoluble in dilute hydrochloric acid seldom contains more than 0.1 of nitrogen per 100 parts of original substance; a greater proportion indicates addition of nitrogenous waste materials. The superphosphate itself should contain about 0.6 per cent. of nitrogen (see also this vol., ii, 167).

M. J. S.

Separation and Estimation of Arsenic and Antimony in Ores. By O. C. BECK and H. FISHER (*Chem. News*, 1899, 80, 259—261).—A critical examination and comparison of various known methods. The best results for arsenic were obtained by Pattinson's method (Abstr., 1899, ii, 56) of titrating the sulphide with iodine; weighing the sulphide gave results which were too high. Fischer's distillation method (Abstr., 1881, 195) gave good results, but, like Pearce's nitrate method (*Chem. News*, 1883, 48, 85), took too long; the latter, moreover, even when modified, gave low results. For antimony, Weller's method (Abstr., 1882, 1324) and Mohr's method gave fairly concordant results, whilst weighing the antimony as sulphide gave results too high, and as oxide, too low. Jannasch's modification occupied more time and introduced much sulphur, but gave higher results.

D. A. L.

Volumetric Estimation of Boric Acid. By ALFRED STOCK (*Compt. rend.*, 1900, 130, 516—517. Compare this vol., ii, 47).—In estimating boric acid by Jones's volumetric method (Abstr., 1899, ii, 322), it is essential that carbon dioxide should be absent; traces of this gas are most conveniently removed by boiling the solutions employed before titration; the removal of the gas by means of barium chloride is not to be recommended, because the barium carbonate produced interferes with the end point. The presence of salts of the alkali and alkaline earth metals does not affect the process; when iron and aluminium are present, their insoluble hydroxides are produced; the titration must, however, be performed in the presence of these substances, since the precipitate may contain variable quantities of borates; these salts are readily decomposed by the standard sodium hydroxide, and accurate results are obtained even under these conditions.

G. T. M.

The Accuracy of Jörgensen's Method for Estimating Boric Acid in Preserved Meat, and the Separation of Boric Acid from Borax. By ADOLF BETTHIEN and HANS HEMPEL (*Chem. Centr.*, 1900, i, 63—64; from *Zeit. Unters. Nahr.-Genussmitt.*, 2, 842).—Jörgensen's method depends on the fact that a boric acid solution, rendered neutral to phenolphthalein by addition of alkali, becomes acid again on adding a sufficient quantity of glycerol, so that the boric acid can be titrated by an alkali which has been standardised by a boric acid solution of known value, under similar conditions as regards amount and concentration. The results are very satisfactory.

To estimate the boric acid in meat, the substance may either be extracted by warming for several hours with strong sodium hydroxide solution, and the extract evaporated and incinerated, or, more expeditiously and with little loss of accuracy, by direct incineration of the meat itself after carefully and thoroughly saturating it with a large excess of an alkaline solution. The ash, in either case, is dissolved in 50 c.c. of dilute sulphuric acid, the solution warmed gently, which can be done without noteworthy loss, cooled, and made exactly neutral to phenolphthalein: 25 c.c. of glycerol are then added and the titration made. Addition of alcohol renders the end sharper. With mixtures of 100 grams of flesh, and 0.1 gram of boric acid, the results varied from about -5.4 to +1.67 per cent. of the boric acid used.

It has been stated that in cooking salt meat containing boric acid, the greater part of that substance is lost. American salt meat containing 1.12 and 1.17 per cent. of boric acid lost only 0.41 per cent. by soaking and washing, and 0.59—0.67 by boiling; the broth contained 0.60—0.57 part per 100 parts of the original meat. The broth ought therefore never to be consumed.

The authors are experimenting on the use of acetone for separating boric acid and borax. M. J. S.

Estimation of Silicon in Ferro-chromium and of Silica in Chrome Ore. By GEORGE TATE (*Chem. News*, 1899, 80, 235).—Ferro-chromium or chrome ore (1—2 grams) is fused with about five times its weight of sodium peroxide in a nickel crucible, and when cold immersed in water in a nickel dish, neutralised with hydrochloric acid, and evaporated to dryness. The residue is heated with 40 c.c. of strong sulphuric acid until fumes of sulphuric acid appear. When cool, it is treated cautiously with water, transferred to a porcelain dish, made up to about a $\frac{1}{4}$ -litre, boiled to dissolve the sulphates, and the residual silica is washed, dried, ignited, and weighed; if coloured, it is evaporated with hydrofluoric acid and a drop of sulphuric acid, and any residue weighed and deducted. D. A. L.

Estimation of Graphite by Loss. By GEORGE AUCHY (*J. Amer. Chem. Soc.*, 1900, 22, 47—48).—Asbestos is preferable to filter paper for collecting the graphite left on dissolving iron, but attention is called to the retention of water by asbestos (this vol., ii, 309).

The process is not altogether free from sources of error, but these do not appreciably affect the result when the percentage of graphite

is small. The graphite is not always pure carbon, but may contain small quantities of hydrogen, oxygen, nitrogen, and sulphur.

L. DE K.

Iodometric Estimation of Small Quantities of Carbon Monoxide. By LEONARD P. KINNICUT and GEORGE R. SANFORD (*J. Amer. Chem. Soc.*, 1900, 22, 14—18).—The process has been devised for the estimation of small quantities of carbon monoxide in air contaminated by leakage of water-gas, &c. 1000 c.c. of air are drawn through two U-tubes respectively containing sulphuric acid and potassium hydroxide, to absorb unsaturated hydrocarbons, hydrogen sulphide, sulphur dioxide, and similar reducing gases; it then passes through another U-tube containing 25 grams of pure iodine pentoxide, and suspended in an oil-bath heated at 150°. The action of carbon monoxide on the hot iodine pentoxide causes liberation and volatilisation of free iodine, which is collected in a Wolff's blood-absorption-tube containing 0.5 gram of potassium iodide dissolved in 5 c.c. of water. The iodine is then titrated with *N*/1000 sodium thiosulphate.

One milligram of iodine represents 0.4357 c.c. of carbon monoxide.

L. DE K.

Rapid Method of Estimating Carbon Dioxide in Gaseous Mixtures. By LÉO VIGNON and LOUIS MEUNIER (*Compt. rend.*, 1900, 130, 513—515).—A large, cylindrical glass vessel of known capacity is connected with a burette and an inlet tube for the introduction of a gaseous mixture. When the apparatus is filled with the gas, about 40 c.c. of alcohol (93 per cent.), containing a small quantity of phenolphthalein, are run in, and the mixture is titrated with *N*/20 calcium hydroxide solution. The method is applicable to the estimation of carbon dioxide in any mixture of neutral gases; when ammonia and hydrogen sulphide are present, these are removed by passing the gas through an acetic acid solution of lead acetate before collecting it in the titrating cylinder.

G. T. M.

Volumetric Estimation of Magnesia. By JAMES O. HANDY (*J. Amer. Chem. Soc.*, 1900, 22, 31—39).—This is a modification of Stolba's process (1866), which has not found much favour.

The magnesia solution, freed from calcium, aluminium, &c., is precipitated as usual with solution of sodium ammonium hydrogen phosphate, and the precipitate carefully washed with dilute ammonia (1:9). When drained, the filter is opened flat and placed on thick, dry filter paper for a few minutes, then transferred to a second dry paper, and left for 30 to 60 minutes, after the moisture has been practically absorbed. The small amount of ammonia still adhering to the precipitate is then expelled by heating for 20 minutes in an air-bath at 50—60°.

The filter with the precipitate is now put into a small beaker, and an excess of *N*/10 sulphuric acid is added. When the precipitate has dissolved and the paper been disintegrated by stirring, two drops of a 0.1 per cent. alcoholic solution of methyl-orange are added, and the excess of acid titrated with *N*/10 sodium hydroxide. 1 c.c. of *N*/10 sulphuric acid = 0.002 gram of magnesia.

L. DE K.

Estimation of Copper. By M. WILLENZ (*Chem. Centr.*, 1900, i, 490; from *Ann. chim. anal. appl.*, 5, 2).—The method of precipitation by sodium thiosulphate is strongly recommended. The substance is dissolved in nitric acid, the solution evaporated with sulphuric acid, and precipitated boiling with 5–6 grams of thiosulphate for each gram of substance. Cadmium and lead are not precipitated, neither are arsenic and antimony if the solution is strongly acid and hot; they separate, however, on cooling and diluting. Traces of both are therefore contained in the copper precipitate, but can be driven off by intense ignition.

M. J. S.

Precipitation and Separation of Copper in the Presence of Sodium Hydroxide by the Aid of Hydrazine Sulphate or Hydrochloride. By PAUL JANNASCH and K. BIEDERMANN (*Ber.*, 1900, 33, 631–636).—When a 3 per cent. solution of hydrazine sulphate is added to a copper sulphate solution in the presence of an excess of pure sodium hydroxide and the whole warmed on a sand-bath, the copper is deposited in the metallic state and may be filtered by the aid of a double paper, well washed, dried at 90°, and weighed as cupric oxide after ignition, if necessary, in a current of oxygen.

Copper may be readily separated from zinc or arsenic by this method, as in strongly alkaline liquids only the copper salt is reduced; the zinc may then be precipitated as carbonate and the arsenic as magnesium ammonium arsenate. In the separation of tin and copper, the alloy (1 part) is dissolved in as small a quantity of aqua regia as possible; the solution thus obtained is diluted with its own volume of water and is slowly added to a solution of pure sodium hydroxide (15 parts) and hydrazine hydrochloride (2–3 parts); when the sulphate is employed, small amounts of tin are always carried down with the copper. After the mixture has been warmed for some time, the copper is removed and treated as before; the alkaline filtrate is acidified with hydrochloric acid, precipitated with ammonia, the precipitate dissolved in ammonium sulphide, and reprecipitated as sulphide of arsenic by the careful addition of hydrochloric acid.

J. J. S.

Rapid Estimation of the Purity of Commercial Copper Sulphate, and of the Amount of Copper Sulphate in Copper Pyrites. By CARLO MONTANARI (*Chem. Centr.*, 1900, i, 66; from *Staz. sper. agrar. ital.*, 32, 479).—Zecchini's method (*Staz. sper. agrar. ital.*, 32, 117) gives rapid and exact results, especially if a $N/20$ solution be employed instead of that recommended by Zecchini. Scarlata's method (*Mon. Sci.*, [iv], 13, i, 409) is troublesome and inexact.

M. J. S.

Estimation of Aluminium. By ALFRED STOCK (*Ber.*, 1900, 33, 548–553).—The greater part of this paper has already been published (this vol., ii, 247). Aluminium hydroxide, obtained by adding a mixture of potassium iodide and iodate to a faintly acid solution of an aluminium salt, and removing the liberated iodine by sodium thiosulphate (*loc. cit.*), has, after drying in the air, the composition $Al(OH)_3$; after drying over calcium chloride, the composition $2Al_2O_3 \cdot 5H_2O$, and after drying at

130°, $3\text{Al}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$; this last hydrate, when exposed to the air, absorbs water until its composition is again represented by the formula $\text{Al}(\text{OH})_3$. The individuality of the various hydrates is being investigated.

In presence of a large excess of sulphates, the precipitated hydroxide contains sulphuric acid, which is, however, lost on ignition. This circumstance interferes with the alkalimetric titration of alum solutions, but the error may easily be avoided by adding a slight excess of barium chloride to the solution, and then titrating as usual without filtering.

A. H.

Rapid Method for the Estimation of Clay in Soils. By F. POQUILLON (*Bull. Soc. Chim.*, 1900, [iii], 23, 115—116).—In the process described, the mechanical separation of the sand and clay is facilitated by the use of a dilute solution of ammonium chloride instead of pure water, and the number of washings and bulk of liquid employed is diminished. 10 grams of the soil are rubbed up with 25 c.c. of water, and the liquid mixed with 100—120 c.c. of a 0.1 per cent. solution of ammonium chloride and left for 5 minutes. The supernatant liquid is then decanted, and the operation repeated 6—8 times until the washings are clear, when the residual sand is washed, first with dilute hydrochloric acid and then with water, dried, and weighed. The turbid washings are mixed, acidified with hydrochloric acid, left for 2—3 hours, and the precipitated clay is collected on a filter, washed with water, dried, and weighed.

N. L.

Estimation of Nickel in Nickel Ores. By A. C. LANGMUIR (*J. Amer. Chem. Soc.*, 1900, 22, 102—106).—This is a slight modification of Sargent's process (this vol., ii, 51), and may be applied to ores. The method is briefly as follows: the ore is oxidised with nitric acid and bromine, mixed with excess of hydrochloric acid, and boiled down to a small bulk. After diluting with water, copper, &c., are removed by means of hydrogen sulphide. The filtrate is boiled, and the ferrous iron oxidised by cautious addition of nitric acid. Slight excess of ammonia is added, and the filtrate which contains the bulk of the nickel is evaporated in a large casserole. The precipitate is dissolved in hydrochloric acid, boiled down to a pasty mass, dissolved in hydrochloric acid of sp. gr. 1.1, and then agitated with two separate portions of ether. This dissolves the ferric chloride, leaving the nickel in the acid layer. Any iron still remaining is precipitated with bromine and ammonia, and freed from the last traces of nickel by redissolving and precipitating a second time. The ammoniacal solution containing the nickel is now also introduced into the casserole, and the whole evaporated until ammonium chloride begins to separate; this is destroyed by adding a large excess of nitric acid and evaporating to dryness. The nitrate is now converted into sulphate by heating with strong sulphuric acid, the liquid diluted, mixed with excess of ammonia, and submitted to electrolysis.

L. DE K.

Rapid Evaluation of Metallic Tungsten Powders. By FRED IBBOTSON and HARRY BREARLEY (*Chem. News*, 1899, 80, 294—295).—Three grams of the powder are ignited in a tared platinum dish until

completely oxidized, re-weighed, treated with hydrofluoric acid to remove silica, and again weighed. It is boiled with pure caustic soda to dissolve as much tungsten as possible, and the residue, which contains iron, manganese, and some tungsten, is collected, washed, ignited, and weighed; it is then dissolved in a small quantity of hydrochloric acid, and should leave no residue if properly ignited at the commencement. The solution is largely diluted to precipitate the tungsten, which is collected and weighed, whilst the iron and manganese may be estimated in the filtrate. The tungsten in the caustic soda solution may also be determined. In this way, with the pure materials used in steel manufacture, useful numbers may be obtained for the silica, tungsten, iron, and manganese. The proportion of tungstic oxide may be ascertained by treating the unheated sample with a large volume of strong hydrochloric acid, which dissolves the oxide, but not the metal. Carbon may be determined by simply heating in a current of oxygen. Sulphur is not usual in samples for steel making, but if present would interfere with the scheme of analysis set forth, and so must be removed beforehand.

D. A. L.

Analysis of Tungsten Compounds. By FRED IBBOTSON and HARRY BREARLEY (*Chem. News*, 1899, 80, 293—294).—On adding strong nitric acid, drop by drop, to a boiling solution of lead tungstate, a change of colour from white to yellow ultimately takes place, boiling for a short time with a few additional c.c. of the acid then develops the full yellow colour of tungstic oxide; the change is quantitative, and may be applied to the estimation of tungsten, making a correction for the small amount of tungstic acid that passes away in the filtrates. Ammonia, if present, is not eliminated; barium, strontium, calcium, magnesium, zinc, cadmium, manganese, nickel, and cobalt do not interfere with the reaction, but arsenic, mercury, uranium, iron, tin, and silicon do, although the interference of arsenic and mercury may be disregarded. In the presence of uranium salts, the solution containing a small excess of sodium carbonate is heated to boiling, and is poured in a thin stream into hot acetic acid containing excess of lead acetate, with vigorous shaking. The mixture is just boiled, the precipitate washed by decantation, &c. The tungstic oxide finally obtained is free from uranium. Iron and aluminium in small quantities may be dealt with by making the solution just alkaline, then faintly acid with acetic acid; most of the tungsten is precipitated with the iron, and the rest is precipitated by lead acetate. The precipitate is washed by decantation, ignited, and treated with hydrochloric acid as though it were pure lead tungstate. Chromium cannot be treated in this manner, and the interference of tin and silicon cannot be avoided. In the last instance, however, the whole of the tungsten may be precipitated from a neutral solution as mercurous silicotungstate by means of mercurous nitrate, the silica in the ignited residue being removed by hydrofluoric acid. Ammonia and ammonium carbonate effect the separation of silica and tungstic oxide imperfectly.

D. A. L.

Ammonium Molybdate as a Delicate Reagent for Stannous Chloride. By J. P. LONGSTAFF (*Chem. News*, 1899, 80, 282—283).—Tin may be detected in solution, in quantities that might escape detection by the ordinary qualitative tests, by means of the blue coloration produced by ammonium molybdate with stannous chloride. The solution, to be tested, must be freshly prepared, and diluted with boiled water to avoid oxidation as much as possible; moreover, it must not contain strong hydrochloric acid, as this destroys the colour. One part of tin, as stannous chloride, in 1,500,000 of solution has been detected by this means. D. A. L.

Significance of the Detection of Nitrites in Drinking Water. By LEOPOLD SPIEGEL (*Ber.*, 1900, 33, 639—644).—The author criticises Erdmann's proposition (this vol., ii, 243) to employ 1-amino-8-naphthol 4:6-disulphonic acid along with sulphanilic acid as a test for nitrites in drinking water. Erdmann's statements that nitrous acid is present in all water containing a small quantity of animal matter, and that every good drinking water is free from nitrous acid, are shown to be erroneous. The author is of opinion that the presence of nitrites in water is no criterion of its value for drinking purposes, as this can only be deduced from a complete examination of the water, coupled with the knowledge of the nature of the soil in which it occurs.

In place of Erdmann's reagent for nitrous acid, the author proposes to use either of the less sensitive compounds, guaiacol and creosote, which, in dilute aqueous solution, give with nitrous acid an orange and a yellow coloration respectively. These reactions are not interfered with by the presence of oxidising agents, such as nitrates, chlorates, and hydrogen peroxide, or by ferric salts in such concentrations as are met with in potable waters. T. H. P.

Cobalticyanides. By EDMUND H. MILLER and JOHN A. MATHEWS (*J. Amer. Chem. Soc.*, 1900, 22, 62—69).—The authors give instructions for the preparation of the metallic cobalticyanides, and their chief properties are described in an accompanying table.

Potassium cobalticyanide may perhaps be used in quantitative analysis. As the lead salt is very soluble, whilst those of silver, copper, and bismuth are insoluble in water or nitric acid, it may perhaps be useful in the assay of pig lead. The bismuth may then be separated from the copper by treatment with hydrobromic acid, which dissolves the bismuth cobalticyanide and leaves the copper, together with any silver compound, undissolved; or by treating the precipitate with ammonia in which the copper and silver compounds dissolve, leaving the bismuth. The bismuth may be separated from the compound as hydroxide by digesting it with aqueous potassium hydroxide.

It also affords a means of separating zinc, manganese, nickel, or cobalt from ferric iron, as the latter is not precipitated in the presence of sufficient ammonium sulphate. The zinc compound may be separated from the others by dissolving it in aqueous potassium hydroxide, which leaves the manganese, cobalt, and nickel in the form of hydroxides. Further results are promised. L. DE K.

Chemistry and Analysis of Wines. By MAXIMILIAN RIPPER (*Chem. Centr.*, 1900, i, 436—437; *Zeit. Landw. Vers.-Wesens. Oesterr.*, 3, 26).—In continuation of previous work on this subject (*Abstr.*, 1899, ii, 699), attention is directed to the aldehydes and their compounds contained in wine. Aldehydes or ketones may be detected in all wines by distilling 200 c.c. of the wine, and testing the first 20 c.c. of the distillate with phenylhydrazine hydrochloride, Guyon's reagent, *m*-phenylenediamine hydrochloride, ammoniacal silver solution, or resorcinol and hydrochloric acid. For estimation, 50 c.c. of the wine are mixed with 5 c.c. of sulphuric acid (1 : 3) and some starch, and titrated with *N*/50 iodine solution. To another 50 c.c. in a flask 50 c.c. of *N*/50 potassium hydrogen sulphite are added, and the corked flask is kept for $\frac{1}{4}$ hour, at the end of which time 5 c.c. of sulphuric acid are added and the mixture is titrated with the iodine solution. The iodine value of the sulphite solution is also estimated. The amount of iodine required by the wine alone is subtracted from that consumed by the mixture of wine and sulphite, and this difference is subtracted from the amount of iodine required by the sulphite alone. The difference is calculated into acetaldehyde. M. J. S.

Estimation of Cresols by Determining their Capability of forming Bromo-substitution Derivatives. By ROBERT CLAUSER (*Chem. Centr.*, 1900, i, 118; from *Oesterr. Chem.-Zeit.*, 2, 585—588).—*o*-Cresol may be estimated by Koppeschaar's method, with a maximum error of +0.5 per cent. The solution should contain only 1/30,000—1/40,000th of its weight and the quantity of the bromide-bromate solution added should be sufficient to supply 6 atoms of bromine for each mol. of cresol present. As soon as the yellow coloration appears, the action requires to be checked by adding potassium iodide and allowing the mixture to remain for half an hour.

E. W. W.

Estimation of the Reducing Power of Urine, Blood, and other Animal Fluids. By HEINRICH ROSIN (*Chem. Centr.*, 1900, i, 48; from *Münch. med. Woch.*, 46, 1456).—The author formerly proposed to effect this object by ascertaining the amount of methylene-blue decolorised by a given volume of the urine under certain conditions. A more satisfactory method is to use the methylene-blue merely as an indicator, and to employ potassium permanganate as the oxidising agent. The urine is diluted five-fold; 25 c.c. are placed in a small Erlenmeyer flask, mixed with 1 c.c. of officinal potassium hydroxide solution, covered with paraffin oil to exclude air, and heated, but not to boiling. From a burette, the point of which dips below the paraffin layer, 1 c.c. of methylene-blue solution (1 : 3000) is then introduced, and then in a similar manner *N*/100 permanganate, until a bluish-green colour is obtained. The permanganate required is a measure of the reducing power of the urine. M. J. S.

Detection of Sucrose in Margarine. By MECKE (*Chem. Centr.*, 1900, i, 435; from *Zeit. öffent. Chem.*, 5, 496).—To communicate to margarine the properties of natural butter, sucrose and yoke of egg are added to it. Sucrose can be estimated in presence of lactose by the polarimeter, but the difficulty of obtaining clear solutions from

margarine renders this method inadmissible. The sugars are therefore estimated gravimetrically before and after inversion with citric acid.

M. J. S.

Analysis of Golden Syrup. By RICHARD BODMER, NORMAN LEONARD, and HARRY M. SMITH (*Analyst*, 1899, 24, 253—257).—Attention is called to the growing practice of adulterating golden syrup with glucose, the product of the hydrolysis of starch.

The adulteration may be detected and even approximately estimated by taking the copper-reducing power of the sample (calculated on the dry substance) before and after inversion; another inversion experiment is made in which not only the sucrose but any dextrin or maltose is also inverted. The copper-reducing power, coupled with a polarimetric test, is sufficient to enable an opinion to be formed on the sample. In the equation given to facilitate the calculation, it is assumed that commercial starch-glucose has a copper-reducing power of 53 and a specific rotation of $+134^\circ$ for sodium light. The analyses of several commercial samples of golden syrup are given in a table (compare following abstract).

L. DE K.

Analysis of some Sugar Syrups. By ALEXANDER K. MILLER and J. P. POTTS (*J. Soc. Chem. Ind.*, 1899, 18, 1091—1093).—The authors criticise the process recently introduced by Bodmer, Leonard, and Smith (preceding abstract).

Owing to the uncertain nature of commercial glucose, analyses made by means of the polariscope are untrustworthy quantitatively, although they have a qualitative value. For such a qualitative test, the following procedure is recommended:—Determine the polarimetric reading of a 10 per cent. solution (or other suitable strength) of the syrup; invert the cane-sugar in a portion of the solution and again determine the rotation. From the difference between the two readings, the cane-sugar can be determined, and from this the rotation due to the cane-sugar calculated. If this is deducted from the original rotation, the difference will represent the rotation due to the dextrose and lævulose, if the sugar is a genuine sugar syrup, and the result will generally be a lævo-rotation. The process should be supplemented by a fermentation experiment; further investigation seems very desirable.

L. DE K.

Effect of the Presence of Glycuronic Acid on the Phenylhydrazine Test for Sugar in Urine. By PAUL MAYER (*Chem. Centr.*, 1900, i, 284—285; from *Berlin klin. Woch.*, 37, 5—7. Compare this vol., ii, 155).—When ordinary urine is treated with phenylhydrazine and a 50 per cent. solution of acetic acid, a brown, amorphous precipitate is formed which consists chiefly of a decomposition product of phenylhydrazine, probably diphenylhydrazine. When, however, the urine contains large quantities of derivatives of glycuronic acid, a phenylhydrazine compound may be obtained, as some of these glycuronic acid compounds are decomposed by heating with acetic acid. Thus, whilst urines containing thymol- or naphthol-glycuronic acid do not give phenylhydrazine compounds, a crystalline substance melting at $200\text{--}215^\circ$ may be obtained from a urine containing mentholglycuronic acid, but in this case, although the urine

slowly reduces Fehling's solution and is slightly laevorotatory, it cannot be fermented. The decomposition of mentholglycuronic acid also takes place when the urine is kept, orcinol and menthol being formed. Urines containing urochloralic acid and more than normal amounts of phenol-, indoxyl-, or scatoxyl-glycuronic acid also yield phenylhydrazine compounds. In all these cases, however, the fermentation test furnishes a trustworthy indication of the presence or absence of sugar.

E. W. W.

Isolation of Glycogen from Horseflesh and Preserved Meats. By G. BREUSTEDT (*Arch. Pharm.*, 1899, 237, 637—659).—Several methods of isolation have been studied, and the properties of the glycogen compared with those of the products formed at the same time from any pepper present in the sausages, &c. The conclusion is drawn that at present it is impossible to isolate glycogen with certainty from sausages containing pepper as well as horseflesh; in any case, the employment of alkalis should be avoided when pepper is present, and water used for the extraction. For all preparations that contain no starch, the use of alcoholic, rather than aqueous, potash is recommended in order to extract the glycogen.

The method is as follows: The meat is minced finely and freed from fat by kneading it with warm light petroleum, and decanting the latter; 100 grams of it are mixed in a beaker with 25 c.c. water, 100 c.c. of 90 per cent. alcohol, and 7 grams of caustic potash if the meat is fresh, or 10—15 grams if it has been smoked and more or less dried. The whole is then warmed on the water-bath and stirred for 20—60 minutes, until the muscle fibres are destroyed. The now fairly thin liquid is diluted to 350 c.c. with 95 per cent. alcohol, and allowed to remain at 40° until the solid matter has settled; the liquid is decanted through a plug of glass wool, and the residue washed twice with 50—75 c.c. of alcohol (60 per cent. by vol.). The glass wool is now placed in the beaker, the alcohol remaining evaporated off, the residue mixed with 25 c.c. of water, acidified with hydrochloric acid, and treated with Brücke's reagent (*Sitzungsber. Wien. Akad.*, 1871, Abt. II., Bd. 63) until a further addition of this produced no precipitate. The precipitate is collected and washed with a little water containing a few drops of hydrochloric acid and Brücke's reagent, the filtrate precipitated with twice its volume of 95 per cent. alcohol, and filtered after a little while. The filter is then perforated, the precipitate rinsed with a little hot water into a beaker, the liquid acidified with hydrochloric acid when cold, and treated with a few drops of potassium mercuriodide solution, to precipitate any proteids still present, filtered, the precipitate washed as before, the filtrate mixed with twice its volume of alcohol, and the precipitate of glycogen collected at once on a filter (previously dried at 110° and weighed), washed first with 95 per cent. alcohol, and then with ether, dried at 110°, and weighed.

C. F. B.

Estimation of Glycogen, and Relative Quantities of Glycogen in Different Parts of the Flesh of the Horse. By JOHN K. HAYWOOD (*J. Amer. Chem. Soc.*, 1900, 22, 85—93).—50—60 grams of ground meat are heated with 300 c.c. of a 1 per cent. solution of potassium

hydroxide for 6 hours on the water-bath, water being added from time to time so as to keep the volume of the liquid at 150 c.c. Dilute hydrochloric acid (1 : 5) is now added until the liquid is slightly acid and solution of mercuric potassium iodide (a 10 per cent. solution of potassium iodide saturated with mercuric iodide at boiling heat) is added so long as a precipitate is formed. The whole is diluted to 500 c.c., well shaken, and 250 c.c. collected by filtering through a fluted filter. After adding a drop or two of phenolphthalein, the liquid is neutralised with potassium hydroxide, the amount used being noticed; if a precipitate forms, the liquid must be again filtered and an aliquot part of the filtrate collected, 3—4 drops of hydrochloric acid added, and then twice the volume of 95 per cent. alcohol. After a few hours, the glycogen is collected on a filter, washed first with 60 per cent., then with 95 per cent. alcohol, and finally with ether. The filter is dried at 105° and weighed; the glycogen is now extracted with boiling water and after drying at 115°, the filter is reweighed. Tables are given showing the amount of glycogen in the various parts of the carcase of the horse.

L. DE K.

New Method for the Estimation of Acetic Acid in Vinegar. By DURIEU (*J. Pharm.*, 1900, [vi], 11, 22—23).—As the ordinary methods for the estimation of acetic acid in vinegar are not applicable when the liquid is highly coloured, the following method has been devised. 6 c.c. of a solution of sodium hydrogen carbonate (1/20) are introduced into a graduated tube, then 6 c.c. of alcohol (95°) are carefully added, care being taken that the liquids do not mix. 1 c.c. of a 7 per cent. solution of acetic acid is next added, the tube closed with the thumb, shaken and inverted over water, and the volume of gas evolved is noted. A similar experiment is made with the vinegar, and from the volume of gas evolved and the data obtained in the first experiment, the percentage of acetic acid is readily calculated. It is, of course, essential that the vinegar should contain no other acid than acetic acid.

H. R. LE S.

Estimation of Oxalic Acid in Acid Beet Leaves. By KARL BÜLOW (*Chem. Centr.*, 1900, i, 374; from *J. Landw.*, 47, 359—367).—This is a slight modification of Schloesing's process. 5 grams of the leaves are rubbed in a mortar with 5 c.c. of 22 per cent. sulphuric acid and 5—6 grams of pumice powder added so as to form a dry mass. The mixture is then placed in an open glass tube plugged at the lower end with cotton wool and extracted with ether. The ethereal solution is put into a beaker containing 50 c.c. of water and heated on the top of a water-oven until the ether has evaporated. The aqueous liquid is filtered, neutralised with ammonia, again acidified with acetic acid, and precipitated with calcium acetate; the precipitated calcium oxalate is freed from sulphate by repeated solution in hydrochloric acid and reprecipitation with ammonia.

L. DE K.

Action of Iodine Solution and Alkaline Permanganate on Uric Acid. By ADOLF JOLLES (*Zeit. physiol. Chem.*, 1900, 29, 193—204).—It has been stated by Kreidl (*Abstr.*, 1893, ii, 558)

that in alkaline solution uric acid can be estimated by adding an excess of iodine solution, and after the lapse of $\frac{3}{4}$ hour, acidifying the mixture and titrating the unabsorbed iodine, but that a shorter time results in the consumption of more iodine. The author shows that the anomaly is due to the fact that uric acid slowly decomposes potassium iodide with liberation of iodine. By allowing the action to proceed for exactly $\frac{3}{4}$ hour, the amount of iodine consumed is proportional to that of uric acid present, but with a prolongation of the time the amount increases, although Kreidl's ratio of 3.5 atoms of iodine to 1 mol. of uric acid was not even approximately attained. The method therefore seems useless for practical purposes. Experiments with Hübl's reagent gave a similar result, but potassium iodide being absent the anomaly noticed above does not occur.

The author confirms the accuracy of Hopkins's method of titrating uric acid with permanganate in acid solutions, but experiments on the action of permanganate in alkaline solutions show that the amount reduced depends (1) on the quantity of permanganate added, and (2) on the length of the boiling, and is, moreover, largely increased by the presence of ammonium carbonate, which, according to Folin's method, is employed for washing the ammonium urate precipitated from urine by ammonium acetate.

M. J. S.

Hübl's Iodine Method for Oil Analysis. By AUGUSTUS H. GILL and WALTER O. ADAMS (*J. Amer. Chem. Soc.*, 1900, 22, 12—14).—A process is described which is quite as easy of execution as the original Hübl method, and has the advantage of giving the true iodine figure.

30 grams of mercuric iodide and 25 grams of iodine are dissolved in a litre of pure absolute methyl alcohol and 30 c.c. of this solution are then used in the test. The results differ slightly from those of Hübl. The average iodine absorption of pure oleic acid is given as 90.2, that of olive oil as 79, of cotton seed oil as 91.9, of prime lard as 71.8, and of neat's-foot oil as 55.8 per cent.

L. DE K.

The Determination of the Iodine Value. By JULIUS LEWKOWITSCH (*Analyst*, 1899, 24, 257—259).—Hübl's process for the iodine value of oils has been modified by Wijs (*Abstr.*, 1898, ii, 412), who recommends using a solution of iodine monochloride in pure glacial acetic acid instead of a solution of iodine and mercuric chloride in alcohol; this solution is infinitely superior to the alcoholic solution as regards stability.

The author now states that both solutions, if carefully applied, give identical results.

L. DE K.

The Meaning of the Acetyl Value in Fat Analysis. By JULIUS LEWKOWITSCH (*Analyst*, 1899, 24, 319—330. Compare *Abstr.*, 1898, ii, 316).—The author has ascertained the acetyl number of many fats, waxes, and oils, and has tabulated the results.

The acetyl value indicates the presence of hydroxy-acids, free

alcohols, oxidised fatty acids, and unknown acids, to which must be added mono- or di-glycerides and rancid fats. L. DE K.

Rapidity of Saponification of Some Fats. By HANS KREIS and OTTO WOLF (*Chem. Centr.*, 1900, i, 376; from *Zeit. Unters. Nahr.-Genussm.*, 2, 914—915).—By means of Henriques' cold saponification process, the progress of the reaction being investigated at fixed intervals, it has been proved that there is no appreciable difference in the rate of saponification of butter and margarine. The saponification of beef-tallow proceeds the most quickly. Olive oil, during the first hour, is saponified more slowly, but afterwards more rapidly, than butter. L. DE K.

Analysis of Milk. By L. GALLIEN (*J. Pharm.*, 1900, [vi], 11, 61—64).—In the estimation of lactose in milk by the ordinary polarimetric method, quite an appreciable error is introduced by the fact that the milk serum examined is regarded as occupying the same volume as the original milk, and no account is taken of the volume occupied by the casein, albumin, and butter fat. A simple method of analysis, and a formula and a set of tables are given, by the use of which the true percentage of lactose in milk may be determined. H. R. LE S.

Modification of Duclaux's Method for Estimating Total Solids and Fat in Milk. By UMBERTO MORINI (*Chem. Centr.*, 1900, i, 69; from *Staz. sper. agrar. ital.*, 32, 517).—Duclaux's method (*Le lait*, 1887, 20, 176), and *Principes de lacterie*, 111, 258) is especially suitable for butters containing much water and proteids. The author prefers, however, to work with 20 grams of substance, and to extract the fat with Förster's apparatus (*Zeit. anal. Chem.*, 1888, 27, 30). M. J. S.

Estimation of Fat in Milk. By R. LÉZÉ (*Chem. Centr.*, 1900, i, 69; from *Ann. chim. anal. appl.*, 4, 371).—8 grams of caustic potash are dissolved in 10 c.c. of pure ammonia, 55 c.c. of ethyl alcohol, and 15 c.c. of amyl alcohol are added, and the mixture made up to 100 c.c. with ammonia. 36 c.c. of the milk and 10 c.c. of the above mixture are placed in a 50—60 c.c. flask which has a narrow neck graduated in tenths of a c.c., and after heating for 10 minutes in boiling water, the clear fat is driven up into the neck by adding water, and its volume read off at 40°. As milk fat has an average density of 0.9 at 40°, one-fourth of the volume gives grams of fat per litre of milk; the results agree well with those obtained by extraction. M. J. S.

Changes in the Constants of Butter Fat under the Influence of Feeding. By A. RUFFIN (*Chem. Centr.*, 1900, i, 69—70; from *Ann. chim. anal. appl.*, 4, 383).—The author finds numerous analytical anomalies in Baumbert and Falke's work (*Abstr.*, 1899, ii, 689). His own observations on the influence of feeding with various kinds of oil-cake on the composition of the butter, originally published in 1890, gave the following numbers:

	Refraction.	Saponification number.	Volatile fatty acids.
Ordinary fodder, hay, lucerne...	30 —33	224 —232	27·6—34·9
Cotton-seed cake	28·5—30	222 —228	26·4—29
The same, with ordinary fodder	29·5—30	221 —229	28·4—30
Earthnut cake	30 —31	225 —228	26·9—29
The same, with ordinary fodder	28 —30	221·9—229	28 —32
Cocconut oilcake	32 —33	231 —240	25·5—31
			M. J. S.

Testing Margarine and Butter for Sesamé Oil. By HERMANN BREMER (*Chem. Centr.*, 1900, i, 374—375; from *Pharm. Zeit.*, 45, 7—8).—A controversy with Soltsien on the value of the furfuraldehyde test for sesamé oil. If the reagents are pure, the process is not likely to cause error. L. DE K.

Testing Margarine and Butter for Sesamé Oil. By PAUL SOLTSIEN (*Chem. Centr.*, 1900, i, 375; from *Pharm. Zeit.*, 55, 25—26).—A reply to Bremer (preceding abstract). The author states that the colour produced by furfuraldehyde and hydrochloric acid is not always due to sesamé oil. L. DE K.

Halphen's Reaction and its Application to the Estimation of Cotton-seed Oil. By CASIMIR STRYZYROWSKI (*Chem. Centr.*, 1900, i, 373; from *Pharm. Post*, 32, 736—738).—The author confirms the trustworthiness of Halphen's test; it may be used also for the estimation of cotton-seed oil in other oils. 2 c.c. of the fat and 2 c.c. of the reagent are heated on a boiling water-bath for 45 minutes, the residue is diluted with carbon disulphide to 6 c.c., and the depth of the red coloration compared with that produced by a mixture of known composition under the same conditions. If, however, the added cotton-seed oil has been heated to 200°, the estimation is no longer trustworthy.

The active principle which causes the reaction is not removed from the oil by animal charcoal. If cotton-seed oil is treated with Bechi's reagent until this no longer gives a reaction, and filtered, the filtrate does not give the Halphen test. L. DE K.

Analysis of Fish Oils [Thranen]. By HENRIK BULL (*Chem. Zeit.*, 1899, 23, 996).—Some kilograms of fatty acids derived from fish oil are distilled in a current of superheated steam at 200°, and then passed through a series of receivers, the temperatures of which are 160°, 140°, 120°, and 100° respectively. Four groups of fatty acids are thus obtained, analytical data of which are communicated.

Four groups of acids may also be obtained as follows. The oil is saponified with solution of potassium hydroxide in absolute alcohol, and the potassium soap crystallised as far as possible. After recovering the fatty acids from the mother liquor, they are treated with alcoholic soda, and further crystals of sodium soap obtained. The mother liquor is now evaporated to dryness, and the residue treated with anhydrous ether, to obtain the sodium salts readily soluble in that solvent; on agitating the ether with water, some remain in solution, whilst others pass into the aqueous layer. L. DE K.

Analysis of Soap. By AL. A. SHUKOFF and K. T. NOGIN (*Chem. Centr.*, 1899, ii, 1140—1141; from *Chem. Rev. Fett.-Harz-Ind.*, 6, 205—207).—4—5 grams of the sample, taken from the centre by means of a cork borer, are quickly weighed in a beaker and gently warmed with 30 c.c. of normal sulphuric acid until the fatty acids are perfectly liquefied. When cold, the aqueous liquid is filtered, and the fatty acids again melted, and treated with 30 c.c. of water, which is afterwards poured through the same filter. The cake is washed thrice with cold water, and then dissolved in alcohol; the solution is evaporated in a weighed dish, and the residue dried for 20 hours at 95—100°. The molecular weight of the acids is then found by dissolving them in 10 c.c. of alcohol, and titrating with normal sodium hydroxide. The acid filtrate is also titrated, and the loss in sulphuric acid represents the total alkali; the difference between this and the alkali required by the fatty acids represents free alkali.

A direct estimation of the water in soap is not advisable.

L. DE K.

Water-softening (or so-called "scouring") Power of Soaps. By FREDERIC W. RICHARDSON and ADOLF JAFFÉ (*J. Soc. Chem. Ind.*, 1899, 18, 998—1001).—2.5 grams of the soap are dissolved in 40 c.c. of diluted methylated spirit (1 proof strength), and this solution is diluted to 250 c.c. The liquid is then added from a burette to 100 c.c. of Clark's standard hardness solution (16 grains of calcium carbonate per gallon) until the lather is permanent for one minute. The authors prefer making the stock solution 10 times the usual strength, and then diluting it before use. An average curd soap gives a reading of 28 c.c.; the foam value or water-softening power of the sample is then expressed by $x = 2800/A$, where A represents the number of c.c. of soap solution required to give the requisite foam. Results are communicated in a table, from which it appears that there is no strict relation between the total fatty acids in soaps and their scouring power.

L. DE K.

Estimation of Formaldehyde. By the VEREIN FÜR CHEMISCHE INDUSTRIE IN MAINZ (*Zeit. anal. Chem.*, 1900, 39, 60—63).—The following procedure is adopted for Romijn's titration by iodine (*Abstr.*, 1897, ii, 166): 30 c.c. of normal sodium hydroxide and 5 c.c. of the dilute formaldehyde solution are placed in a well-stoppered bottle, and $N/5$ iodine (40—70 c.c.) added until the liquid becomes yellow. After shaking for about a minute, the liquid is acidified with 40 c.c. of normal acid, and the residual iodine titrated with $N/10$ thiosulphate. A blank titration should be made.

The estimation by the reaction with an alkali hydroxide, $2\text{HCHO} + \text{NaOH} = \text{HCO}_2\text{Na} + \text{MeOH}$, is recommended in the following form: 50 c.c. of normal sodium hydroxide are placed in a strong, narrow-necked 250 c.c. flask and 5 c.c. of the formaldehyde solution, added. The flask is closed with a rubber stopper and completely immersed in water which is kept for 7 hours at 85—87°; after cooling, the excess of alkali is titrated. Several estimations should be made simultaneously, and only those accepted in which the mixture remains colourless; a yellow coloration would indicate secondary reactions.

The same reaction may be employed for estimating methyl alcohol in formalin, 100 grams of which are cohobated for 2 hours with 700 grams of 2*N* sodium hydroxide, using a condenser cooled by ice to avoid loss of methyl alcohol. The methyl alcohol is then distilled off and its amount ascertained from the density of the distillate. From the total quantity found, that resulting from the formaldehyde present is then deducted. The results are of only approximate accuracy, since secondary reactions cannot be wholly avoided.

Another method depends on oxidation with a standard potassium dichromate solution acidified with sulphuric acid. The mixture (0.5 gram of formaldehyde, 2.952 grams of dichromate, 3.2 grams of sulphuric acid, and 100 c.c. of water) is heated in a sealed tube for 6 hours at 140°, and the unreduced chromate then estimated with potassium iodide and thiosulphate. The methyl alcohol, formaldehyde and formic acid present are all oxidised to carbon dioxide and water, and after deducting the amount of chromate reduced by the two latter, the remainder is calculated into methyl alcohol.

M. J. S.

Estimation of Chloral Alcoholate. By FRANZ SCHMIDINGER (*Monatsh.*, 1900, 21, 36—38).—The author shows that Zeisel's method of estimating ethoxy-groups by treatment with hydrogen iodide, and determining the ethyl iodide formed, will also serve to determine the amount of alcoholate present in impure specimens of chloral hydrate.

R. H. P.

[Detection of] Furfuraldehyde in Beer. By C. HEIM (*Bied. Centr.*, 1900, 29, 71; from *Zeit. ges. Brauwesen*, 21, 155—158).—Test paper for furfuraldehyde is prepared by soaking thick filter-paper in a solution of freshly-distilled aniline (9 parts) in glacial acetic acid (6 parts). The solution must be protected from air and light, and must be frequently renewed. By means of this paper, 1 part of furfuraldehyde can be detected in 1,000,000 parts of beer; 1 part in 100,000 is sufficient to affect the taste of beer.

Whilst furfuraldehyde could be detected in English and Belgian beer, Munich beer was found to be free from it. The process of brewing employed in Munich renders the production of furfuraldehyde impossible. The greater the amount of acid in beer, the more readily is furfuraldehyde detected.

N. H. J. M.

Estimation of Vanillin. By PAUL WELMANS (*Zeit. anal. Chem.*, 1900, 39, 58—60; from *Pharm. Zeit.*, 1898, 634).—A gram of the substance is dissolved in 25 c.c. of alcohol and shaken in a stoppered bottle with 25 c.c. of *N*/2 alcoholic potash until completely dissolved. The excess of potash is then titrated with *N*/2 hydrochloric acid and phenolphthalein. The exact value of the 25 c.c. of potash is estimated under similar conditions, and the difference, multiplied by 0.076, gives the amount of vanillin. Of vanillin sugar, 10 grams are dissolved in 50 c.c. of water, the alcoholic potash is added, and the operation carried on as above. The presence of vanillic acid confuses the end-point. To detect acetanilide, an adulterant frequently employed, 1 gram of vanillin, may be dissolved in 10 c.c. of normal potash; acetanilide remains undissolved unless heat is applied.

M. J. S.

Estimation of Glycyrrhizin in Liquorice Extract. By B. HAFNER (*Chem. Centr.*, 1900, i, 68; from *Zeit. Oesterr. Apoth. V.*, 37, 542).—Ten grams of the coarsely powdered extract are warmed for several hours with 200 c.c. of 95 per cent. alcohol and 25 c.c. of *N* sulphuric acid, and the insoluble matter is washed with alcohol. The filtrate, made feebly alkaline with ammonia, and diluted with an equal volume of water, is evaporated, made up to 100 c.c. with water and a few drops of ammonia, filtered, and precipitated with dilute sulphuric acid. The precipitated glycyrrhizin is washed with 2—3 per cent. sulphuric acid, dried in the desiccator, and then extracted with acetone on the water-bath. After adding water and barium carbonate, the acetone is expelled on the water-bath, the residue digested with 200 c.c. of hot water, and the filtered solution evaporated, dried at 100°, and weighed. The barium glycyrrhizate thus obtained should contain 18.76 per cent. of barium, which may be confirmed by evaporating with sulphuric acid, and igniting. M. J. S.

The Florence Reaction. By HEINRICH STRUVE (*Zeit. anal. Chem.*, 1900, 39, 1—8).—The iodine reaction proposed in 1895 by Florence for the medico-legal detection of stains produced by spermatie fluid has no special character, but is produced by all substances of the choline group, such as betaine, neurine, muscarine, amanitine, sinalbin, sinigrin, &c. The mode of using the reagent must be varied somewhat according to the substance under examination, but the general method is as follows. A few drops of an aqueous solution or extract of the substance are dried at 100° on an object glass, then moistened with a solution containing 6 parts of potassium iodide and 2 parts of iodine in 100 parts of water, and, after the superposition of a cover-glass, observed with a magnifying power of 70. After a few moments, peculiar, brownish-black crystals are seen. Should no result be obtained, the experiment is repeated with addition of some dilute hydrochloric acid. In other cases, special methods are necessary for obtaining the reaction. The reaction has been observed with nasal mucus, phlegm, blood, ethereal extract of yolk of egg evaporated with hydrochloric acid for the decomposition of the lecithin, and with many substances of vegetable origin, such as extracts of black and white pepper, *Penicillium glaucum*, *Secale cornutum*, extracts of leaves, flowers, and fruits, and even with wine. From coffee berries, and the leaves of *Erythroxylon coca*, however, no crystals could be obtained. Nothing is known as to the composition of the brown crystals, as their existence is extremely ephemeral. Their growth can be followed under the microscope, but as soon as they reach a maximum size they begin to liquefy and disappear. They can be reproduced as often as desired by redrying the preparation and treating afresh with the reagent. These facts indicate the great stability and wide distribution of substances of the choline group. M. J. S.

General and Physical Chemistry.

Chemical Action of Light contrasted with that of the Silent Electric Discharge. By MARCELLIN P. E. BEETHÉLOT (*Ann. Chim. Phys.*, 1900, [vii], 19, 150—154. Compare Abstr., 1897, i, 330; 1898, ii, 393; 1899, i, 657; ii, 1, 197; and this vol., i, 3).—Benzene remains unaltered when exposed to bright sunlight for several months in sealed tubes containing hydrogen or argon, although it combines with oxygen, yielding resinous products; if placed over mercury, a brown sediment, which is derived from the thiophen present in the hydrocarbon, forms at the junction of the liquids. Carbon disulphide, under these conditions, undergoes a partial decomposition, and the sides of the containing vessel become coated with a brown deposit; when exposed to diffused light, it remains unaltered, and does not react with hydrogen or argon.

When a mixture of argon and gaseous carbon disulphide is submitted to the action of the silent electric discharge for three months in diffused light, the electrodes being maintained at a difference of potential of 200 volts, the former gas remains unaltered, whilst 60 per cent. of the latter is converted into yellow, resinous products. G. T. M.

Influence of Pressure on the Rotation of Solutions of Sucrose. By L. H. SIERTSEMA (*Arch. néerland sci. exp. nat.*, 1899, [ii], 3, 79—87).—The rotations of solutions of sucrose at various pressures were determined, plates of quartz being used to partially compensate the rotation of the solution and render small variations more evident. The variation of rotation for 100 atmospheres pressure are then calculated, and corrections introduced for the variation of rotation of the quartz, after which the variation of rotation per centimetre is calculated. This is dependent on the variation of concentration and of specific rotation, and, of these, the first is calculable from Amagat's compressibility values. The values so obtained are as follows, where c is concentration, k the internal pressure according to Tammann, $\Delta c/c$ the concentration change, $\Delta\beta/\beta$ the change of rotation per cm., and $\Delta\gamma/\gamma$ the change of specific rotation $= \Delta\beta/\beta - \Delta c/c$.

c .	k .	$\Delta c/c$.	$\Delta\beta/\beta$.	$\Delta\gamma/\gamma$.
9.48	238	0.00449	0.00268	-0.00181
18.70	465	0.00418	0.00252	-0.00166
27.84	669	0.00398	0.00270	-0.00128

If, as Tammann supposes, the variations of specific rotation with concentration are due to variations of internal pressure, then, by the use of the above values for $\Delta\gamma/\gamma$, the internal pressure of the solutions is calculable, but the values do not agree with those obtained by Tammann by other methods; the author, however, makes no attempt to estimate the undoubtedly great probable error in the above values of $\Delta\gamma/\gamma$. In many cases, the variations of rotation consequent on the addition of an inactive salt are completely explicable on Tammann's hypothesis, but, as agreement is not found in all cases, the author

considers that Tammann's theory is insufficient to explain the changes of rotation (compare Tammann, *Abstr.*, 1896, ii, 13, 289, and previous abstracts).
L. M. J.

Spectrum of Bromine. By JOSEF M. EDER and EDUARD VALENTA (*Chem. Centr.*, 1900, i, 453; from *Denkschr. math.-nat. Klasse K. Akad. Wiss. Wien.*, 1—8).—The line spectrum is most distinct with a pressure of 8—10 mm.; when the pressure is lowered, the spectrum becomes faint, and when the pressure is raised, there is marked broadening of the lines. Besides this line spectrum, a continuous spectrum was observed in the violet also at low pressures. A third spectrum was observed at a pressure of 45 mm., corresponding probably with the normal band spectrum of other elements. The authors consider the line spectrum especially characteristic.
J. C. P.

Fluorescence of Metallic Compounds under the Influence of Röntgen and Becquerel Rays. By PAUL BARY (*Compt. rend.*, 1900, 130, 776—778).—The author has examined a large number of salts under the influence of the Röntgen rays; those which become fluorescent belong, with the exception of uranium, to the families of the alkalis and alkaline earths; of these salts, the halogen compounds appear to always become fluorescent, but many other salts may be inactive. Similar results were obtained by exposure to the radiations from a radio-active metal supplied by Curie (compare this vol., ii, 82, 126), and these are also probably radiations of very short wave-length. The permanent luminescence of some barium salts may be due to the action of the Becquerel rays on the barium salt itself, or to the fluorescence of contained radium.
L. M. J.

Nature of Electrocapillary Phenomena. I. Their Relation to the Potential Differences between Solutions. By S. W. J. SMITH (*Phil. Trans.*, 1899, A, 193, 47—87; also *Zeit. physikal. Chem.*, 1900, 32, 433—476).—The Lippmann-Helmholtz theory of the capillary electrometer contains two assumptions. According to the first, the variation of the potential difference at the capillary electrode of an electrometer is the same as that of the applied E.M.F. To test this, the effect of depolarisation has been investigated and determined. The second assumption, that electrocapillary phenomena depend simply on the variation of the electrostatic surface energy, leads to difficulties, for (1) the form of the electrocapillary curve is remarkably dependent on the nature and concentration of the electrolyte; (2) if it be assumed that the potential difference between the solution and the capillary electrode is zero when the surface tension is a maximum, large potential differences must exist between certain solutions.

According to the Nernst-Planck theory, the potential difference between equally concentrated solutions of potassium chloride and potassium iodide is negligible; with this conclusion, the first assumption of the Lippmann-Helmholtz theory is in accord. Combination of the two hypotheses shows that the surface tension of mercury (for a certain range of potential differences) in two solutions is the same for a given potential difference between the mercury and the respective solutions, if they are equally concentrated and possess the same

cation; it is further shown that it is immaterial whether the cation be K, Na, or H.

The work described in the paper points to the first assumption of the Lippmann-Helmholtz theory being correct, and the second incorrect; the electrocapillary curves are never completely free from influences other than electrostatic. J. C. P.

Potential Differences with Manganese Dioxide Electrodes. By OLIN F. TOWER (*Zeit. physikal. Chem.*, 1900, 32, 566—577).—Experiments are recorded supplementing the author's previous work (Abstr., 1896, ii, 142) and that of Smith (Abstr., 1897, ii, 5). The

concentration of the H^+ ions in a solution at a manganese dioxide electrode is found to have about four times as much influence on the

E.M.F. as the concentration of the Mn^{++} ions. A number of experiments have been made to determine by this method the dissociation of numerous dibasic organic acids, but the author concludes that the method is not exact. The differences between the results actually obtained and those theoretically deducted cannot be satisfactorily explained. J. C. P.

Dielectric Constant of Hydrogen Peroxide. By HARRY T. CALVERT (*Ann. Phys.*, 1900, [iv], 1, 483—485).—The dielectric constant of a 45.9 per cent. solution of hydrogen peroxide, as determined by one of Drude's methods (Abstr., 1897, ii, 438), has the value 84.7 at 18°. If the density of pure hydrogen peroxide is taken as 1.5 (see Abstr., 1895, ii, 346), the application of the mixture rule gives 92.8 as the dielectric constant of pure hydrogen peroxide. The fact that this compound has a considerably greater dielectric constant than water, and that it shows no anomalous electrical absorption, agrees with the views of Brühl, who supposes hydrogen peroxide to contain no hydroxyl groups, and has predicted for it a large dielectric constant on account of free valency (Abstr., 1896, ii, 162; 1897, ii, 198). J. C. P.

Effect of Suspended Particles on Conductivity. By MAX. OKER-BLOM (*Pflüger Arch.*, 1900, 79, 510—533. See this vol., ii, 356).

Electrolytic Conductivity and Internal Friction in Saline Solutions. By P. MASSOULIER (*Compt. rend.*, 1900, 130, 773—775).—Although electrolytic conductivity and internal friction have been found to vary in the same sense, yet no quantitative proportionality has been found, and in almost all the experiments hitherto made the variations of friction have been very slight. The author therefore measured the conductivity and internal frictions of solutions of copper sulphate in water and aqueous glycerol in which great variations of internal friction are obtainable. Determinations were made at 0° and at 15° with the following results for the latter temperature.

Glycerol.	Resistance.	Internal friction.
0	100	100
1/48	104	105
1/24	111	114
1/12	126	132
1/6	161	160
1/3	289	298

The agreement is also stated to be very satisfactory for solutions of the halogen compounds of sodium and potassium. L. M. J.

Conductivity of some Sodium Derivatives of Nitroparaffins.

By OTTOKAR ŠULC (*Zeit. physikal. Chem.*, 1900, 32, 625—629).—Nitromethane, nitroethane, nitropropane, and nitroisopropane are found to be compounds of acidic character, for their sodium derivatives in aqueous solution are good conductors. The following results were obtained:

	μ_{1000}	μ_{25}
$\text{CH}_3\text{Na}\cdot\text{NO}_2$	108.6	84.4
$\text{CH}_3\cdot\text{CHNa}\cdot\text{NO}_2$	81.9	69.0
$\text{CH}_3\cdot\text{CH}_2\cdot\text{CHNa}\cdot\text{NO}_2$	80.8	67.8
$\text{C}(\text{CH}_3)_2\text{Na}\cdot\text{NO}_2$	93.1	65.0

The numbers for the last compound are somewhat uncertain.

J. C. P.

Finding the Ionisation of Complex Solutions of given Concentration, and the Converse Problem. By JAMES G. MACGREGOR (*Chem. Centr.*, 1900, i, 390—391; from *Trans. Nova Scot. Inst. Sci.*, 10, 67—78).—Two electrolytes in mixed solution and containing a common ion may be supposed to occupy distinct portions or regions of the solution: on this supposition, the equations are deduced:—(1) $a_1/V_1 = a_2/V_2$; (2) $N_1V_1 + N_2V_2 = 1$; (3) $a_1/V_1 = f_1(V_1)$; (4) $a_2/V_2 = f_2(V_2)$, where a_1 and a_2 are the ionisation coefficients of the two electrolytes, N_1 and N_2 their concentrations, V_1 and V_2 their regional dilutions in litres per gram equivalent. The functions f_1 and f_2 are very complex, and the equations cannot be solved algebraically. The present paper shows how, by a graphic method, the ionisation in a mixed solution may be calculated from the concentrations, and, conversely, how the composition of the solution may be calculated when the degree of dissociation is given. This method of calculation is compared with those of Schrader and Kay.

J. C. P.

Conductivity, Specific Gravity, and Surface Tension of Aqueous Solutions containing Potassium Chloride and Sulphate. By JAMES BARNES (*Chem. Centr.*, 1900, i, 391; from *Trans. Nova Scot. Inst. Sci.*, 10, 49—66).—The methods given by MacGregor for calculating the conductivity (compare previous abstract) and other properties of a mixed solution of two electrolytes have been tested by the author. It is found that the values for the conductivity, sp. gr., and surface tension of mixed solutions of the above-named salts agree within the limits of experimental error with those calculated from the properties of the separate solutions.

J. C. P.

Electrolytic Decomposition Point of Aqueous Solutions.

By ALBERT GOCKEL (*Zeit. physikal. Chem.*, 1900, 32, 607—624).—When a gradually increasing E.M.F. is applied to the electrodes of an electrolytic cell, there is, according to Le Blanc (*Abstr.*, 1891, 1405; 1894, ii, 4), a definite point at which decomposition of the electrolyte begins, as evidenced by a sudden increase of the current passing through the circuit. The author's experiments, made with different

electrolytes and under varying conditions, show that in the curves connecting the applied E.M.F. with the current passing through the cell there is absolutely no distinct break. He regards the so-called E.M.F. of decomposition as in no way characteristic of the particular ion involved, but supposes it to depend on the conditions, and to be the point at which the electrolysis first becomes evident; possibly it is the point at which the products of the electrolysis begin to react with the solvent, the dissolved gases, or the electrode. J. C. P.

Electrolysis of Fused Salts. By RICHARD LORENZ [with A. HELFENSTEIN] (*Zeit. anorg. Chem.*, 1900, 23, 97—110. Compare Abstr., 1900, ii, 61).—An investigation of this subject from the point of view of Faraday's law shows the great importance of keeping the electrodes apart, and indicates the conditions under which trustworthy values of the E.M.F. of polarisation and its temperature coefficient can be obtained (compare Abstr., 1899, ii, 267, 724). The current yield in the electrolysis of fused lead chloride diminishes rapidly as the temperature rises, having the value zero at the boiling point of the salt; this rapid fall is due, not only to the accelerated diffusion of the lead and chlorine vapour in the fused mass, but also to the increasing vapour tension of the lead. At constant temperature, the yield increases with the current density and with the distance between the electrodes; it diminishes as the depth of immersion of the anode increases, whilst it is almost quantitative when the anode is quite separated from the cathode. From the above results, it follows that a tube with the electrodes close together is an unsuitable and uneconomical form of apparatus for the electrolysis of fused salts; in such an arrangement, the longer the experiment lasts the poorer is the percentage yield, owing to the more complete diffusion of the products. J. C. P.

Molecular Susceptibility of the Salts of the Rare Earths. By H. DU BOIS and OTTO LIEBKNECHT (*Ber.*, 1900, 33, 975—977. Compare this vol., ii, 127).—In reply to the criticism of Meyer (this vol., ii, 186), the authors point out that the agreement between the numbers obtained by them and those obtained by Meyer is satisfactory in view of the fact that different methods were employed. It is probable that the observed paramagnetism of the yttrium compounds is in reality due to the presence of erbium compounds. A. H.

Thermal Conductivities of Mixtures and of their Constituents. By CHARLES H. LEES (*Phil. Mag.*, 1900, [v], 49, 286—293).—Three expressions have been used to connect the conductivity of a mixture of two components with the separate conductivities. Of these, one is an expression for the conductivity itself, the second for the inverse, or the resistivity, and the third for the logarithm of the conductivity, each being a simple mixture formula; these formulæ correspond with various modes of disposition of the components in the mixture. In order to test the relative values of the three expressions, the author has compared the calculated values with the found values in the case of the following mixtures, tin-bismuth, water-ethyl alcohol, water-glycerol, water-acetic acid, water-methyl alcohol, glycerol-ethyl

alcohol, vaselin-marble, lard-zinc sulphate; it was found that the conductivity formula is the most, and the logarithmic formula the least, unsatisfactory. The latter gives in general values which are too high, the resistivity formula yields values too low. An empirical formula, $k^n = (p_1 k_1^n + p_2 k_2^n) / (p_1 + p_2)$, gives values in fair accord with the determinations, where n is an arbitrary constant.

L. M. J.

Bunsen's Ice Calorimeter. By J. W. MELLOR (*J. Physical Chem.*, 1900, 4, 135—136).—To fill the ice calorimeter with water free from air, the author gives the following method. The calorimeter about one-third full of distilled water is connected with a tube dipping under water contained in a distilling flask with condenser connected to a pump. The calorimeter and flask are heated with the pump in action until the water gives the 'click' of air-free water. The calorimeter is then allowed to cool, and fills with the air-free water.

L. M. J.

Heat of Combustion of very Volatile Liquids. By MARCELLIN P. E. BERTHELOT and MARCEL DELÉPINE (*Compt. rend.*, 1900, 130, 1045—1049).—The following values were obtained by burning the substances in a calorimetric bomb containing oxygen under a pressure of 25 atmospheres:

	Molecular heat of combustion in calories		Heat of formation.
	at constant volume.	at constant pressure.	
Acetaldehyde	278·86	279·16	47·45
Methylal	461·9	462·5	96·4
Methyl formate ...	233·2	233·2	93·4
Ethyl formate ...	391·4	391·7	98·2
Propaldehyde	433·8	434·35	55·55
Acetone	426·3	426·9	63·0

The calculated values for formation from the elements, carbon (diamond), hydrogen (gas), and oxygen (gas) are also given.

H. R. LE S.

Heat of Vaporisation of Nitriles and other Organic Compounds. By WLADIMIR LUGININ (*Chem. Centr.*, 1900, i, 451; from *Arch. sci. phys. nat. Genève*, 9, 5—26).—The constants previously recorded (*Abstr.*, 1899, ii, 354) are supplemented by the following:

Compound.	Specific heat.		Heat of vaporisation.	$\frac{MS}{T}$
	Limits.	Value.		
Propionitrile ...	19·2—95·1°	0·5378	134·40	19·97
Benzonitrile ...	21 —186	0·4412	87·71	19·47
Acetophenone...	20 —196	0·4744	77·24	19·44
m-Cresol	21 —197	0·5534	100·46	22·86
Acetic acid	22·5—111·4	0·5323	89·79	13·74

In the above table, M is the molecular weight, S the heat of vaporisation, and T the boiling point on the absolute scale. The first three compounds give a value for the expression MS/T approximately = 20, and are therefore not polymerised, although Ramsay and Shields found that propionitrile molecules polymerised. The high value obtained for m-cresol points to polymerisation on the part of

this compound. The author finds for the heat of vaporisation of acetic acid a value considerably greater than that (84.9) obtained by Berthelot and Ogier. If 80 be added to the value of S for acetic acid, corresponding with the change from double to single molecules, the expression $MS/T = 26.28$.

J. C. P.

Freezing Point of Aqueous Solutions of Non-electrolytes. By ELMER H. LOOMIS (*Zeit. physikal. Chem.*, 1900, 32, 578—606).—The author considers that his earlier method of determining the freezing point of dilute solutions (*Ann. Phys. Chem.*, 1893, [ii], 51, 500) satisfies the condition that the convergence temperature of the apparatus agrees with the true observed freezing point. In the earlier experiments, the thermometer, when not in use, was kept completely surrounded with ice; this procedure is now regarded as an error, as only the lower part of the thermometer should be so preserved.

The author finds the value of van't Hoff's constant in dilute solutions of propyl alcohol, butyl alcohol, amyl alcohol, glycerol, acetone, dextrose, sucrose, mannitol and aniline to be 1.86; abnormal values are found for methyl alcohol (1.82), ethyl alcohol (1.84), and ether (1.50).

J. C. P.

Freezing Point Curve for Water containing Hydrogen Chloride and Phenol. By J. A. EMERY and FRANK K. CAMERON (*J. Physical Chem.*, 1900, 4, 130—134).—The freezing point of a saturated aqueous solution of phenol was found to be -1.179° . By the addition of hydrogen chloride, a linear freezing point curve is obtained for dilute solutions, the molecular depression being 3.648, whilst in pure water it was found by Jones to be 3.630. It follows that the effects of the two compounds in producing cryoscopic depression are purely additive.

L. M. J.

Minimum Volume of Liquids. By DANIEL BERTHELOT (*Compt. rend.*, 1900, 130, 713—716).—If a curve be drawn with the values of the mean of the densities of liquid and saturated vapour as ordinates, and with temperatures as abscissæ, the result is a straight line, and since at the absolute zero the density of the saturated vapour may be regarded as zero, it follows that by the prolongation of this line the value of the density of the liquid at absolute zero is obtained and hence also the volume which may be regarded as the minimum volume. The minimum volumes so obtained are given for nitrogen, oxygen, chlorine, bromine, carbon dioxide, sulphur dioxide, ethylene, carbon tetrachloride, stannic chloride, ethyl ether, benzene, fluorobenzene, chlorobenzene, bromobenzene, iodobenzene, pentane, isopentane, hexane, and heptane. The examination of these values is deferred, but the author states that the chief point of interest is that if the volumes are measured from these minima and a different zero of temperature be taken for each compound, then the discrepancies from the law of corresponding states disappear (see also Guldberg, this vol., ii, 264; Meyer, this vol., ii, 263).

L. M. J.

Dissociation of Dissolved Substances. I. By AD. VANDENBERGHE (*Chem. Centr.*, 1900, i, 391; from *Bull. Acad. med. Belg.*, [iii], 37, 657—679).—Freezing point and boiling point methods give

values for the molecular weight which are often too low on account of dissociation, or too high on account of association. The author, in determining the influence of temperature and concentration on these phenomena, uses chemically similar solvents, namely, methyl, ethyl, and propyl alcohols. The molecular weights of picric acid, naphthalene and carbamide have been determined in these solvents by a boiling point method. The extent of dissociation increases as the boiling point of the solvent rises, and the extent of association increases with the concentration of the dissolved substance.

J. C. P.

Viscosity of Solutions. By R. HOSKING (*Phil. Mag.*, 1900, 49, 274—286).—The apparatus and method of observation employed were essentially similar to those used by Thorpe and Rodger (*Phil. Trans.*, 1894), and the accuracy of the determinations is seen by the close agreement of the results for water with those of Thorpe and Rodger, Slotte, Sprung, and Poiseuille. Solutions of (1) sodium chloride, and (2) sucrose, were examined, these being selected as typical electrolytic and non-electrolytic solutions; the results are as follows:

(1) Sodium chloride.

Temp.	0 per cent.	5 per cent.	10 per cent.	20 per cent.
0°.....	0·01794	0·01862	0·02041	0·02666
20	0·01009	0·01083	0·01194	0·01540

L. M. J.

Drop Methods for the Determination of Molecular Weights. By G. ROSSER (*Bull. Soc. Chim.*, 1900, [iii], 23, 245—250).—The variation of the surface tension of solutions is proportional to the molecular concentration of the solute, and hence the measurement of the constant is of use for the determination of molecular weights. The author has studied the drop method with the object of finding its availability as a speedy and accurate process. The weights of a hundred drops and also of equal volumes of the solutions were determined, and hence the number of drops in equal volumes can be found. These numbers are inversely proportional to the capillary constants f/d , where f is surface tension and d the density, and vary as a linear function of concentration, so that $1/n_1 = 1/n - kx$ where x is the concentration. In the case of sodium chloride solutions, this expression was verified for concentrations up to 10 per cent. at 23°, and to 30 per cent. at 24°; above 20 per cent., the accord between the determinations and calculated values is not satisfactory, so that the expression does not hold at these high concentrations. It was found that the pressure has a great effect on the number of drops, the weight of 100

drops of water decreasing from 8.192 grams to 7.570 grams when the pressure rose from 29 mm. to 150 mm. of water. The time of dropping was found to be approximately inversely proportional to the pressure. Owing to the great effect of pressure, it is necessary that all experiment for the determination of molecular weights be made at a constant pressure.

L. M. J.

Molecular Association in Liquids. By DANIEL BERTHELOT (*Compt. rend.*, 1900, 130, 565—568).—By the assumption of the law of corresponding states, it is possible from the values of the critical temperature and pressure, and the value of the density at some other temperature and pressure, to calculate the mol. weight of the compound. The ratio of the mol. weight so obtained to the true value is equal to, greater than, or less than unity according as the compound is normal, associated, or dissociated. Thus, for carbon disulphide, values of from 0.96 to 0.97 are obtained, and for ethyl chloride of from 0.98 to 0.99, hence these are normal. For methyl, ethyl, and propyl alcohols, the values are respectively 1.256, 1.115, and 1.116, so that these compounds are associated. It is not found that the values alter with temperature and pressure, so that the factors of association of these compounds are regarded as practically constant through the whole range of the liquid state; water, however, exhibits considerable differences of association.

L. M. J.

Chemical Reactions in Solution: Vapour Tension of the Solvent. By A. PONSOT (*Compt. rend.*, 1900, 130, 782—785).—By the consideration of a cycle of reversible operations in a homogeneous mixture, the author obtains the following deductions. When spontaneous reactions, taking place at constant pressure and temperature amongst dissolved substances or mixtures modify the system, they cause: (1) an increase to a maximum of the vapour pressure of the solvent, if it takes no part in the reaction; (2) an increase of that of a produced compound, and conversely. It also follows that the sense of the chemical change of a system not in equilibrium is independent of the nature of the solvent.

L. M. J.

Equilibrium in the Partition of an Acid between Zinc Hydroxide and Ammonia. By W. HERZ (*Zeit. anorg. Chem.*, 1900, 23, 222—227).—The equilibrium represented by the scheme, $\text{Zn}(\text{OH})_2 + 2\text{NH}_4\text{Cl} \rightleftharpoons \text{ZnCl}_2 + 2\text{NH}_4\text{OH}$, is analogous to that between manganous salts and ammonia (*Abstr.*, 1899, ii, 752; 1900, ii, 68). The law of mass action leads to $K = [\text{Zn}^{++}]^{1/2}/[\text{NH}_4^+]$, but the values of K obtained from this equation are not constant; the relation, $K = [\text{Zn}]/[\text{NH}_4]$, is more nearly satisfied by the results obtained, but the values of the constant diminish slightly with falling concentration. In more dilute solutions, the point of equilibrium was approached from the other side, namely, by adding ammonia to zinc salt solutions; fairly constant values were then obtained for the expression $[\text{Zn}^{++}][\text{NH}_3]^2/[\text{NH}_4^+]^2$, except when the ammonia was in excess and gave rise to the formation of complex ions. It is immaterial for the equilibrium whether zinc sulphate or zinc nitrate is employed.

From the experiments the solubility of zinc hydroxide is calculated to be 2.6×10^{-5} , agreeing with Bodländer's value 2.5×10^{-5} .

J. C. P.

Decomposition by Sodium of Organic Halogen Compounds dissolved in Amyl Alcohol. By RICHARD LÖWENHERZ (*Zeit. physikal. Chem.*, 1900, 32, 477—493. Compare Abstr., 1899, ii, 639).—Pieces of sodium were added to solutions of iodobenzene, chlorobenzene, benzyl chloride, isobutyl iodide, bromobenzene, and isobutyl bromide in amyl alcohol; the halogen eliminated and the sodium in solution were subsequently determined by titration. Preliminary experiments showed that the quantity of halogen eliminated was generally proportional (1) to the concentration of the halogen compound, (2) to the quantity of dissolved sodium. This leads to the equation $dx/d(\text{Na}) = k(a - x)$, where (Na) is the dissolved sodium in gram atoms per kilogram of solution, a the initial quantity of halogen compound, x the quantity decomposed; k is a constant. On integration, the equation assumes the form $k = 1/(\text{Na}) \cdot \log a(a - x)$. The initial concentration of the halogen compound was in most cases 0.1 gram-mol. per kilogram of solution, and the values of k obtained were satisfactorily constant within the separate series, except in the case of bromobenzene, which, however, gave constant values for k in more dilute solution. For each of the compounds iodobenzene, chlorobenzene, benzyl chloride, and isobutyl iodide, k has the same value; for isobutyl bromide, it is somewhat smaller. In the case of iodobenzene, k was found to diminish both with rising temperature and with falling concentration of the halogen compound.

J. C. P.

Absorption of Hydrogen Chloride and Potassium Chloride from Aqueous Solution by Colloidal Stannic Oxide. By JACOBUS M. VAN BEMMELN and EDUARD A. KLOBBIE (*Zeit. anorg. Chem.*, 1900, 23, 111—125. Compare Abstr., 1882, 571; 1897, ii, 137; 1899, ii, 12, 84).—Metastannic acid has a very considerable power of absorbing hydrogen chloride from aqueous solution; when equilibrium has been established, the concentration of the hydrogen chloride in the colloid is often greater than that in the aqueous solution. The absorption factor $k = (\text{conc. in colloid})/(\text{conc. in solution})$ is not constant, but is dependent on the concentrations at the point of equilibrium. Metastannic acid has an appreciable power of absorbing potassium sulphate. From solutions of potassium chloride and potassium nitrate, the same colloid absorbs as much salt as makes the concentrations in the colloid and in the solution approximately equal.

J. C. P.

Emission and Absorption of Water Vapour by Colloidal Matter. By PIERRE DUHEM (*J. Physical Chem.*, 1900, 4, 65—122). The author has previously shown that hysteresis plays a very important part in many cases of slow chemical change (Abstr., 1897, ii, 439), and Marchis showed that the variations of the zero in thermometers are due to an expansion hysteresis (Abstr., 1899, ii, 545). The author has investigated theoretically the emission and absorption of aqueous vapour by colloids as an example of hysteresis, and shows that the various phenomena observed by van Bemmelen are in

complete accord with the theoretical deductions (compare Abstr., 1897, ii, 137; 1898, ii, 220; 1899, ii, 12, 84, 487, 599). L. M. J.

Metallic Crystallisation by Electric Currents. By DONATO TOMMASI (*Compt. rend.*, 1900, 130, 565. Compare Tommasina, this vol., ii, 185).—A claim for priority, the author pointing out that, in 1882, he had observed that by the passage of an electric current from silver or copper to platinum through distilled water, a crystalline deposit of the anode metal mixed with oxide was obtained in the tube.

L. M. J.

Formation and Transition of Mixed Crystals of Sodium and Potassium Nitrates, and of Sodium and Silver Nitrates. By D. J. HISSINK (*Zeit. physikal. Chem.*, 1900, 32, 537—563).—From fused mixtures of sodium and potassium nitrates, an interrupted series of mixed crystals is formed, the interval extending from 24—85 mols. per cent. of potassium nitrate at 218°. The existence of mixed crystals is shown by the lowering of the transition temperature of potassium nitrate.

The solidification of fused mixtures of sodium and silver nitrates exemplifies Roozeboom's fourth type (this vol., ii, 132). The freezing point rises gradually from 208·6° for pure silver nitrate to 308° for pure sodium nitrate, with a break at 217·5°, corresponding with 19·5 mols. per cent. of sodium nitrate. To the first part of the freezing point curve there correspond mixed crystals of the AgNO_3 type, containing from 0—26 mols. per cent. of sodium nitrate; to the second part of the curve there correspond mixed crystals of the NaNO_3 type, containing from 38—100 mols. per cent. of sodium nitrate. The interval, 26—38 mols. per cent. of sodium nitrate becomes wider as the temperature falls, and at 138° the limits are 4·5 and ± 50 mols. per cent. of sodium nitrate. The transition temperature of mixed crystals of the AgNO_3 type, as determined by an air dilatometer, falls from 159·8° to 138°, as their molecular composition changes from 0—4 per cent. of sodium nitrate. The gap between mixed crystals of the AgNO_3 type and those of the NaNO_3 type becomes still wider with falling temperature, as shown by solubility experiments in aqueous alcohol; at 15°, the interval extends from 1·6—64·4 mols. per cent. of sodium nitrate.

No transition point could be found for sodium nitrate between +270° and -50°; neither could any sudden transition of the mixed crystals of the NaNO_3 type be detected below 138°. J. C. P.

[Crystalline Liquids.] By RUDOLF SOHENCK (*Zeit. physikal. Chem.*, 1900, 32, 564—565).—A reply to Roozeboom's criticisms (*ibid.*, 1899, 30, 428) on the author's work dealing with enantiotropic and monotropic modifications of azoxyanisole (Abstr., 1899, ii, 637).

J. C. P.

Report of the [American] Committee on Atomic Weights. By FRANK W. CLARKE (*J. Amer. Chem. Soc.*, 1900, 22, 70—80).—A résumé of the work published during 1899 on the atomic weights of boron, nitrogen, calcium, nickel, cobalt, molybdenum, tungsten, cerium,

palladium, radium and copper ; a corrected table of the atomic weights of all the elements is appended. E. G.

Lecture Experiment on the Law of Multiple Proportions. By FRIEDRICH EMICH and FRIEDRICH DÖRNER (*Chem. Centr.*, 1900, i, 579—580 ; from *Zeit. phys.-chem. Unterr.*, 12, 281—282).—When lead dioxide is heated, it loses half its oxygen, and by the action of chlorine on the residual monoxide at a red heat, the remainder of the oxygen is liberated. These decompositions are made the basis of a convenient lecture experiment to illustrate the law of multiple proportions. The air is displaced from the tube containing the dioxide by means of carbon dioxide, and the oxygen evolved on heating is measured in a Schiff's nitrometer over potassium hydroxide solution, the last traces of oxygen being finally driven over by means of carbon dioxide. Chlorine is then passed over the residual lead monoxide, which is raised to a red heat, and the oxygen liberated is again measured as before over potassium hydroxide solution. E. W. W.

New Gasometer of Constant Pressure, Adjustable at Will. By JOSEPH RIBAN (*Bull. Soc. Chim.*, 1900, [iii], 23, 222—226).—In its general appearance, this apparatus resembles the ordinary laboratory gasometer, but differs from the latter in having two water reservoirs, an upper exterior one capable of being fixed at any desired height, and a lower interior reservoir in the upper part of the gas container. The gas is delivered at a constant pressure measured by the difference in height between the levels of the water in the two reservoirs. There are also various minor improvements which facilitate the expulsion of air before filling the gasometer with gas and prevent escape of gas or entry of air resulting from alterations in temperature. N. L.

Inorganic Chemistry.

Preparation and Properties of Anhydrous Perchloric Acid. By DANIEL VORLÄNDER and RUDOLF VON SCHILLING (*Annalen*, 1900, 310, 369—380).—Anhydrous perchloric acid is prepared by distilling potassium perchlorate (50 grams) with 96—97.5 per cent. sulphuric acid (150—175 grams) under 50—70 mm. pressure, and after removing chlorine dioxide by means of a current of air, redistilling the product under the same pressure. The anhydrous acid is colourless, boils at 39° under 56 mm. pressure, and has a sp. gr. 1.764 at 22°/4°; it remains liquid in a mixture of ether and solid carbon dioxide. It does not dissolve in carbon tetrachloride, with which it forms a green emulsion, which soon becomes brown, and evolves hydrogen chloride and phosgene; chloroform, however, dissolves it in every proportion, and on exposing the solution to air, crystals of the monohydrate separate, whilst phosphoric oxide produces a violent explosion. When a few c.c. of benzene are added to a drop or two of perchloric acid, heat is generated, and a brown pre-

precipitate is formed; equal volumes yield a green emulsion, which explodes.

The spontaneous decomposition of anhydrous perchloric acid proceeds when the substance is protected from light and maintained at a low temperature; samples of the purest acid, sealed in glass bulbs, become pale yellow in 2 or 3 days, then gradually brown, and after 3 or 4 weeks the bulbs are shattered by the pressure of the gases evolved in the decomposition.

The authors discuss the action of more concentrated sulphuric acid, and of phosphoric and pyrophosphoric acids on potassium perchlorate.

M. O. F.

Molecular Weight of Sulphur as Determined by the Boiling Point Method. By LOUIS ARONSTEIN and S. H. MEIHUIZEN (*Chem. Centr.*, 1900, i, 392—393; from *Arch. néerland. sci. exp. nat.*, [ii], 3, 89—130).—In solutions, sulphur is found to have a molecular weight corresponding with the formula S_8 , whether above or below its transition and melting points. No importance is to be attached to the molecular weight 64 obtained by Orndorff and Terrasse in disulphur dichloride (*Abstr.*, 1896, ii, 358), since this solvent decomposes at its boiling point.

J. C. P.

Sulphur Perfluoride, SF_6 ; a New Gas. By HENRI MOISSAN and PAUL LEBEAU (*Compt. rend.*, 1900, 130, 865—871).—When sulphur is introduced into a vessel containing fluorine, it immediately takes fire, and burns with a livid flame; the product is gaseous, and consists of at least two compounds, for the mixture, although quite insoluble in water, partly dissolves in an aqueous solution of potassium hydroxide. When the fluorine is in excess, the product contains 80—90 per cent. of the insoluble constituent; the inert gas appears, therefore, to be a perfluoride.

The mixture of sulphur fluorides is liquefied by cooling to -80° , freed from foreign gases by fractional distillation, treated with concentrated potassium hydroxide solution, and finally dried over the fused alkali; the perfluoride thus obtained is freed from traces of nitrogen by liquefaction and fractionation, the latter gas passing off in the first portion of the distillate.

Sulphur perfluoride, SF_6 , is a colourless, inodorous, tasteless, combustible gas, which does not support combustion; it is very sparingly soluble in water, dissolving to a slightly greater extent in absolute alcohol; when cooled to -55° , it solidifies to a white, crystalline mass, which melts and boils at slightly higher temperatures. The perfluoride is a very inert gas, resembling nitrogen more than sulphur chloride; potassium hydroxide, whether fused or in alcoholic or aqueous solution, does not act on it, and it is not affected by lead chromate, copper oxide, silver, copper, phosphorus, arsenic, boron, silicon, or carbon, even at a red heat. Fluorine, and the halogens, ammonia, and hydrogen chloride have no action on the gas, even at high temperatures. No change occurs when the gas is heated alone up to the fusing point of hard glass; at the temperature of the induction spark, however, it is partially decomposed, but even after prolonging the action for over 2 hours, 11 per cent. of the perfluoride remains unchanged. When

sparked in the presence of excess of hydrogen, the perfluoride is completely decomposed with the production of hydrogen sulphide and hydrogen fluoride; these compounds, acting on the glass of the containing vessel, form a yellow solid, which consists of sulphur, silica, and hydrofluosilicic acid. A mixture of the perfluoride and oxygen, when strongly sparked, yields a brown, flocculent solid; one part by volume of the latter gas is absorbed, and the total contraction is two volumes; when the current intensity is diminished, the reaction takes a different course, an oxyfluoride of sulphur being produced, which is less rapidly decomposed by water than thionyl fluoride.

When the perfluoride is heated with sulphur vapour in a glass vessel, lower fluorides of sulphur are produced, and these act on the glass, forming silicon fluoride and sulphur dioxide; if the heating is prolonged, the decomposition is complete. Selenium behaves in a similar manner, but the reaction is more complicated, a mixture of silicon fluoride and the dioxides of sulphur and selenium being obtained.

Calcium and magnesium, when heated in the gas, are only superficially attacked; boiling sodium, however, rapidly absorbs the perfluoride. When the gas is heated with hydrogen sulphide, the following reaction takes place: $\text{SF}_6 + 3\text{H}_2\text{S} = 6\text{HF} + 4\text{S}$; the hydrogen fluoride immediately attacks the glass of the vessel, so that hydrofluosilicic and silicic acids are the ultimate products.

The paper contains a description of the apparatus employed in preparing the mixed fluorides.

G. T. M.

Density and Analysis of Sulphur Perfluoride. By HENRI MOISSAN and PAUL LEBEAU (*Compt. rend.*, 1900, 130, 984—988).—The gaseous sulphur perfluoride (preceding abstract) has a sp. gr. 5.03 (air=1); its analysis was effected by heating it with sodium vapour, a mixture of sodium sulphide and fluoride being thus obtained, and also by heating with sulphur in glass vessels, and measuring the volume of the silicon fluoride and sulphur dioxide produced. The perfluoride was also decomposed by heating with selenium. The results thus obtained are in close agreement with the formula SF_6 .

N. L.

Sulphuric Acid containing Selenium. By CHARLES F. SCHLAG-DENHAUFFEN and C. PAGEL (*J. Pharm.*, 1900, [vi], 11, 261—262).—A large number of samples of so-called "pure" sulphuric acid were found to contain selenium; a very delicate test for the latter consists in adding a fragment of codeine to 4 or 5 drops of the concentrated acid, when a green coloration is produced in the cold, which changes to bluish-green at 100°.

W. A. D.

Passage of Argon through Thin Films of Indiarubber. By LORD RAYLEIGH (*Phil. Mag.*, 1900, [v], 49, 220—221).—Air was allowed to diffuse into an indiarubber balloon, and the composition of the contents then determined; it was found that the argon now formed 1.93 per cent. of the argon and nitrogen, whilst corresponding percentage for air itself was 1.19. Argon, therefore, passes through indiarubber more readily than nitrogen, but not in such a degree as to render the process suitable for the concentration of argon from the atmosphere.

L. M. J.

Electrolysis of Alkali Chloride Solutions with a Diaphragm. By FRITZ FOERSTER and F. JORRE (*Zeit. anorg. Chem.*, 1900, 23, 158—219).—Theoretical considerations show that the yield of chlorine obtained in the electrolysis of neutral alkali chloride solutions will in general be less than the yield of alkali, so long as the existence of hypochlorite in the anode solution is possible (compare this vol., ii, 72). When a diaphragm is used, the nature of the process depends on three factors—the ordinary electrical conduction in the diaphragm, the diffusion, and the electrical endosmose.

Experiments with a platino-iridium anode, in which the anode and cathode solutions were analysed after the electrolysis, showed that the total yield of alkali diminishes with increasing concentration of the alkali hydroxide. The yield of chlorine was found to be less than the yield of alkali, especially in the first stages of the electrolysis; the difference vanished later on when the chlorate and hydrogen chloride concentrations became appreciable. The chloride concentration, owing to the electrical endosmose, falls much more slowly in the cathode solution than in the anode solution. Analysis of the anode solution after electrolysis indicated the presence of free hypochlorous acid and alkali chlorate, but not of alkali hypochlorite. The proportion of oxygen liberated at the anode increases regularly with the progress of the electrolysis.

When carbon anodes are used, the process of electrolysis is essentially the same; the gas liberated at the anode contains carbon dioxide, and hydrogen chloride is found in the anode solution at a higher alkali chloride concentration than when platino-iridium anodes are used.

Solutions of potassium chloride give a better current yield than those of sodium chloride; this is connected partly with the greater dissociation of the former salt, and the greater velocity of migration of the potassium ion.

J. C. P.

Production of Iodated Potassium and Ammonium Carnallites. By AUGUST DE SCHULTEN (*Bull. Soc. Chim.*, 1900, [iii], 23, 158—159. Compare Abstr., 1898, ii, 512).—Substituted carnallites of the formulæ $KI, MgI_2 + 6H_2O$ and $NH_4I, MgI_2 + 6H_2O$ are obtained when solutions of the mixed salts are left to evaporate over sulphuric acid in a vacuum. The crystals form flattened prisms, are very hygroscopic, and have respectively the sp. grs. 2.547 and 2.346 at 15°. N. L.

Action of Chlorine on Metallic Silver in the Light and in the Dark. By V. VON CORDIER (*Monatsh.*, 1900, 21, 184—199).—The action of chlorine on pure silver has been tried under varying degrees of illumination, and it is found that (i) dry chlorine has no action, either in the light or in the dark; (ii) moist chlorine has a weak action, which, within certain limits, varies with the intensity of the light; (iii) illumination of the chlorinated silver in a stream of an indifferent gas causes a decrease in weight of the silver, probably due to a decomposition of the silver chloride; (iv) an intense illumination of the chlorine before contact with the silver causes an increased absorption; (v) electric sparking of the chlorine has the same effect.

Copper, treated under similar conditions to silver, gives different results. R. H. P.

Reducing Action of Calcium Carbide. By H. CHR. GEELMUYDEN (*Compt. rend.*, 1900, 130, 1026—1029).—Boric oxide reacts with calcium carbide, at the temperature of the electric furnace, to form calcium boride, CaB_2 . Under the same conditions, the sulphides of iron, lead, antimony, and magnesium are also reduced, the metals being completely volatilised, except in the case of iron. Aluminium sulphide is not reduced by calcium carbide. N. L.

Hydrated Barium Peroxides. By ROBERT DE FORCRAND (*Compt. rend.*, 1900, 130, 778—780; 834—837).—The results given in the first of these papers are incorrect, the heat of dissolution of hydrated barium hydroxide having been taken as +14.1 Cal. instead of -14.1 Cal.; the correct figures are given in the second paper. Experiments with various proportions of hydrogen peroxide and barium oxide lead to the conclusion that $\text{BaO diss.} + \text{H}_2\text{O}_2 \text{ diss.} = \text{BaO}_2 \text{ ppt.} + \text{H}_2\text{O}$ develops +25.497 Cal., whilst the dissolution of the peroxide in dilute hydrochloric acid develops +2.723 Cal. These results differ somewhat from the earlier results of Berthelot.

The barium peroxide obtained in this manner is never quite free from monoxide, but, contrary to the general belief, the proportion of peroxide is highest when the barium monoxide, and not the hydrogen peroxide, is in excess.

The conversion of the peroxide into the trioxide, and of the latter into the tetroxide, by the action of a large excess of hydrogen peroxide, seems to be accompanied by no appreciable thermal disturbance. The conversion is, as a rule, incomplete, and the composition of the product varies with the conditions. C. H. B.

Heat of Formation of Hydrated and Anhydrous Strontium Dioxide. By ROBERT DE FORCRAND (*Compt. rend.*, 1900, 130, 1017—1019).—The heat of formation of the precipitated, hydrated dioxide, $\text{SrO}_2 + 9\text{H}_2\text{O}$, obtained by mixing solutions of the monoxide and hydrogen peroxide, is 26.576 Cal., which is about 1 Cal. higher than the corresponding figure for barium dioxide (preceding abstract); its heat of dissolution in hydrochloric acid is 1.744 Cal. The heat of dissolution of the anhydrous dioxide in hydrochloric acid is 22.225 Cal., whence it is calculated that the heat of formation of the dioxide from the solid monoxide and gaseous oxygen is 10.875 Cal., whilst its heat of hydration is 20.481 Cal. (liquid water) and 7.611 Cal. (solid water). Comparison of these figures with the heat of formation (12.10 Cal.) and hydration (18.20 Cal.) of barium dioxide explains why anhydrous strontium dioxide is less stable and less easy to obtain free from monoxide than the barium compound, whereas, with the hydrated dioxides, the relative stability is reversed. N. L.

Reactions of Magnesium, Zinc, and Iron with Solution of Cupric Sulphate. By ROBERT M. CAVEN (*J. Soc. Chem. Ind.*, 1900, 19, 18—22. Compare *Proc.*, 1897, 13, 221; 1898, 14, 57).—The action of magnesium, zinc, and iron on solutions of copper sulphate is not one of simple displacement of copper by the other metal only, but

is attended with several complicated reactions, such as evolution of hydrogen, formation of cuprous oxide, basic cupric sulphate, cuprous sulphate, and even free sulphuric acid ; also of oxides, or basic sulphates of magnesium, zinc, or iron.

The experiments have been conducted with solutions of copper sulphate of varying strength and at different temperatures, and the results are tabulated.

L. DE K.

Influence of Ammonia on Magnesium Salts. By W. SCHIEBER (*Chem. Centr.*, 1900, i, 652 ; from *Oesterr. Chem. Zeit.*, 3, 83—84).—The addition of ammonia to a solution of a magnesium salt containing as much as 4 mols. of ammonium salt to 1 mol. of magnesium salt will often cause the solution to become turbid, and on boiling a precipitate is always formed. The prevention of the precipitation of magnesium hydroxide by means of ammonium salts is not only dependent on the relative quantities of the ammonium and magnesium salts present, but also on the amount of free ammonia added, and possibly also on the concentration, hence, in separating alumina from magnesia, a considerable quantity of ammonium chloride is required, but the ammonia added should be reduced to a minimum.

E. W. W.

Electrolytic Deposition of Brass. By J. LIVINGSTON R. MORGAN (*J. Amer. Chem. Soc.*, 1900, 22, 93—99).—The theory of this operation is discussed. For the deposition of brass, it is necessary (1) that the solution contain zinc and copper ions in such a proportion that $P/p : P_1/p_1 :: 30 : 70$, where P and P_1 are the electrolytic solution pressures of zinc and copper, p and p_1 the osmotic pressures of their ions in the solution ; (2) that the solution contain complex ions of zinc and copper. From solutions of their simple salts, the metals would not be deposited in the requisite proportion ; this would change the composition of the liquid, and the zinc and copper of the anode would no longer dissolve in the required ratio. Further, (3) the maximum concentration of copper ions should be as small as possible, in order that copper may be easily dissolved from the anode.

The above conditions are fulfilled by a solution of the mixed zinc and copper salts in potassium cyanide. From such a solution, containing as it does the complex ions $\text{Zn}(\text{CN})_4$ and $\text{Cu}(\text{CN})_4$, zinc and copper may be deposited in varying proportions according to the current density.

J. C. P.

Zinc Selenide and its Dimorphism. By HENRI FONZES-DIAON (*Compt. rend.*, 1900, 130, 832—834).—Zinc selenide obtained by the action of zinc chloride vapour on a mixture of nitrogen and hydrogen selenide crystallises in long, rhombohedral needles carrying, laterally, hemimorphic hexagonal prisms, or in rhombohedra with striated faces, which act strongly on polarised light. The selenide obtained by the action of hydrogen on the selenate also crystallises in long needles belonging to the hexagonal system, whereas, when prepared in the electric furnace, the crystals are optically inactive, and seem to belong to the cubic system, like the crystals obtained by Margottet by heating the amorphous selenide

in hydrogen. The dimorphism of zinc selenide is therefore established, and is analogous to that of the sulphide.

Hexagonal cadmium selenide has been prepared in a similar way.
C. H. B.

Production of Cadmium Vanadinites. By AUGUST DE SCHULTEN (*Bull. Soc. Chim.*, 1900, [iii], 23, 159—160).—*Cadmium chlorovanadinite*, $3\text{Cd}_3(\text{VO}_4)_2\text{CdCl}_2$, is obtained by heating to fusion a mixture of cadmium chloride, cadmium carbonate, and vanadium pentoxide, in the form of long, hexagonal prisms having a sp. gr. 5.264 at 15° . The crystals are readily soluble in dilute acids, and melt and decompose when heated to redness. *Cadmium bromovanadinite*, $3\text{Cd}_3(\text{VO}_4)_2\text{CdBr}_2$, obtained in a similar manner from cadmium bromide, closely resembles the chlorovanadinite; it has a sp. gr. 5.456 at 15° . The corresponding iodine compound could not be obtained in a pure state.
N. L.

Action of Hydrogen on Mercury Selenide and the Inverse Action. By H. PÉLABON (*Bull. Soc. Chim.*, 1900, [iii], 23, 211—216).—Mercury selenide is attacked by hydrogen at temperatures above 400° with the production of hydrogen selenide and mercury, the reaction being limited by the inverse action of hydrogen selenide on mercury. The proportion of hydrogen selenide found in the gaseous products of the reaction increases with the temperature and with a diminution of the initial pressure. Thus, at 540° with an initial pressure of 760 mm. equilibrium is attained when 15 per cent. of hydrogen selenide is present, whilst at 440° only 0.52 per cent. is formed. On the other hand, with initial pressures of about 380 mm. and 190 mm. at 540° , the percentages of hydrogen selenide formed become 19 and 27 respectively. These results are shown to be in accordance with thermodynamical reasoning.
N. L.

Formation of Mercuriammonium Iodide by the Regulated Action of Concentrated Ammonia on Mercuridiammonium Iodide. By MAURICE FRANÇOIS (*Compt. rend.*, 1900, 130, 1022—1024). When a solution of ammonia of sp. gr. 0.923 is added in large quantity to mercuridiammonium iodide, dimercuriammonium iodide is formed (this vol., ii, 208, 280), but if the ammonia is added slowly and in small portions at a time, mercuriammonium iodide, NH_2HgI , is obtained. The reaction is limited and reversible, since the new compound is reconverted into mercuridiammonium iodide by the action of ammonia and ammonium iodide. Mercuriammonium iodide is a white, crystalline substance, which does not redden on exposure to air and is insoluble in ether.
N. L.

Separation of Rare Earths. By G. URBAIN (*Ann. Chim. Phys.*, 1900, [vii], 19, 184—274).—A detailed account of the fractionation of the rare earths from *æschynite* and *monazite* by methods which have been previously indicated (compare Abstr., 1897, ii, 318; 1898, ii, 518; 1899, ii, 28, 424, 789).
G. T. M.

Separation of the Rare Earths. By R. CHAVASTELON (*Compt. rend.*, 1900, 130, 781—782).—On adding a neutral solution of the salts of cerium, lanthanum, didymium, and thorium to a saturated

solution of sodium sulphite, the last named element remains in solution whilst the others are precipitated as sulphites; the separation is practically complete, the thorium solution containing only traces of the other elements. The mixed sulphites are dissolved in hydrochloric acid and the trace of thorium carried down with these salts is precipitated by treating the solution of the chlorides with hydrogen peroxide; the oxides of the other metals, precipitated from the filtrate by ammonia, are suspended in a solution of an alkali hydrogen carbonate saturated with carbon dioxide, when the cerium oxide dissolves forming a brown solution, the operation being repeated with fresh quantities of the hydrogen carbonate until the residue no longer develops a brown coloration with hydrogen peroxide. The residue now consists of the double sodium carbonates of lanthanum and didymium; the cerium separates in the form of a light yellow precipitate on adding an alkali hydroxide to the brown solution or as an orange-brown precipitate on adding hydrogen peroxide. The latter precipitate dissolves in acids with evolution of carbon dioxide and when hydrochloric acid is employed chlorine is also evolved; the solutions obtained in the cold are yellow and are rendered colourless on warming; these reactions indicate that the compound is a ceric carbonate.

As an alternative method of separation, the oxides of the four elements, obtained by adding ammonia and hydrogen peroxide to solutions of their chlorides, are treated with a solution of an alkali hydrogen carbonate, the peroxides of cerium and thorium dissolve forming a brown solution and the separation of these metals may be effected by either of the following processes: (1) reduction of the peroxides and formation of the sulphites by the action of sulphurous acid and the precipitation of thorium by hydrogen peroxide from a hydrochloric acid solution of these salts; (2) reduction of the brown solution of ceric and thoracic carbonates with sulphurous acid in the presence of sufficient sodium carbonate to keep the whole of the thorium dissolved as the double sodium sulphite. In the latter process, the solution must be constantly agitated during the addition of the sulphurous acid in order to prevent the formation of acid sulphite, otherwise some of the cerium will be dissolved whilst traces of thorium will be precipitated.

G. T. M.

New Method of Fractionating some Rare Earths. By EUGÈNE DEMARÇAY (*Compt. rend.*, 1900, 130, 1019—1022).—The method consists in the fractional crystallisation of the double nitrates of magnesium and the rare earths from nitric acid of sp. gr. 1.3. These salts have the general formula $M_2(NO_3)_6 \cdot 3Mg(NO_3)_2 + 24H_2O$, and are formed by lanthanum, cerium, and the other earths up to holmium, but not by yttrium; their solubility increases with the molecular weight.

N. L.

Austrium. By RICHARD PRIBRAM (*Monatsh.*, 1900, 21, 148—155. Compare Abstr., 1886, 773).—The orthite investigated by Linnemann (*loc. cit.*) has been re-examined by the author, who agrees with Lecoq de Boisbaudran (*Compt. rend.*, 1886, 102, 1436) that Linnemann's "austrium" is identical with gallium. However, from a minute

spectroscopic examination of the mineral, he comes to the conclusion that it contains a new element yet to be isolated. This is provisionally named *austrium*, although it is quite distinct from the element described originally by Linnemann. R. H. P.

New Hydrate of Alumina. By V. ZUNINO (*Gazzetta*, 1900, 30, i, 194—199).—When aluminium is immersed in mercury and afterwards exposed to moist air, a voluminous, greyish, spongy mass is formed on the surface of the metal; the author shows that this substance consists essentially of a *hydrated alumina*, of the composition $\text{Al}_2\text{O}_3 + 5\text{H}_2\text{O}$, small quantities of aluminium, iron, and carbon being also present. This compound is also formed by the action of amalgamated aluminium on water, large quantities of hydrogen being evolved at the same time. T. H. P.

Natural and Artificial Pozzuolana. By GIOVANNI GIORGIS and UGO ALVISI (*Gazzetta*, 1899, 29, i, 185—263, and 1900, 30, i, 96—125).—A bibliographical and historical paper, treating of the subject under the four heads: 1. Natural volcanic and non-volcanic pozzuolana. 2. Artificial pozzuolana. 3. Technical notes on pozzuolana. 4. The principal theories concerning the setting of hydraulic cements. The first three of these divisions are here considered. T. H. P.

A Crystallised Selenide and an Oxy-selenide of Manganese. By HENRI FOMES-DIAON (*Compt. rend.*, 1900, 130, 1025—1026).—Cubical crystals of manganese selenide, MnSe , are obtained by the action of hydrogen selenide on a solution of manganese acetate containing a small quantity of hydrochloric acid, by reducing manganese selenate with carbon in the electric furnace, or by fusing the precipitated selenide at a high temperature. Prismatic crystals of the same composition are produced by the action of hydrogen selenide on manganese chloride at a red heat. Crystallised manganese selenide has a sp. gr. 5.59 at 15° , is slightly acted on by water at 100° , and is readily attacked by dilute acids; treatment with hydrogen peroxide converts it into manganese selenate.

Manganese selenate is reduced by hydrogen at a bright red heat with the formation of a green oxy-selenide, analogous to the oxy-sulphide which is formed by a similar reaction. N. L.

Iron Carbonyls and their Importance in the Industrial Application of Water-Gas. By M. VAN BREUKELEVEEN and A. TER HORST (*Rec. Trav. Chim.*, 1900, 19, 27—32).—Gaseous mixtures containing carbon monoxide have a marked action on iron even under the ordinary pressure. A sample of producer gas containing 37 per cent. of the monoxide, after remaining for 1 week in contact with a polished iron surface, yields a large amount of a volatile iron compound. When the percentage of carbon monoxide is low, the action is inappreciable; a sample of coal gas containing only a small amount of this oxide remained quite free from iron carbonyl after a week's exposure to iron surfaces. The producer gas may be freed from iron carbonyl by passing it over copper heated to 300° , or over moistened potassium permanganate. G. T. M.

Constitution and Genesis of Iron Sulphates. By RUDOLF SCHARIZER (*Zeit. Kryst. Min.*, 1900, 32, 338—354).—Compare Abstr., 1899, ii, 30).—The second paper of this series deals with the action of solutions of various strengths of normal ferric sulphate on ferric hydroxide and on precipitated basic ferric sulphate. In both cases, there are obtained solutions of basic ferric sulphate, $\text{Fe}_2\text{S}_2\text{O}_8$, which is decomposed when the solution is diluted or warmed. L. J. S.

Nickelous Arsenide. By ALBERT GRANGER and GASTON DIDIER (*Compt. rend.*, 1900, 130, 914—915. Compare Abstr., 1894, ii, 392; 1896, ii, 602).—A *nickelous arsenide* having the formula Ni_2As_2 is produced by heating the finely divided metal at 600° in the vapour of arsenious chloride; the compound thus obtained forms reddish, crystalline granules having a metallic lustre and resembling the impure arsenide isolated by Wöhler from smalt residues. Although the arsenide differs in composition from the phosphide, Ni_3P , obtained under similar conditions, it resembles this compound in its chemical properties, being decomposed by heat, soluble in nitric acid and aqua regia, and readily attacked by chlorine and fused alkalis.

G. T. M.

Decomposition of Nickel Carbonyl in Solution. By VICTOR LENHER and HERMANN A. LOOS (*J. Amer. Chem. Soc.*, 1900, 22, 114—116).—By the action of moisture on solutions of nickel carbonyl in organic solvents, a green precipitate is produced similar to that furnished by the pure substance in contact with water or moist air. Berthelot (Abstr., 1892, 279) considered this product to be nickelous hydroxide free from carbon, whereas, according to Mond (*J. Soc. Chem. Ind.*, 1892, 11, 750), it is a nickel carbonate of varying composition. The present authors show that it is a decomposition product containing nickel carbonyl and nickelous hydroxide; analysis of a specimen from a toluene solution gave results which point to the composition $\text{Ni}(\text{CO})_4 \cdot 2\text{Ni}(\text{OH})_2 \cdot 4\text{H}_2\text{O}$. E. G.

Nature of the Change from Violet to Green in Solutions of Chromium Salts. By FRANCIS P. VENABLE (*J. Amer. Chem. Soc.*, 1900, 22, 111—114).—A reply to Whitney (this vol., ii, 211), in which the author accepts his results as conclusive. E. G.

Double Carbonates of Chromous Oxide; Saline Oxide of Chromium. By GEORGES BAUGE (*Ann. Chim. Phys.*, 1900, [vii], 19, 158—184).—A *résumé* of work already published. Compare Abstr., 1896, ii, 426; 1898, ii, 294, 592; 1899, ii, 157). G. T. M.

New Method for the Preparation of Double Sulphates of Chromium. By C. PAGEL (*Compt. rend.*, 1900, 130, 1030—1032).—When, as in toxicological investigations, the destruction of organic matter is effected by heating with sulphuric acid and potassium dichromate, the double sulphate, $\text{Cr}_2(\text{SO}_4)_3 \cdot 3\text{K}_2\text{SO}_4$, is produced, whilst if sodium dichromate is employed the analogous sodium salt is obtained. Both compounds crystallise in the hexagonal system, the potassium salt in green plates, and the sodium salt in green prisms. A sodium salt of the same composition, but crystallising in pale green,

slender needles is obtained by heating together sodium hydrogen sulphate, ammonium sulphate, and chromium sulphate. N. L.

Tungsten Diphosphide. By ED. DEFAQZ (*Compt. rend.*, 1900, 130, 915—917).—*Tungsten diphosphide*, WP_2 , produced by heating tungsten hexachloride at 450° in a current of hydrogen phosphide, forms a black, crystalline mass insoluble in water and the ordinary organic solvents, and having a sp. gr. 5.8. Fluorine attacks the diphosphide at temperatures above 100° , forming phosphorous and tungsten fluorides; chlorine and bromine react similarly at a red heat; when liquid chlorine is employed at 60° , a chlorophosphide is produced. Sulphur and nitrogen both displace the phosphorus from this compound at high temperatures, forming the disulphide and nitride respectively; the disulphide is also produced by the action of hydrogen sulphide on the phosphide at 500° . The diphosphide readily burns in air or oxygen, forming tungstic and phosphoric oxides, its combustion in the latter gas being attended by a very dazzling flame. A complete reduction of the phosphide is effected by heating it with copper or zinc, tungsten being liberated, and the corresponding metallic phosphide produced; the reduction by hydrogen commences at 525° , but is incomplete even at 900° .

Lead at 900° only partially reduces the diphosphide, and copper phosphide at 1400° produces another tungsten phosphide; when heated with iron, the diphosphide is converted into a double *iron tungsten phosphide*; with aluminium, the reaction is even more complicated, and the product contains a large amount of silicon derived from the crucible. Hydrofluoric and hydrochloric acids do not act on the diphosphide, but a mixture of the former with nitric acid dissolves this compound even in the cold, whilst aqua regia decomposes it on warming; sulphuric and nitric acids, when heated, are reduced by the phosphide, sulphurous acid and blue tungsten oxide being formed in the first case, and nitrous and tungstic acids in the second. The diphosphide is dissolved by fused caustic alkalis and potassium hydrogen sulphate, and is even more readily attacked by heated mixtures of alkali nitrates and carbonates. G. T. M.

Paratungstates. By L. A. HALLOPEAU (*Ann. Chim. Phys.*, 1900, [vii], 19, 92—144).—A *résumé* of work already published (compare Abstr., 1895, ii, 503; 1896, ii, 607; 1897, ii, 178, 498; 1898, ii, 540; 1899, ii, 32, 158, 159, 555). G. T. M.

Actinium: A New Radio-active Element. By A. DEBIERNE (*Compt. rend.*, 1900, 130, 906—908).—The new radio-active element, *actinium*, belonging to the iron group (compare this vol., ii, 20), may be obtained in a more concentrated form by submitting the substances containing it to the following operations: (1) Addition of excess of sodium thiosulphate to solutions slightly acidified with hydrochloric acid; (2) action of hydrofluoric acid and potassium fluoride on the freshly precipitated hydroxides suspended in water; (3) oxidation of neutral solutions of the nitrates by hydrogen peroxide; (4) precipitation of insoluble sulphates. In every case, the precipitate or residue is strongly radio-active, and contains nearly the whole of the actinium;

the second process serves to separate this substance from titanium. The element itself has not been isolated from these mixtures, and in all probability the above reactions are not peculiar to actinium, the radio-active substance being precipitated along with other insoluble compounds, just as ferric oxide is carried down by barium sulphate. By a methodical application of these processes, however, the greater portion of the new element may be extracted from pitchblende.

Chemical and spectroscopic examination of the most active fractions indicates that the predominant element is thorium. Unlike radium or polonium, the new element is not affected by the precipitants for barium or bismuth.

The rays emitted by actinium produce the same effects as those from radium and polonium; a portion of the rays is deflected in a strong magnetic field, the deviation being in the same sense as that of the radium and cathode rays; actinium induces permanent radio-activity on substances placed in its vicinity; its inductive action is, however, very feeble.

Actinium seems to resemble thorium in its chemical properties, and the slight radio-activity exhibited by compounds of the latter may possibly be due to the presence of the former substance. G. T. M.

Thorium Salts. By ARTHUR ROSENHEIM and JOHANNES SCHILLING (*Ber.*, 1900, 33, 977—980).—When thorium hydroxide is washed with alcohol, dissolved in alcoholic hydrogen chloride, and evaporated under diminished pressure, the *hydroxychloride*, $\text{ThCl}_2(\text{OH})_2 + 8\text{H}_2\text{O}$, crystallises in slender, white, hygroscopic needles. The mother liquor from these yields the normal *chloride*, $\text{ThCl}_4 + 9\text{H}_2\text{O}$, which forms well developed crystals and slowly deliquesces. A *hydroxychloride* of the formula $\text{OH} \cdot \text{ThCl}_3 + 11\text{H}_2\text{O}$ is obtained when the solution of the hydroxide in alcoholic hydrogen chloride is evaporated almost to dryness, and the residue treated with aqueous hydrochloric acid. It has been found impossible to obtain the compound of thorium chloride with hydrogen chloride, H_2ThCl_6 , in the free state, but a stable pyridine salt of this acid has been prepared, $(\text{C}_5\text{H}_5\text{N})_2\text{H}_2\text{ThCl}_6$, which forms a compact, crystalline crust.

Thorium hydroxybromide, $\text{ThBr}_2(\text{OH})_2 + 11\text{H}_2\text{O}$, forms small, quadratic crystals, whilst the *bromide*, $\text{ThBr}_4 + 7\text{H}_2\text{O}$, crystallises in well-developed needles. *Pyridine thoribromide*, $(\text{C}_5\text{H}_5\text{N})_2\text{H}_2\text{ThBr}_6$, closely resembles the corresponding chloride, but soon decomposes with evolution of hydrogen bromide.

Chlorides of thorium containing $8\text{H}_2\text{O}$ and $7\text{H}_2\text{O}$, and bromides containing $8\text{H}_2\text{O}$ and $10\text{H}_2\text{O}$ have been described previously. A. H.

A Radio-active Substance Emitted from Thorium Compounds. By E. RUTHERFORD (*Phil. Mag.*, 1900, [v], 49, 1—14).—Schmidt has shown that thorium emits radiations analogous to those emitted by uranium (*Abstr.*, 1898, ii, 550). The author finds that when the radiations proceed from thin layers of thorium oxide, they may be almost completely cut off by a few sheets of paper; but if thick layers of thorium oxide are employed, the radiations are but slightly affected, even by many layers of paper, and further, that the inconstancy of the intensity of the radiations is due to air currents.

The author considers that the radio-activity is due to two causes, (1) radiations, and (2) an emanation which passes away from the oxide, and is capable of passing through paper or metals in thin sheets, but is stopped by mica. This emanation may be carried away by air currents, and the intensity of the radio-activity *slowly* falls, being reduced to about one-half its value in one minute; it passes through cotton-wool without loss of its activity, and may be bubbled through hot or cold water or sulphuric acid; in this respect, it differs from ions. It can affect photographic plates, causes ionisation of gases, and does not appear to be affected by the nature of the surrounding gas. The nature of the emanation is doubtful, as it does not appear to consist of fine dust particles, whilst if a vapour it is insufficient to cause any change in the spectrum of a Plücker vacuum tube. L. M. J.

Radio-activity produced in Substances by the Action of Thorium Compounds. By E. RUTHERFORD (*Phil. Mag.*, 1900, [v], 49, 161—192).—Thorium compounds, especially the oxide, not only possess the property of emitting radiations, but also produce radio-activity in substances placed near them, and in an electric field the radio-activity is chiefly produced, and may be concentrated, upon negatively electrified bodies. This radio-activity is most probably due, not to the radiations from thorium, but to the 'emanation' (preceding abstract), as both emanation and the power of producing radio-activity are removed by air currents and destroyed by high temperatures, whilst further, the intensity of the excited radio-activity is found to be proportional to the current due to the emanation. The radio-activity is independent of the nature of the substance upon which it is produced, metals, wood, and paper being equally affected, and appears to be a surface effect; its intensity falls very slowly, being reduced to about one-half in 11 hours after removal from the influence of the thorium. It decreases with the pressure at low pressures, but is practically constant above about 16 mm., and varies little with the nature of the gas. No dust could be observed to be deposited on excited wires when microscopically examined, neither was any increase of weight found; the activity is not destroyed by heating, but may be removed by long scouring with emery cloth. It is rapidly destroyed by hydrochloric or sulphuric acid, but is only slowly removed by hot or cold nitric acid or sodium hydroxide, and still remained after the electric deposition of a film of copper on the wire. Further, when destroyed by hydrochloric or sulphuric acid, the residue from the acid after evaporation is strongly radio-active. The question as to whether this activity is due to the deposition of positive ions or to that of radio-active particles of the emanation is shortly discussed, although neither view is completely satisfactory (see also Curie, this vol., ii, 126).

L. M. J. :

Action of Hydrogen on Antimony Sulphide. By H. PÉLABON (*Compt. rend.*, 1900, 130, 911—914).—The paper deals with the study of the balanced reaction $\text{Sb}_2\text{S}_3 + 3\text{H}_2 = 3\text{H}_2\text{S} + 2\text{Sb}$ at temperatures above 360° , the reagents being contained in sealed tubes. When the temperature is below the melting point of the sulphide, the product consists of a mixture of two solids in contact with a gaseous mixture,

and from the laws of chemical statics the final composition of the gas should be independent of the pressure and of the mass of the solids, and should depend only on the temperature. In order to verify this conclusion, varying quantities of stibnite were heated with hydrogen for 30 hours at constant temperatures; the tubes were then rapidly cooled, the gas analysed, and the results expressed in terms of the partial pressure of hydrogen sulphide in the gaseous mixture. The weight of stibnite and the initial pressure of the hydrogen were varied considerably, but at 440° the partial pressure was practically the same in every case, the extreme values being 42.98 and 43.6; this result was not affected by the preliminary addition of varying amounts of antimony, the mean of four experiments being 43.29. When the temperature is above the melting point of antimony sulphide, this compound dissolves the liberated antimony, so that in this case the equilibrium is established between two homogeneous systems. The final composition of the gas should now depend on the concentration of the solution of antimony in antimony sulphide, and therefore on the amount of stibnite originally present. The experimental results entirely justify this conclusion; at 610° , the amount of hydrogen sulphide increases as the weight of stibnite employed diminishes.

If an excess of antimony is present, the solution of the metal in its sulphide is always saturated, and in this particular case, providing that all the sulphide is not decomposed, the amount of hydrogen sulphide produced should depend solely on the temperature; in accordance with this generalisation, it is found that the factor determined increases with the temperature, being 48.6 at 510° and 56.92 at 625° . When hydrogen sulphide is left in contact with antimony in sealed tubes at constant temperatures, a certain amount of the gas is decomposed, and if the temperature is below the melting point of the metal, the limiting value of the partial pressure is identical with the factor obtained by treating stibnite with hydrogen at the same temperature. If, however, the antimony has melted, the value obtained for the partial pressure is lower than that observed in the inverse reaction; the discrepancy is probably due to the solution of the sulphide in the fused metal.

When the four substances are all present in the system studied, the value of the factor increases with the temperature, and supposing that, as at 15° , the direct reaction is accompanied by an absorption of heat, the experimental results are in complete agreement with the law relating to the variations of chemical equilibrium produced by changes of temperature.

G. T. M.

Crystallised Bismuth Salts. By AUGUST DE SCHULTEN (*Bull. Soc. Chim.*, 1900, [iii], 23, 156—158).—Three grams of bismuth oxide are dissolved in 300 c.c. of hydrochloric acid of sp. gr. 1.05, and the solution mixed with 2.5 litres of boiling water, filtered, and left to cool, when bismuth oxychloride, BiOCl , separates in colourless, quadratic crystals of sp. gr. 7.717 at 15° ; the crystals are negative and uniaxial. Bismuth oxybromide and oxyiodide are prepared in an analogous manner, and resemble the oxychloride in their crystallographic

and optical properties. The oxybromide is colourless and has a sp. gr. 8.082 at 15°, whilst the oxyiodide is of a coppery tint and has a sp. gr. 7.922. N. L.

Mineralogical Chemistry.

Coals, Bitumen, &c., from the Silurian of Bohemia. By C. FRIEDRICH EICHLER (Chem. Centr., 1900, i, 624—625; from *Verh. k.k. geol. Reichsanst. Wien*, 1899, 348—362).—Several analyses are given of coals and bituminous substances from fossiliferous strata.

L. J. S.

Cerussite from the Altai. By PAVEL V. VON JEREMÉEFF (*Zeit. Kryst. Min.*, 1900, 32, 429; from *Verh. k. russ. min. Ges.*, 1899, 36, Protok., 12—15).—Twin crystals of cerussite from the Sirjanowsk mine gave, on analysis by J. A. Antipoff.

PbO.	CO ₂ .	SO ₂ .	ZnO.	CdO.	Fe ₂ O ₃ .	Al ₂ O ₃ .	H ₂ O.	Insol.	Total.
77.63	14.12	2.07	0.51	0.15	6.63	1.42	1.24	1.38	99.15

This corresponds with 87.60 per cent. PbCO₃; the iron and aluminium belong to the gangue. A crystallographic description is given.

L. J. S.

Pseudomorphs after Olivine from the Urals. By PAVEL V. VON JEREMÉEFF (*Zeit. Kryst. Min.*, 1900, 32, 430; from *Verh. k. russ. min. Ges.*, 1899, 36, Protok., 24—27).—Various pseudomorphs after olivine from different localities in the Schischimsk and Nasjansk mountains, Urals, are described. The following analysis by Nikoléeff of the least altered crystals show them to be monticellite.

SiO ₂ .	Al ₂ O ₃ .	FeO.	CaO.	MgO.	Mn.	Loss on ignition.	Total.
36.44	0.62	2.80	32.11	25.35	trace.	1.68	99.00

The various stages in the process of alteration are suggested to be: the alteration of the olivine to serpentine, then, by the action of a solution containing an aluminosilicate, to epidote, and finally the partial alteration of the epidote to steatite and clay. L. J. S.

Composition of Plagioclase. By W. TARASSENKO (*Zeit. Kryst. Min.*, 1900, 32, 423; from *Tagebuch X. Vers. russ. Naturf. Aertze in Kiew*, 1898, No. 10, 379—380).—Labradorite from Selistsche, Gov. Wolinsk, was powdered and separated by a heavy liquid into six portions of sp. gr. (1) lighter than 2.647 (0.5 gram); (2) 2.647—2.669 (1.1 grams); (3) 2.669—2.675 (9 grams); (4) 2.675—2.680 (11 grams); (5) 2.680—2.710 (2.9 grams); (6) heavier than 2.710 (0.07 gram).

The four portions (2)—(5) gave on analysis the maximum and minimum results under I and II respectively.

	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃ , TiO ₂	CaO.	Na ₂ O.	K ₂ O.	Loss at 120°.	Loss on ignition.
I.	55.33	28.44	0.42	10.32	5.37	1.26	0.11	0.36
II.	55.09	28.02	0.30	10.01	5.04	0.98	0.04	0.33

This is considered to prove that the plagioclases are not isomorphous mixtures, but compounds of the albite and anorthite molecules in definite proportions.

L. J. S.

Two New American Meteorites. By H. L. PRESTON (*Amer. J. Sci.*, 1900, [iv], 9, 283—286).—*Luis Lopez, New Mexico.*—This iron, which weighs 6903 grams, was found in 1896 near Luis Lopez, Socorro Co. It contains numerous nodules of troilite surrounded by zones of schreibersite or of a graphitic substance. The etched surface shows typical octahedral Widmanstätten figures. The structure and chemical composition (anal. I by Mariner and Hoskins) of this iron distinguish it from the five other irons (Costilla, Glorieta, El Capitan, Sacramento Mts., and Oscuro) recently found in this portion of New Mexico.

	Fe.	Ni.	Co.	Si.	P.	S.	C.	Total.	Sp. gr.
I.	91.312	8.170	0.160	trace	0.338	0.013	0.012	100.000	7.7
II.	94.734	4.620	0.180	—	0.442	0.015	0.009	100.000	7.5

Central Missouri.—All that is known of the history of this iron is that it was found in the fifties in Central Missouri. About half the mass weighs 12360 grams. It is penetrated by numerous fissures filled with a graphite-like substance, and in part by schreibersite. The etched surface is minutely pitted. Analysis by Mariner and Hoskins gave the results under II.

L. J. S.

Water from Jouhe, near Dôle (Jura). By PAUL BOURCET (*Bull. Soc. Chim.*, 1900, [iii], 23, 144—145; *J. Pharm.*, 1900, [vi], 11, 223—224).—This water is only very slightly mineralised, the principal constituents being sodium and magnesium chlorides and calcium sulphate and hydrogen carbonate, whilst, contrary to the local opinion, it contains only a trace of dissolved hydrogen sulphide; the reputation for therapeutic power that it holds does not thus appear to be justified.

W. A. D.

Physiological Chemistry.

Relative Digestibility of Certain Fats in the Human Intestine. IV. Lard Substitute ("Kunstspeisefett"). By H. LÜHRIG (*Zeit. Nahr. Genussm.*, 1900, 3, 73—87).—Comparative experiments with genuine lard, and with two mixtures of fats sent into commerce as cheap lard-substitutes, of which the first consists of two parts of tallow and three parts of cotton-seed oil, and the second of

equal parts of the first and lard, show that the coefficient of digestibility of the three preparations is identical. As in former work on the digestibility of margarine (this vol., ii, 224) lecithin and unsaponifiable substances were allowed for. The analytical constants of the fats extracted from the faeces differed widely from those of the fats consumed, and there was no means of knowing whether these fats were secretions from the walls of the intestine, or consisted of unabsorbed residues of the alimentary fats. M. J. S.

The Proteid-sparing Action of Alcohol. By RUDOLF ROSEMAN (Pflüger's Archiv, 1900, 79, 461—483. Compare this vol., ii, 92).—Polemical. The author maintains his original contention and directs his criticisms against Offer (Wiener klin. Woch., 12, No. 41), who has disagreed with him. W. D. H.

Parachymosin. By IVAR BANG (Pflüger's Archiv, 1900, 79, 425—441).—Rennet ferment is destroyed by long digestion with pepsin-hydrochloric acid. Some differences in the details of the time relations of this destruction suggested that in different rennet preparations there were differences in the ferment itself. Further investigation was considered to prove that there are at least two rennet ferments; one, the ordinary rennet of the calf's stomach, termed here *chymosin*, and the other, found hitherto in preparations from the stomach of pigs and men, termed *parachymosin*. The differences between the two ferments are (1) on dilution with water the proportional loss of ferment activity gives a different curve in the two cases; (2) the hastening action of calcium chloride on their activity is quantitatively different; (3) chymosin is destroyed at 70°, parachymosin at 75°; (4) chymosin is more resistant to alkali than parachymosin. W. D. H.

Animal Juices and Tissues from the Physico-chemical Standpoint. II. Influence of the Blood Corpuscles on the Electrical Conductivity of Blood. Effect of Suspended Particles generally on Conductivity. By MAX OKER-BLOM (Pflüger's Archiv, 1900, 79, 510—533. Compare Abstr., 1900, ii, 290).—The electrical conductivity of a solution is mechanically diminished by suspended non-conducting particles, the extent of the diminution depending on the quantity and distribution of the particles, but being independent of their size (within certain limits), as well as of the absolute conductivity of the solution. The blood may be regarded as an electrolyte in which the corpuscles play the part of suspended non-conducting particles. For a given concentration of corpuscles, the ratio between the conductivity of the serum and that of the blood is constant, and independent both of the absolute conductivity of the serum and of the size of the individual corpuscles. J. C. P.

Specific Heat of Blood. By H. BORDIER (Compt. rend., 1900, 130, 799—800).—The values of the specific heats of arterial and venous blood, given by Landois in his *Traité de Physiologie*, are respectively 1.031 and 0.892, and the author, doubting the correctness of these values, has made fresh determinations, employing the method of cooling. Blood from the ox, calf, and dog, arterial and defibrinated,

as well as blood serum and venous blood, were examined, and the means of the results are: arterial blood, 0.906; venous blood, 0.893. The mean specific heat of the whole body is probably between 0.7 and 0.8.

BERTHELOT, in a footnote to the above paper, draws attention to the fact that the author has overlooked a paper (Abstr., 1890, 274) in which he showed that the specific heat varies notably with physiological conditions, and in which he recorded many determinations of the values.
L. M. J.

Oxygen in Human Blood. By A. LOEWY (*Chem. Centr.*, 1900, i, 49; from *Centr. Physiol.*, 13, 449—453).—From investigations on the influence of lessened oxygen supply on metabolism in man, the conclusion is drawn that the process can take a normal course, even when the oxygen tension is extremely low (35, or even 30 mm.). If the alveolar oxygen tension sinks below this, 'tissue dyspnoea' sets in, because, owing to the dissociation of oxyhæmoglobin, the supply of oxygen is insufficient. New work has led to some numerical results which differ from those of Hüfner (*Arch. Anat. Physiol.*, 1890); with oxygen tension of 36—37 mm. of mercury, the oxygen saturation of hæmoglobin is 80 per cent.; at 22—23 mm. mercury, it is 58.25 per cent. Hüfner worked with crystallised hæmoglobin, the present author with fresh blood. Possibly oxygen is more firmly held in the former than in the latter case.
W. D. H.

The Sense of Smell and the most important Perfumes. By ERNST ERDMANN (*Zeit. angew. Chem.*, 1900, 103—116).—The paper, which is of a popular character, contains a list of the more important substances used as perfumes, classified as (1) aldehydes, (2) alcohols and esters, (3) ketones, (4) phenols and phenyl ethers, (5) acids and acid anhydrides, (6) nitrogenous substances, (7) hydrocarbons.

C. F. B.

Different Effect of Ions on Animal Tissues. By JACQUES LOEB (*Amer. J. Physiol.*, 1900, 3, 383—396).—A controversy exists as to whether in the heart, and also in such animals as jelly fish, the contractions are of muscular or nervous origin. In *Gonionemus*, the medusa selected for experiment, it appears certain that ordinarily—that is, in the presence of the potassium and calcium salts of the sea-water—the impulses start in the margin, and, therefore, probably in the nervous system. Above all, it is the chemical, not the histological, structure of ganglia which is important. The central portions of the medusa beat rhythmically in pure solutions of sodium chloride or bromide. Curarised skeletal muscles do the same, provided potassium and calcium are absent. The calcium, &c., is not the stimulus for rhythmical contractions in the heart and other tissues, but the sodium, calcium, and potassium must exist in definite proportions in the tissue itself. Thus, if the amount of sodium is too small, an increase produced by placing the tissue in a pure sodium chloride solution will initiate rhythm. If the amount of calcium is too small, an increase of it will start rhythmical contractions. Thus, skeletal muscle may be made to beat by increasing the amount of sodium, or by decreasing that of calcium by precipitation.

Potassium annihilates muscular activity rapidly, but ciliary action and cell division, which are considered generally to be protoplasmic actions of the same order, continue in the presence of enormous quantities of potassium salts. The riddle of contractility is therefore still unsolved if the contractile processes are the same in all these cases. The most important combination for the furtherance of various vital processes is a mixture of $5/8 N$ potassium chloride and a small amount of $10/8 N$ calcium chloride. In such a solution, the development of ova progresses well. That sodium salts are absent suggests that the main importance of the metals lies in the influence they have on the physical properties of protoplasm; thus, magnesium chloride will often serve as a substitute for the potassium chloride in the above mixture. The arguments in the paper are based on the theory of ionic dissociation of salts in solution. W. D. H.

Chemistry and Physiology of the Thyroid. By AD. OSWALD (*Pflüger's Archiv*, 1900, 79, 450—460. Compare Abstr., 1899, ii, 439).—Polemical. Criticism is directed against Blum's conclusions. W. D. H.

Elimination of Mercury by Patients treated with this Metal. By FRIEDRICH ESCHBAUM (*Chem. Centr.*, 1900, i, 628; from *Deut. med. Woch.*, 26, 52—55).—See this vol., ii, 368.

[Elimination of] Carbohydrates [in Urine]. By G. ROSENFELD (*Chem. Centr.*, 1900, i, 657—658; from *Centr. inn. Med.*, 21, 177—189).—The alcohols dulcitol, mannitol, and sorbitol resemble their respective carbohydrates, galactose, mannose, and dextrose, in regard to their capability of being eliminated in urine, and in this respect follow in the order given, the position of the first two, however, being still doubtful. Mannitol and dulcitol contribute little if anything to the formation of glycogen. Disregarding the possibility that the carbohydrates are converted into glycogen before being oxidised, then considerable quantities of these substances should occur in urine, and in fact 40 per cent. of the mannitol and 60 of the dulcitol ingested were found in human urine. These alcohols thus behave like dextrose in cases of diabetes. Pentacetyl galactose, when administered in large doses, is more easily oxidised than galactose, and also passes into the urine more readily without partaking in the production of glycogen. In this case, the pentacetyl galactose may possibly undergo an abnormal decomposition and not yield acetic acid and galactose. E. W. W.

Pharmacology of Chloretone [Acetonechloroform]. By T. B. ALDRICH and E. M. HOUGHTON (*Proc. Amer. Physiol. Soc.*, Dec., 1899; *Amer. J. Physiol.*, 1900, 3, xxvi—xxvii).—Acetonechloroform is regarded as an ideal anæsthetic for experimental purposes. The bodily functions are but little affected, and even after hypnosis lasting for days the animal recovers completely. Its action on the central nervous system is like that of other anæsthetics of the fatty series, although it differs in not depressing the circulatory system. The application of the drug to the exposed frog's heart produces slowing, but more complete contraction, much as digitalis does. It is a powerful germicide. It can be recovered from the brain substance, and although volatile

it is not eliminated from the lungs. The chlorides of the urine are increased, and small quantities of chloretone appear there also. As a surgical dressing it is satisfactory, wounds healing by first intention. Cilia and spermatozoa remain active for hours in a saturated aqueous solution.

W. D. H.

Physiological Action of Formaldehyde. By GIUSEPPE BRUNI (*Chem. Centr.*, 1900, i, 51—52; from *Ann. Farm. Chim.*, 1899, 324—345).—Formaldehyde of completely neutral reaction can be borne better than the acid commercial material by the animal organism. Administered internally, even in dilute solutions, formaldehyde causes vomiting. In a few days, with non-poisonous doses, there is hardening of the tissues. The acid solution is much more fatal to micro-organisms than the neutral. The antiseptic properties of formaldehyde are far greater than those of boric acid.

W. D. H.

[Physiological Action of] Mercury Derivatives of Aromatic Amines. By ALBERICO BENEDICENTI and ORESTE POLLEDRO (*Atti. Real. Accad. Torino*, 1900, 35, 297—318).—A series of experiments has been carried out on the toxicological action of *p*-mercuriodiphenylene-tetraethylmercuridiammonium acetate, called shortly diethyline.

Diethyline facilitates the precipitation of albumin and the coagulation of blood serum; it also hinders the putrefaction of these substances, its action in this respect resembling that of calomel. Like calomel, too, diethyline does not entirely stop the fermentative processes brought about by ptyalin and pepsin, which are, however, rendered less active; it does not impede the digestive processes of the stomach juices, but prevents putrefaction, the same action being exercised also in the intestines of the living animal. The only lower animals subjected to the action of diethyline were earthworms, which died much more quickly when immersed in a solution of the substance in olive oil than when in the pure oil; when given with food, diethyline probably acts as a vermifuge in the intestines, as in the faeces of rabbits to which it was administered numbers of small dead worms were always found.

On the vertebrates, diethyline has a slow cumulative poisoning action similar to that of other mercurial preparations; after death, the intestine shows hyperæmia, although much less intense than in acute poisoning, the liver being of a dark colour and the kidneys exhibiting small hæmorrhages. The pressure of the blood is diminished and the pulse slackened, whilst the urine shows the presence of mercury and an optically active sugar, but not of albumin.

T. H. P.

Chemistry of Vegetable Physiology and Agriculture.

Bacteria which Destroy Nitrates. By ALBERT STUTZER and R. HARTLEB (*Bied. Centr.*, 1900, 29, 126—128; from *Mitt. landw. Inst. Breslau*, 1900, Heft i, 108).—Hexoses and pentoses, like salts of

organic acids, can serve as sources of food and energy for bacteria which destroy nitrates. The non-denitrifying bacteria hitherto employed did not permanently hinder denitrification, and it is improbable that microbes exist which check the activity of those which destroy nitrates, so long as these have assimilable organic matter at their disposal under conditions of limited aëration.

It is suggested that stable manure should receive layers of calcareous material to neutralise the organic acids which act unfavourably on the bacteria present in the manure, in order, as quickly as possible, to get rid of the carbonaceous substances which are utilised by denitrifying microbes. Loss of ammonia may be hindered by covering the calcareous layers with soil or peat litter. N. H. J. M.

Denitrification and Decomposition of Animal Matters in Soil. By CASIMIR ROGÓYSKI (*Ann. agron.*, 1900, 26, 121—140).—Soil (233 or 200 grams), both alone and with addition of sodium nitrate, horse-dung, and urine, singly and in different mixtures, was kept for different periods of several weeks in funnels under glass shades, with provision for aëration and for absorbing any ammonia which might be evolved. At the commencement and at the conclusion of the experiments, the amounts of nitrogen in different forms was determined.

The conclusion is drawn that when denitrification takes place in presence of abundance of dung, the nitric nitrogen may, according to the conditions, be eliminated in the free state, or else it may be partly or wholly transformed into insoluble nitrogenous compounds.

When urine or ammonium salts are applied to soil along with much dung or straw, the nitrogen of the urine may be liberated in the free state, or converted into an insoluble state. The insoluble substances thus produced seem to undergo nitrification readily.

The above conclusions only hold good when dung is employed in much greater amounts than occurs in practice. With amounts of dung less excessive (but still in excess of the amounts ordinarily employed), nitrates remain unchanged in the soil, and urine is nitrified. The practical conclusions drawn from the results of the German experiments on denitrification are therefore not justified (compare Dehérain, *Abstr.*, 1898, ii, 630, and 1899, ii, 800; and Warington, *ibid.*, ii, 800). N. H. J. M.

Importance of Bacteria for the Development of Plants. By JULIUS STOKLASA (*Zeit. Zuckerind. Böhm.*, 1900, 24, 222—227).—*Brassica oleracea* was grown in enclosed vessels containing sterilised loamy sand (16 kilos.) manured with minerals and nitrate. One vessel remained sterilised in each experiment, whilst the other was inoculated with a mixture of the following soil-bacteria: *Bacillus mycoides*, *B. fluorescens liquefaciens*, *B. proteus vulgaris*, *B. subtilis*, *B. butyricus* Hueppe, *B. megatherium*, *B. uræ*, *B. mesentericus vulgatus*, and *B. coli commune*. The inoculated vessels received 5 grams of dextrose. At the conclusion of the experiment, it was found that the sterilisation of the vessels which had not been inoculated had been maintained. In the second experiment, the seed sown in the two vessels was obtained

from the corresponding plants of the first experiment. The following amounts of dry produce were obtained :

	I.		II.		III.	
	Stems, &c.	Seed.	Stems, &c.	Seed.	Stems, &c.	Seed.
Sterilised ...	11.65	1.63	8.84	0.72	9.00	0.33
Inoculated...	15.34	3.06	13.9	2.67	12.8	2.62

The results show that in absence of micro-organisms vegetation is abnormal, and that incompletely developed seed is produced.

N. H. J. M.

Influence of Light on the Respiration of Lower Fungi. By R. KOLKOWITZ (*Bied. Centr.*, 1900, 29, 121—122; from *Jahrb. wiss. Bot.*, 33, 37).—In constructing a respiration apparatus, the Pettenkofer method was adopted with some modification. Compressed air free from carbon dioxide, contained in a steel cylinder, is passed over the object of the experiment, the carbon dioxide evolved being absorbed by baryta. Electric light was employed, and electricity was also employed for heating.

It was found that light increased the respiration of *Aspergillus niger*, *Penicillium*, *Micrococcus prodigiosus*, *Proteus vulg.*, *Oidium lactis*, and *Mucor spec.* to the extent of about 10 per cent.

Different investigators have obtained very divergent results, and it is thought to be necessary that the experiments should be greatly extended.

N. H. J. M.

Production of Sucrose from Dextrose in the Cell. By J. GRÜSS (*Bied. Centr.*, 1900, 29, 136; from *Ber. deut. bot. Ges.*, 1898, 16, 17—20; and *Bot. Centr.*, 1898, 75, 15).—In experiments with barley embryos from seeds kept for 12—18 hours in water, it was found that sucrose can be formed from dextrose in the cells, and that starch and cellulose can be produced from sucrose. No aldehyde group in the sucrose molecule becomes free in the production of starch and cellulose.

N. H. J. M.

Influence of Nitrogen on the Growth of Roots. By HERMANN MÜLLER-THURGAU (*Bied. Centr.*, 1900, 29, 101—103; from *Jahresber. Wädenswil.*, 6, 45).—Water-culture experiments were made with various plants, in which portions of the roots were kept immersed in nutritive solutions containing mineral food and nitrate, the rest being in similar solutions, but without nitrate.

It was found that root development was greatest in presence of nitrate, that the roots were then more branched, and that they were richer in proteids than those which were not directly fed with nitrate.

The conclusion is drawn that roots are able to produce proteids when sugar is supplied from the leaves.

N. H. J. M.

Metamorphoses and Migrations of Compounds of the Linalool Group in Plants. By EUGÈNE CHARABOT (*Bull. Soc. Chim.*, 1900, [iii], 23, 189—191).—General remarks on the results described in previous papers by the author (*Abstr.*, 1899, i, 620, 711; this

vol., i, 241; ii, 101). The changes undergone by linalool and its derivatives during development are well shown in the essential oils obtained from the leaves, flowers, and fruit of the orange (*Citrus bigaradia*). The oil from the leaves contains about 60 per cent. of acetates of linalool and geraniol, and 20—25 per cent. of the free alcohols, whilst the proportion of limonene is small, but increases as growth proceeds. In the flowering stage, the amount of limonene is considerably increased, whilst the esters and total alcohols have fallen to 15 and 50 per cent. respectively. When localised in the rind of the fruit, the proportion of limonene in the oil is still greater, but the alcohols have almost completely disappeared, the linalool having been converted into limonene and the geraniol into citral. N. L.

Influence of Active Vegetative Growth on the Formation of Thujone and Thujol. By EUGÈNE CHARABOT (*Compt. rend.*, 1900, 130, 923—926. Compare Abstr., 1899, i, 441, 620, 711, and this vol., i, 241, and ii, 101).—The author's researches on the transformation of the terpenoid constituents of the essential oils during the growth of essence yielding plants, indicate that the changes take place in two distinct stages corresponding with the principal phases of the growth of the organism. The elaboration of the alcohols and their conversion, by the elimination of water, into esters, ethers, and terpenes occurs in the green parts of the plant and corresponds with the period of active assimilation.

The second stage of the transformation involves the oxidation of the primary and secondary alcohols into aldehydes and ketones respectively, and this corresponds with that phase in the life of the plant when the respiratory function predominates over the assimilative energy.

An examination of two samples of the essential oil of *Artemisia Absinthium* indicates that, during a period of slow growth, the amount of thujol (tanacetyllic) alcohol oxidised to thujone (tanacetone) is comparatively large, but that after a period of rapid assimilation the formation of the ketone does not keep pace with the elaboration of the alcohol. G. T. M.

Pure Culture of a Green Alga. Formation of Chlorophyll in the Dark. By MAXIME RADAIS (*Compt. rend.*, 1900, 130, 793—796).—The author, having succeeded in isolating the unicellular green alga *Chlorella vulgaris* of Beyerinck, cultivated specimens of the plant in total darkness in media rich in proteid matter and carbohydrate; under these conditions, the organism passes through an etiolated stage and then develops chlorophyll; when grown in the presence of light, the development proceeds in a similar manner, only the etiolated phase is shorter. Spectroscopic examination of the alcoholic and carbon disulphide extracts of the cells cultivated in the dark confirms the presence of chlorophyll and shows that it is identical with the colouring matter obtained from the plant when grown under ordinary conditions; the amount of chlorophyll produced is approximately the same in both cases. G. T. M.

Oil of Carthamus Tinctorius (Safflower Oil). By HENRY R. LE SUEUR (*J. Soc. Chem. Ind.*, 1900, 19, 104—106).—The following are

the means obtained in the determination of the constants of safflower oils: sp. gr. at 15.5°, 0.9267; saponification value, 189.83; acid figure, 6.14; iodine number, 141.29; Reichert-Meissl number, *nil*; insoluble fatty acids, 95.3; acetyl number, 16.1. Roughly speaking, the oil consists of 90 per cent. of glycerides of unsaturated acids and 10 per cent. of glycerides of saturated acids. The acids identified were stearic, palmitic, oleic, and linoleic, the last-named forming the larger portion of the oil. The oil has very good drying properties.

L. DE K.

Toxic Action of Compounds of the Alkaline-earth Metals towards the Higher Plants. By HENRI COUPIN (*Compt. rend.*, 1900, 130, 791—793).—A study of the action of calcium, strontium, and barium salts on young wheat plants shows that with soluble homologous compounds the toxic effect increases with the atomic weight; the insoluble salts of these metals are all innocuous. The soluble salts of calcium and strontium have a marked toxic action on plants, and their iodides are very poisonous; the soluble barium salts are all very injurious to plant life, the action being most intense in the case of the chlorate and iodide. The toxic equivalents of these compounds are arranged in tabular form.

G. T. M.

Assimilation by Plants in Soils containing different Amounts of Sand. By EMANUEL GROSS (*Bied. Centr.*, 1899, 29, 73—74; from *Fühling's landw. Zeit.*, 1899, 291).—Pot experiments are described in which barley and white mustard were grown in soil, and in the same soil (100 parts) mixed with 33, 100, and 300 parts of sand. No manure was added. In both cases, the yield and the amounts of nutritive constituents assimilated diminished, but this diminution was not in relation to increasing dilution of the soil with sand. As the amount of sand increased, the percentage amounts of the nutritive constituents of the soil which were assimilated also increased. In pots 1 (barley), with soil alone, and 4 (soil with 3 parts of sand), the percentage amounts utilised by the plants were: N, 27.3 and 58.5; K₂O, 37.9 and 86.8; CaO, 3.5 and 8.2; P₂O₅, 30.2 and 72.5. It is concluded that light sandy soils require plenty of manure, not only because they are poor in nutritive substances, but because the assimilating power of plants is greater in sandy than in heavier soils.

N. H. J. M.

Relation between the Weight and the Percentage of Nitrogen in Barley Grain. By WILHELM JOHANNSEN (*Bied. Centr.*, 1900, 29, 110—112; from *Meddel. Carlsberg. Lab.*, 1899, 4, 228—313).—Ripe, completely developed grains from different ears of the same variety of barley, grown on a small experimental bed, showed great variations in the percentage of nitrogen; an average analysis of barley grain is therefore insufficient for determining the quality, from a chemical point of view, of the crop. The different ears from one plant do not as a rule vary much in composition, but occasionally they varied a good deal. This lends support to the view that the nature of an entire plant and not of a part of the plant should be

taken into account in selecting for the purpose of obtaining improved varieties.

The percentage of nitrogen generally increased with the weight of the grain; but the different series showed considerable variations, the rise in percentage of nitrogen being sometimes great, and sometimes hardly appreciable. Ears, with large grain and low percentage of nitrogen, selected for three generations, gave, in the fourth generation, grain which was somewhat heavier, and which contained distinctly less nitrogen than the grain of previous crops.

The author considers that the doctrine of the "incompatibility of the valuable properties of cultivated plants," advocated by Schindler and von Proskowetz, is of very limited scientific value, and that, practically, it only means that certain improvements are more difficult to obtain than others.

N. H. J. M.

Fenugreek. By GIUSEPPE D'ANCONA (*Landw. Versuchs.-Stat.*, 1899, 51, 387—396. Compare Pasqualini, *Ann. Staz.-Agrar. Forlì*, 1873, 1874, and 1876; and Jahns, *Abstr.*, 1886, 85).—Analysis of two samples of fenugreek gave the following results: Nitrogenous matter, 13.74 and 13.02; fat, 3.31 and 3.54; crude fibre, 31.75 and 29.36; nitrogen-free extract, 45.79 and 48.14; ash, 5.42 and 5.94 per cent. in the dry matter. The pure ash contained (per cent.):

	K ₂ O.	Na ₂ O.	CaO.	MgO.	Fe ₂ O ₃ .	P ₂ O ₅ .	SO ₃ .	SiO ₂ .	Cl.
1.	19.37	7.60	30.73	1.19	4.71	8.24	4.35	21.97	1.23
2.	18.85	7.55	28.92	0.96	5.08	7.87	3.91	25.19	0.99

In composition, fenugreek resembles *Trifolium incarnatum*. Its cultivation is recommended on account of the large crops which can be got without making a great demand on the soil. There seems to be no doubt that feeding with fenugreek gives rise to an unpleasant taste both in meat and in milk, and it is suggested that the fodder might be employed for working animals. The peculiar odour of the plants observed in April and May disappears, however, at the time of cutting. The odour is attributed to the presence of an oil (Jahns, *loc. cit.*).

N. H. J. M.

Amount of Mineral Matter and Nitrogen in Sugar Beet variously manured and in different Soils. By W. SCHNEIDEWIND (*Bied. Centr.*, 1900, 29, 81—84; from *Blätt. Zuckerrübenbau*, 1899, 6, 145).—The results of several years' experiments showed that the amount of sugar in fresh beet generally varies, in single years, inversely with the amount of ash. When the plants take up much potash, the percentage of sugar is only lowered when the amount of ash exceeds a certain limit; a slight increase in the amount of ash, when due to potash, will even raise the percentage of sugar.

In wet soils, the plants take up more water and mineral matter, but this does not involve greater production of organic non-saccharine matter. Except on peat land, the better kinds of beet contain very little ash compared with the varieties formerly grown; even when heavily manured with nitrate or with dung and nitrate, the percentage of ash remains low. Application of large amounts of manure results

in a high percentage of ash in the leaves, and the production of leaf is increased by large amounts of nitrogenous manure.

In the first periods of growth, sodium nitrate is more effective than potassium nitrate, owing, it is thought, to its being more readily soluble and diffusible, and to the fact that soda is not, like potash, absorbed by the soil. At the present time, sugar-beet contains only about half as much potassium and about twice as much sodium as formerly. As regards magnesium, the amounts present in roots have not changed much, but the leaves contain a good deal less than formerly. In the case of phosphoric acid, the roots contain less than formerly, whilst in the leaves the amount has remained the same. The employment of Stassfurt salts does affect the percentage of sugar, as the chlorides are stored in the leaves; the presence of chlorides is, besides, beneficial, since they diminish the amount of organic acids to which the production of molasses is mainly due. N. H. J. M.

Use of Commercial Fertilisers for Forcing House Crops. By EDWARD H. JENKINS and W. E. BRITTON (*21st Annual Rep. Agr. Exper. Stat. Connecticut* for 1897, 278—308. Compare Abstr., 1899, ii, 511).—*Tomatoes.* A mixture of coal ashes and peat with chemical manures gave greater yields than a rich compost of peat and manure. The greatest yield was obtained after application of sodium nitrate, 6·4 lb., dissolved bone black, 1 lb., and ammonium chloride, 2·4 lb. per 100 square feet. In presence of large amounts of soluble plant food in ashes and peat, the root system is much less extensive than in the case of plants growing in compost.

The experiments with carnations and radishes (*loc. cit.*) were also continued. N. H. J. M.

Vegetation Experiments with Sugar Beet. By H. WILFARTH and G. WIMMER (*Zeit. Ver. Deut. Zucker-Ind.*, 1900, 173—194).—The cultivation of sugar beet involves greater difficulties than is the case with cereals, potatoes, tobacco, &c., the quality as well as the yield being affected by unsuitable conditions. Variations in quality occur chiefly in the percentage of sugar and in the quotient; and not only the total nitrogen, but especially the amount of amides, has to be considered.

Excess or deficiency of water, nitrogen, and potassium are the conditions which most affect the beet-crop; and large amounts of nitrogen are only permissible when other conditions are satisfactory. The tendency to rot is shown to be connected with an alkaline secretion, due to the separation of the bases of the nitrate. To overcome this difficulty, gypsum is applied in conjunction with potassium nitrate, and the amount of humus is increased by addition of peat. Even when calcium nitrate is employed, lime may be liberated more quickly than it can be converted into carbonate. In dry seasons, abundance of potassium seems to compensate for deficiency of water.

Amides were determined by boiling the pulp (50 grams) with water (250—300 c.c.) and hydrochloric acid of sp. gr. 1·124 (6 c.c.) for half an hour, and distilling with *magnesia usta* into standard sulphuric acid.

Paraffin is added to prevent frothing. The small amounts of ammonia produced from proteids, &c., are not of practical importance.

N. H. J. M.

Does Nitrogenous Manure injure succeeding Crops when applied to Seed Beet? By H. WILFARTH (*Zeit. Ver. Deut. Zucker-Ind.*, 1900, 58—65).—The results of the author's experiments indicate that heavy applications of nitrogenous manure to sugar-beet grown for seed have no injurious effect on subsequent crops grown from the seed so obtained. The conclusion accords with what has been observed in practice (compare Rimpau, *Oesterr. Zeit. Zuckerind.*, 19, 615; Marek, *ibid.*, 1885, 768; Strohmer, Briem, and Stift, *ibid.*, 1892, 21, 244; and 1895, 279, 788, and Abstr., 1896, ii, 538; and Drechsler, *J. Landw.*, 1877, 117).

N. H. J. M.

Analytical Chemistry.

Gas Absorption Apparatus. By ARMAND GAUTIER (*Bull. Soc. Chim.*, 1900, [iii], 23, 141—144).—The apparatus consists of two bulbs, each of about 10 c.c. capacity, connected together by a straight, vertical tube 10—12 cm. long, reaching nearly to the bottom of the lower bulb, and also by a long spiral wound round the vertical tube. The gas first enters the lower bulb and then ascends the spiral, where it is broken up into a series of small bubbles and brought into intimate contact with the absorbing liquid, which subsequently descends into the lower bulb by means of the straight, vertical tube. The apparatus is compact, readily weighed with accuracy, and very efficient.

N. L.

Estimation of Iodic Acid in Sodium Nitrate. By R. AUZENAT (*Chem. Centr.*, 1900, i, 571; from *Mon. sci.*, [iv], 14, i, 72).—Both nitrates and iodates liberate iodine from potassium iodide on addition of sulphuric acid, but only the latter do so when acetic acid is used. A colorimetric estimation is based on this fact.

M. J. S.

Estimation of Sulphites and Thiosulphates in the presence of each other. By GEORG LUNGE and D. SEGALLER (*J. Soc. Chem. Ind.*, 1900, 19, 221—223).—The authors state that the unsatisfactory results obtained by Richardson and Akroyd with Lunge and Smith's process for the estimation of mixed sulphites and thiosulphates by means of standard iodine and potassium permanganate (*ibid.*, 1883, 2, 463) were caused by their not exactly following the directions laid down in the original paper. The process has been tried again with results quite as satisfactory as those given by Richardson and Akroyd's own process (Abstr., 1898, ii, 91).

In Lunge and Smith's process, there are only two titrations to be made, whilst in Richardson and Akroyd's process there are three; the former method is consequently the more expeditious.

L. DE K.

Estimation of Phosphoric Acid soluble in 2 per cent. Citric Acid Solution. By ALEXANDER HERZFELD (*Zeit. Ver. Deut. Zucker-Ind.*, 1900, 77—78).—The abnormal result previously described (this vol., ii, 243) was due to the want of full details of the method employed by the German Experiment Stations.

The method, which has been published by Wagner, is as follows: a half-litre flask containing alcohol (5 c.c.) and the basic slag (5 grams) is filled to the mark with 2 per cent. citric acid solution (at 17.5°), placed at once in a rotary apparatus (turning 30—40 times a minute) for half an hour, and then immediately filtered.

(1) 50 c.c. of the filtrate are treated with molybdate solution (100 c.c.), placed for 10—15 minutes in a water-bath heated at 60° or 90—95°. When cold, the precipitate is collected, washed with 1 per cent. nitric acid, and dissolved in about 100 c.c. of cold 2 per cent. ammonia. The solution is precipitated with 15 c.c. of magnesia mixture, being well stirred, and left for about 2 hours.

(2) 50 c.c. of the extract is at once treated with 50 c.c. of magnesia mixture containing citrate, and stirred, or violently agitated, for 30 minutes. The precipitate is filtered within half an hour.

N. H. J. M.

Volumetric Estimation of Boric Acid. By BERNHARD FISCHER (*Zeit. Unters. Nahr. Genussm.*, 1900, 3, 17—21).—To obtain accurate results by Jörgensen's method, the following precautions should be observed. The boric acid should be in combination with potassium or sodium. Organic matter should be destroyed by incineration, which may be carried to complete fusion if a little alkali carbonate is added. The aqueous solution of the fused mass is coloured by methyl-orange, and dilute sulphuric acid is added in the cold until the mixture is distinctly red. A few drops more acid are added, and the liquid is boiled for a moment to expel carbon dioxide. The liquid, which has become yellow on heating, is again completely cooled, when the red colour should return. It is then accurately neutralised, by first adding sodium hydroxide until yellow, and then $N/2$ sulphuric acid until the transition tint is obtained. Glycerol and phenolphthalein are added, and the acidity is estimated with $N/2$ soda. When the red colour is obtained, it is well to add a further quantity of glycerol, and if no more soda is then required than that necessary for the acidity of the glycerol itself (which should always be estimated and allowed for), the titration may be regarded as finished. With careful observations of the indicator tints the results are very close, and with such substances as margarine (saponified without using alcohol) are of almost theoretical accuracy; but the method is inapplicable to meat (compare Beythien and Hempel, this vol., ii, 313), since phosphates disturb the results seriously.

M. J. S.

Colorimetric Method for the Estimation of Silica in Mineral Waters. By ROBERTO SALVADORI and G. PELLINI (*Gazzetta*, 1900, 30, i, 191—194).—The estimation of silica by Jolles and Neurat's method (*Abstr.*, 1898, ii, 455) gives good results with the water of Bagnoli (*Abstr.*, 1899, ii, 771), but with waters containing a large proportion of salts, especially halogenated compounds, discordant

numbers are obtained. The presence of phosphoric or arsenic acid has no disturbing influence on the determination. The yellow colour with molybdic acid solution is just visible with a solution containing 0.003 gram of silica per litre, which must be regarded as the limit of sensitiveness of the method.

T. H. P.

Mechanical Analysis of Soils. Separation of Clay and Sand. By GIUSEPPE SCARLATA (*Chem. Centr.*, 1900, i, 571; from *Staz. sperim. agrar. ital.*, 32, 634).—About 5 grams of the soil are placed in a thin beaker, of 500 c.c. capacity, furnished at one side with a stop-cock syphon, and at the other with a stop-cock tube by which water can be admitted. The soil is acidified with hydrochloric acid, and water is added until it reaches to 2 cm. from the edge of the beaker, and while keeping the level constant, a slow stream of water is passed through the vessel, which meanwhile is gently warmed. When the supernatant liquid is perfectly clear, the flow of water should be stopped, and the contents of the beaker boiled; if the separation is complete, the liquid will remain clear. The results agree well with those obtained with Schloësing's apparatus.

M. J. S.

Detection of Mercury in Urine. By M. HOEHNEL (*Chem. Centr.*, 1900, i, 627—628; from *Pharm. Zeit.*, 45, 126).—1 litre of urine is concentrated on the water-bath to 250 c.c., 3—4 grams of pure potassium cyanide are added, and the whole heated for half an hour at 60—70°. Into the brown filtrate 2 or 3 strips of carefully cleaned copper foil are introduced, and the whole is left for 2 hours at 60—70°; the strips of copper are then taken out, washed with water and alcohol, and exposed for half an hour to the air. If the urine contained mercury, this will form the well-known deposit on the copper, which may be further verified in the usual manner.

L. DE K.

Clinical Estimation of Mercury in Urine. Elimination of Mercury in Patients treated with this Metal. By FRIEDRICH ESCHBAUM (*Chem. Centr.*, 1900, i, 628; from *Deut. med. Woch.*, 26, 52—55).—The process is briefly as follows. The urine is boiled with some dextrose, and a sufficient amount of aqueous sodium hydroxide is added to precipitate the phosphates. After pouring off the clear, supernatant liquid, the precipitate is dissolved in hydrochloric acid and then heated at 45—60° with copper gauze. This, after being duly washed with alkali, water, and alcohol, is dried for half an hour in the air and then heated in a glass tube; the mercury which condenses on the cold sides of the tube is removed by introducing a weighed piece of silver foil with which it instantly amalgamates. The increase in weight represents the mercury; by way of a check, the silver may be heated and the mercury found by the loss in weight.

The urine of patients treated with Werler's ointment, which contains 10 per cent. of colloidal mercury, showed, after 48 hours, distinct traces of mercury; this could still be detected for 6 weeks after the cure.

L. DE K.

Electrolytic Estimation of Lead in the Sulphate and Chromate. Application to the Analysis of Lead Glass and Lead Chromates. By CH. MARIE (*Compt. rend.*, 1900, 130, 1032—1033).—The lead sulphate or chromate is dissolved in a mix-

ture of nitric acid and ammonium nitrate, and the solution electrolysed at 60—70° in the usual manner. Lead glass is subjected to a preliminary treatment with sulphuric and hydrofluoric acids in order to convert the bases into sulphates. N. L.

Analysis of Copper. By JOHN CLARK (*J. Soc. Chem. Ind.*, 1900, 19, 27—28).—The solution, which must contain free hydrochloric acid, is mixed [with excess of potassium iodide and then with sufficient sodium sulphite to remove the free iodine. If the solution should contain free nitric or sulphuric acid, it must first be rendered alkaline with sodium carbonate, and afterwards be cleared by means of hydrochloric acid. The cuprous iodide, derived from at least 10 grams of the metal to be tested, is thrown on a filter and washed, first with dilute hydrochloric acid, and then with cold water. The filtrate is boiled until the sulphur dioxide is expelled, and then mixed with excess of ammonia or aqueous sodium hydroxide, which should not produce a precipitate; ammonium or sodium sulphide is added to precipitate the last traces of copper, and also any lead, bismuth, &c.; arsenic, tin, and antimony are not precipitated. By adding excess of hydrochloric acid and passing hydrogen sulphide, the arsenic, tin, and antimony are precipitated as sulphides, and may be separated by boiling in a distilling flask with strong hydrochloric acid, whereby the arsenic sulphide is decomposed and volatilised (*Trans.*, 1892, 61, 424); the arsenic may then be recovered from the distillate by means of hydrogen sulphide. The solution left in the flask, and containing the antimony and tin, is then boiled with steel turnings, which throw down the antimony as metal, and reduce the tin to the stannous state; this is precipitated as sulphide, and finally converted, as usual, into oxide and weighed. The antimony and the undissolved steel are dissolved in hydrochloric acid and potassium chlorate, precipitated with hydrogen sulphide, and the antimony finally weighed as sulphide.

The metals which have been precipitated with ammonium sulphide in the alkaline tartrate solution may be dissolved in hydrochloric acid and a little potassium chlorate, precipitated with hydrogen sulphide, and then redissolved by means of hydrochloric acid and potassium chlorate. The bismuth and copper are precipitated by means of steel turnings (see this vol., ii, 371), converted into sulphides, dissolved in nitric acid, and the bismuth thrown down with ammonium carbonate, and weighed as oxide. To the filtrate from the bismuth and copper, excess of sodium acetate is added, and any lead (unless this has already been removed before precipitating the copper with potassium iodide) is precipitated with sulphuric acid and weighed as sulphate. Iron, nickel, zinc, &c., are estimated in the usual way.

The process previously referred to for separating arsenic, antimony, and tin will be found very useful in qualitative analysis. The mixed sulphides are introduced into a small flask, mixed with about 20 c.c. of strong hydrochloric acid, and distilled into a test-tube containing water; if arsenic is present, a yellow precipitate, due to arsenic trisulphide, makes its appearance. The residual liquid is filtered, if necessary, boiled with steel (not iron) turnings to precipitate the antimony, and the filtrate tested for stannous tin with mercuric

chloride. The antimony is mechanically removed from the steel, then dissolved in hydrochloric acid and potassium chlorate, and its solution divided into two parts; in one of these, the antimony is tested for with hydrogen sulphide, and to the other the test with zinc on platinum foil is applied.

L. DE K.

Estimation of Copper in Cyanide Solutions. By J. E. CLENNELL (*J. Soc. Chem. Ind.*, 1900, 19, 14—16).—10 to 50 c.c. of the solution to be tested, which must be perfectly clear, are placed in a 100 c.c. flask, and *N*/10 sulphuric acid is added from a burette with continual shaking, until the turbidity formed ceases to disappear, but leaves the liquid slightly milky. After carefully reading the burette, a further quantity (A) of the acid is added, more than sufficient to precipitate the whole of the copper. The flask is now filled up to the mark with water and thoroughly shaken, when the precipitate will generally settle rapidly in a flocculent condition. 50 c.c. of the supernatant liquid are now filtered and titrated with *N*/10 solution of sodium carbonate, a single drop of methyl-orange (1:400) serving as indicator. The strength of the sodium carbonate solution must be accurately determined with reference to the sulphuric acid used in the first stage of the test. The number of c.c. of sodium carbonate used, multiplied by 2, gives approximately the equivalent of the excess of sulphuric acid beyond that required to precipitate the copper.

Let B represent the number of c.c. of sodium carbonate used for 50 c.c. of the filtrate, and C the number of c.c. of sulphuric acid equivalent to 2B, then $A - C$ represents the number of c.c. of sulphuric acid equivalent to the copper present.

L. DE K.

[Analysis of] Molybdenum Sulphides. By MARCEL GUICHARD (*Bull. Soc. Chim.*, 1900, [iii], 23, 147—156).—The preparation of molybdenum disulphide and sesquisulphide has been already described (this vol., ii, 144 and 211); in the present paper an account of the analytical methods employed is also given. The sulphides are decomposed by heating with nitric acid or by fusion with potassium nitrate and sodium carbonate, and the nitric acid removed by evaporation with hydrochloric acid; the sulphuric and molybdic acids thus formed are finally weighed as the barium and lead salts respectively. The molybdenum alone may be estimated by igniting the sulphide, with or without previous treatment with nitric acid, at a temperature below redness, and weighing the residue of molybdenum trioxide. Molybdenite may be conveniently heated to bright redness in a current of oxygen when molybdenum trioxide sublimes, whilst the iron and silica are found in the residue.

N. L.

Phosphotungstic Acid as a Reagent for Potassium. By EMIL WÖRNER (*Chem. Centr.*, 1900, i, 517; from *Ber. Deut. pharm. Ges.*, 10, 4).—Neutral or acid solutions of potassium and ammonium salts give a white precipitate with phosphotungstic acid. Slight warming favours, alcohol hinders, the precipitation. To distinguish potassium from ammonium, the precipitate may be boiled with sodium hydroxide, and after acidifying with hydrochloric acid, the reagent added afresh. A fraction of a milligram of potassium chloride gives the reaction distinctly.

M. J. S.

Separation of Bismuth from Lead. By JOHN CLARK (*J. Soc. Chem. Ind.*, 1900, 19, 26—27).—The solution containing the two metals, which should be in the form of chlorides, is boiled with steel turnings which rapidly bring down the bismuth; care must be taken to have a slight excess of the steel, as otherwise a portion of the bismuth will redissolve.

The bismuth and the undissolved steel are washed with water, dissolved in hydrochloric acid with the aid of potassium chlorate, and the bismuth is then precipitated as sulphide; this, after being thoroughly washed free from iron, is dissolved in nitric acid and precipitated with ammonium carbonate. The bismuth carbonate is then converted into oxide and weighed.

L. DE K.

Detection of Minute Quantities of Gold in Ores. By THEODOR DÖRING (*Chem. Centr.*, 1900, i, 516—517; from *Berg.-Hüttenm.*, 59, 49).—Otto has shown that a white, infusible ash of paper acquires a rose-red to purple coloration if the paper has been soaked in a solution which leaves metallic gold when ignited, and has suggested the extraction of ores with either tincture of iodine or bromine water for the purpose. The author finds the most efficient solvents to be a mixture of ether and bromine, or one of equal volumes of bromine and aqueous hydrobromic acid of sp. gr. 1.49. An aqueous solution of iodine in hydriodic acid also dissolves gold readily. Otto's method will detect 0.75 gram of gold in a ton of ore.

M. J. S.

New Microchemical Reaction of Palladium. By M. E. Pozzi-Escot and H. C. Couquet (*Compt. rend.*, 1900, 130, 1073).—If, after the addition of potassium nitrite to a solution of palladium chloride, an excess of an alkali hydroxide or ammonia is immediately added, the temperature of the mixture being kept low, a palladium potassium nitrite is formed which is deposited as slightly yellow, rhombohedral crystals. This microchemical reaction is a characteristic and delicate test for palladium salts.

H. R. LE S.

Estimation of Iridium in Alloys of the Noble Metals. By W. MIETZSCHKE (*Chem. Centr.*, 1900, i, 572—573; from *Berg.-Hüttenm. Zeit.*, 59, 61).—To extract the iridium from an alloy containing gold, silver, and platinum, with or without oxidisable metals, four quantities of 0.25 gram are taken, cupelled, fused with silver (quartated), and two of the buttons boiled with nitric acid, two with sulphuric acid. The gold is submitted to quartation a second time, and then boiled with nitric acid, by which means silver and platinum are removed. Part of the iridium will be found floating in the silver solution, which should be filtered to recover it. The iridium-gold is dissolved in aqua regia, when most of the iridium will be left undissolved. The gold is thrown down by ferrous sulphate, and the remainder of the iridium is obtained by evaporating the filtrate.

If the iridium-gold alloy is free from other metals, it may be fused in a crucible in a muffle, and kept at a high temperature for 1—2 hours. The whole of the iridium will deposit on the crucible. After pouring off the fused gold, litharge and a reducing flux with a cover

of common salt are fused in the crucible ; the lead button is cupelled with much silver and the silver alloy examined for iridium. M. J. S.

Method and Apparatus for Incinerating Vegetable and Animal Substances. By A. E. SHUTTLEWORTH (*Bied. Centr.*, 1900, 29, 117—121; from *J. Landw.*, 1899, 47, 173; and *Inaug.-Diss.*, Göttingen, 1899. Compare Shuttleworth and Tollens, this vol., ii, 111).—Fusion of ash, and the consequent increase in the amount of ash constituents insoluble in hydrochloric acid, is avoided by addition of calcium acetate (compare Wackenroder, *Arch. Pharm.*, [ii], '53, 9). Pure calcium acetate (free from magnesia) is prepared by dissolving marble in hydrochloric acid, and after separating the iron, precipitating as oxalate. This is well washed and afterwards ignited, and the lime dissolved in boiling dilute acetic acid. A 1 per cent. solution is convenient, 20 c.c. being employed for 5—6 grams of oat straw, sufficient water being added to enable the acetate to be properly distributed. The amount of lime corresponding with the acetate employed is deducted from the weight of the ash.

The apparatus for incinerating consists of a deep dish, several covers and caps for covering the dish, and an air-pipe which passes through the cover and cap into the dish. The whole is made of platinum and weighs about 70 grams; a sketch is given in the original paper.

The method enables ashes to be prepared in less than four hours, without fusion or volatilisation of chlorides. The carbon dioxide in the ash can be determined in the apparatus. N. H. J. M.

Estimation of Naphthalene in Coal Gas. By HAROLD G. COLMAN and JAMES F. SMITH (*J. Soc. Chem. Ind.*, 1900, 19, 128—130).—The process employed is based on that adopted by Küster (*Abstr.*, 1894, ii, 333) for the separation of naphthalene from other solid hydrocarbons which do not form stable compounds with picric acid. The gas to be tested is passed by means of a specially constructed apparatus through a series of absorption bottles filled with a standardised solution of picric acid; this forms an insoluble compound with naphthalene, and the excess of picric acid is then titrated with decinormal barium hydroxide, using lacmoid as indicator. L. DE K.

Volumetric Estimation of Iodoform in Dressings. By MARTIN LEHMANN (*Chem. Centr.*, 1900, 19, 693; from *Pharm. Zeit.*, 45).—10 grams of the material are treated in a stoppered bottle with 100 grams of "spiritus æthereus" at 15—20° for 30 minutes with frequent shaking. 10 grams of the solution are mixed in an Erlenmeyer flask with 15—20 drops of fuming nitric acid, an excess of *N*/10 silver nitrate is added, and the whole heated on the water-bath until the silver iodide has deposited and the supernatant liquid is colourless. When cold, the liquid is diluted with 125—140 c.c. of water, and the excess of silver titrated according to Volhard's directions. L. DE K.

Some Analyses of Modern "Dry" Champagne. By OTTO ROSENHEIM and PHILIP SCHIDROWITZ (*Analyst*, 1900, 25, 6—8).—A table is given showing the analysis of 13 representative samples of modern "dry" French champagne.

Carbon dioxide was estimated by regulating the flow of gas by means of a hollow corkscrew with an accurately-fitting tap, drying the gas by means of sulphuric acid, and absorbing it in a weighed soda-lime tube, the last traces of gas being removed from the liquid by heating in a water-bath and transmitting a current of pure air.

The other figures were obtained by working according to the instructions laid down in the German Wine Law, 1896, and include: specific gravity at 15°, rotation in 20 cm. tube, alcohol by weight, free acidity calculated as tartaric acid, volatile acidity calculated as acetic acid, extract, ash, total tartaric acid, sugar as invert sugar, glycerol, extract (sugar - 1), and the relation of reduced extract and ash.

L. DE K.

Isolation of Pentose and Methylpentose [from Urine]. By PETER BERGELL and FERDINAND BLUMENTHAL (*Chem. Centr.*, 1900, i, 518; from *Arch. Anat. Phys.*, 1900, 155).—Several litres of urine are feebly acidified with sulphuric acid and concentrated on the water-bath to 300 c.c. The liquid is then decolorised with animal charcoal and made alkaline with barium hydroxide. After filtration, double the volume of alcohol is added, whereon the barium compound, $(C_5H_{10}O_5)_2 + BaO$, is precipitated, if at least 1.5 per cent. of pentose is present. If less is present, dextrose should be added, the barium compound of which will carry down the pentose. Methylpentose does not yield a barium compound of sparing solubility in alcohol.

M. J. S.

Estimation of Sugar in Glycerin-soaps. By FRANZ FREYER (*Chem. Centr.*, 1900, i, 693—694; from *Oesterr. Chem. Zeit.*, 3, 25—26).—16.28 grams of the soap are dissolved in 50—100 c.c. of water on the water-bath, a slight excess of 10 per cent. solution of barium chloride is added, and the whole diluted to 260 c.c., the extra 10 c.c. being supposed to compensate for the volume occupied by the barium soap.

The filtrate is then tested, as usual, for sucrose, by means of the polariscope before and after inversion; or Fehling's solution may be used.

L. DE K.

Automatic Apparatus for the Estimation of Pentosans. By VL. STANĚK (*Zeit. Zuckerind. Böhm.*, 24, 227—230).—In the Chalmot-Tollens method of estimating pentosans by distilling with 12 per cent. hydrochloric acid, after each 30 c.c. of distillate has collected, 30 c.c. of fresh acid are added to the distilling flask. To avoid the constant attention required by the ordinary method of carrying out this process, an apparatus has been devised by which the necessary additions of fresh acid are made automatically. An electrical indicator comes into action when the total distillate reaches any desired volume.

T. H. P.

Estimation of Formaldehyde. By JULES WOLFF (*Zeit. Unters. Nahr. Genussm.*, 1900, 3, 87—93).—For concentrated formaldehyde solutions, Blank and Finkenbeiner's method (*Abstr.*, 1899, ii, 188) is employed with slight modifications. A quantity of the substance containing about 0.4 gram of formaldehyde is treated with 10 c.c. of

3*N* sodium hydroxide, and 15 c.c. of hydrogen peroxide of 12 volumes per cent. previously diluted to 50 c.c. with water. A stronger peroxide solution is to be avoided. The reaction is complete in 10—15 minutes. Any acidity in either the hydrogen peroxide or the formaldehyde solution is estimated and allowed for. For solutions containing only traces of formaldehyde, a colorimetric process, based on Trillat's reaction (Abstr., 1899, ii, 130) may be used. A measured quantity of the solution is placed in a stoppered 50 c.c. flask, and mixed with 1 c.c. of glacial acetic acid and 1 c.c. of dimethylaniline; the flask is shaken for 2 minutes and then heated for 4—5 hours at 60°, keeping closely stoppered. Comparative estimations with solutions of known strength, and one without formaldehyde, are started and carried on simultaneously. Each mixture is then transferred to a small distillation flask, and after making feebly alkaline with sodium hydroxide (using phenolphthalein as indicator), 30 c.c. are distilled from it to remove excess of dimethylaniline. The residue is then acidified with acetic acid, and all the solutions are made up to the same volume. Equal quantities are now placed in test-tubes of equal diameter and mixed with lead peroxide suspended in water (4 grams per litre), adding sufficient to develop the blue colour to its fullest extent. The final comparisons are made after heating the contents of the tubes to boiling. The limit to the detection of formaldehyde by this reaction is 0.56 mg. in 50 c.c. If much alcohol is present, the liquid must be diluted five-fold with water, and the mixture with dimethylaniline must not be warmed, but should be left for 20 hours at 15—20°. The comparison solutions should be made up with the addition of the same amount of pure alcohol as in the quantity of substance taken.

M. J. S.

Testing of Acetone. By JAMES T. CONBOY (*J. Soc. Chem. Ind.*, 1900, 19, 206—209).—According to the specification issued by the Government, acetone should show the following properties: (1) It should have a sp. gr. of 0.800 at 60° F. Mixed with distilled water, it must show no turbidity, and must leave no residue on evaporation at 212° F. On distillation, 80 per cent. by volume should distil over below 138° F. The liquid left in the distilling flask should not contain any ingredient foreign to crude acetone. (2) 1 c.c. of a solution of potassium permanganate (1:1000) added to 100 c.c. of the sample should retain its distinctive colour for not less than 30 minutes. (3) The sample should not show more than 0.005 per cent. of acetic acid when tested as follows: 50 c.c. are diluted with 50 c.c. of distilled water, mixed with 2 c.c. of solution of phenolphthalein (1:1000 proof spirit) and then titrated with *N*/100 soda.

Commenting on these tests, the author calls attention to the influence exercised by the temperature on the permanganate test; a definite temperature should therefore be fixed. When estimating the acidity, great care should be taken to use distilled water completely free from carbon dioxide, and blowing the pipette should be avoided. It is also stated that samples which are to be submitted to these tests should not be exposed to light, as the effect will be prejudicial.

L. DE K.

Examination of Violet Preparations for Ionone. By R. SCHMIDT (*Zeit. angew. Chem.*, 1900, 189—192).—A crude oil is first isolated, in the case of an alcoholic solution by diluting it with water and extracting it with ether; in the case of a pomade by distilling it with steam and extracting the distillate with ether. The crude oil left on evaporation of the ether must itself be employed for estimations; for qualitative tests, it may be distilled under reduced pressure, and the fraction boiling at 125—135° under 12 mm. pressure utilised.

As a preliminary experiment, a little of the oil may be mixed with an acetic acid solution of *p*-bromophenylhydrazine. The crude hydrazones of α - and β -ionone melt at 138—140° and 110—115° respectively; the pure substances melt at 143° and 118°.

In order to isolate the ketones, the crude oil is shaken with a slightly acid solution of sodium *p*-hydrazinebenzenesulphonate, then made slightly alkaline, and shaken with ether and so much ammonium sulphate as will cause a separation into three layers, the ethereal layer being removed and renewed frequently. The two aqueous layers are together treated with phthalic anhydride, and distilled with steam; the distillate is extracted with ether, and the ethereal solution distilled. A loss of 10 per cent. is inevitable. For qualitative tests, the crude ketones may be distilled, and the fraction boiling at 125—135° under 12 mm. pressure employed.

In order to separate and detect the α - and β -ionone, the crude ketones are boiled with a little alcohol and an aqueous solution of sodium sulphite and hydrogen sulphite. The solution is purified by extraction with ether, and then distilled, when β -ionone passes over, and may be identified by means of its semicarbazone, which melts at 148°. Sodium hydroxide is added to the residue, and the distillation continued, when α -ionone passes over; it may be identified by means of its *p*-bromophenylhydrazone.

The method last described permits of the detection of a small amount of β -ionone in the presence of much α -ionone. In order to detect a little α -ionone in presence of much β -ionone, the semicarbazones are prepared under such conditions that all of the α - and some of the β -semicarbazone remain dissolved, whilst much of the latter separates. The alcoholic mother liquor is warmed with dilute sulphuric acid and then extracted with ether; the oil extracted is converted into the crude *p*-bromophenylhydrazone, by repeated crystallisation of which the pure α -derivative is obtained.

Exact details of the processes are given in the paper. C. F. B.

Estimation of Propionic and Butyric Acids in Acetic Acid. By MAX MUSPRATT (*J. Soc. Chem. Ind.*, 1900, 19, 204—206).—If the acetic acid is known to contain either propionic or butyric acid (usually isobutyric acid), the amount may be estimated indirectly by first titrating the mixture with pure sodium hydroxide and afterwards weighing the mixed anhydrous sodium salts.

If both propionic and isobutyric acids are suspected, the mixture is neutralised within about 5 per cent., and distilled to dryness. A convenient quantity of the distillate is then carefully neutralised with sodium carbonate, and evaporated in a platinum dish. From the weight

of the anhydrous salt and the acidity of the distillate, the results are calculated as acetate and isobutyrate. Sufficient absolute alcohol is now added to dissolve the butyrates, and after evaporating the solution, the residue is weighed, ignited, and titrated. The isobutyrate calculated from this should agree with that found previously, unless propionic acid is present.

If the results do not agree, the presence of propionic acid is assured. The author recommends for its detection the process recommended by Linnemann, which is based on the insolubility of basic lead propionate in boiling water. As, however, the basic lead salt of *n*-butyric acid is also very insoluble, *n*-butyric acid interferes with the test.

L. DE K.

Separation of Oleic Acid from other Fatty Acids. By JULIUS LEWKOWITSCH (*Analyst*, 1900, 25, 64—66).—The process recommended by Twitchell, based on the insolubility of sulphonated oleic acid in light petroleum (Abstr., 1899, ii, 69), and that recommended by Farnsteiner, based on the insolubility of barium oleate in a mixture of benzene and alcohol (Abstr., 1899, ii, 705), are found to be untrustworthy.

L. DE K.

Free Fatty Acid in Olive Oil. By RUSSELL W. MOORE (*J. Soc. Chem. Ind.*, 1900, 19, 223).—7.05 grams of the oil are introduced into a 4 oz. bottle by means of an accurate pipette, 50 c.c. of a 10 per cent. sodium chloride solution are added, and the free acids titrated with *N*/4 alkali, using phenolphthalein as indicator, and thoroughly shaking the mixture after each addition of alkali.

The number of c.c. of alkali used represent the percentage of free (oleic) acid in the sample. The process can also be used for solid fats by employing hot sodium chloride solution.

L. DE K.

Determination of the Iodine Value. By J. J. A. WILS (*Analyst*, 1900, 25, 31—33. Compare Lewkowitsch, this vol., ii, 323).—A controversy with Lewkowitsch on some minor points in the determination of the iodine value by means of a solution of iodine monochloride in acetic acid.

The author agrees that allyl alcohol is not a substance specially suitable for deciding the respective values of the different methods for determining iodine values. Lewkowitsch's objection to the use of acetic acid of 95 instead of 99 per cent. strength is overruled.

L. DE K.

The Iodine Value of Oils. By ARTHUR MARSHALL (*J. Soc. Chem. Ind.*, 1900, 19, 213—215).—A solution of iodine monochloride in pure carbon tetrachloride is recommended instead of the ordinary Hübl solution, as it may be obtained perfectly free from any moisture, thus preventing secondary actions.

L. DE K.

Relation between the Specific Gravity, Fat, and Solids not Fat, in Milk. By NORMAN LEONARD (*Analyst*, 1900, 25, 67—69).—This is a slight modification of the formula proposed by Richmond in 1895: $T = 0.25, G + 1.2, F + 0.14$, in which *T* represents the total solids, *G* the excess of the sp. gr. over 1000, and *F* the fat.

The new formula given is $F=0.796$, $T=0.210$, $G=+0.30$.

Both formulæ give, however, practically the same results, and it is only in the case of rich milks that the difference may amount to more than 0.1 per cent.

L. DE K.

Adulteration of Cotton-seed Oil with Maize Oil. By GIULIO MORPURGO and ALB. GÖTZL (*Chem. Centr.*, 1900, 1, 694—695; from *Oesterr. Chem. Zeit.*, 3, 53—54).—The two oils are chiefly distinguished by their iodine numbers, and by the melting points of their fatty acids. The iodine numbers of cotton-seed oil and maize oil are respectively 111—113 and 130.2—151.4; the melting points of the fatty acids, 36—37° and 18—20°. Notwithstanding this, 25 per cent. of maize oil may be added to cotton-seed oil without its presence being readily detected.

L. DE K.

Detection of Margarine in Cheese. By G. FASOETTI and F. GHIGI (*Chem. Centr.*, 1900, i, 573—574; from *Staz. sperim. agrar. ital.*, 32, 593).—The solvent employed to extract the fat from cheese must be one which does not alter it in any respect; the cheese should therefore first be extracted with water at 30—35°, and then the fat dissolved out with ether. Leffmann and Beam's modification of the Reichert-Meissl method avoids certain sources of error and saves time. In genuine cheese, the volatile acid number exceeds 18, margarine cheese gives values below 15, and generally below 6. As shown by Windisch, the proportion of free acids of both natural and artificial cheese-fats is but little affected by the ordinary conditions of ripening. The refraction values at 35° of genuine cheese lie below 47.5°, those of margarine cheese above 48°, but the latter fall during ripening. Complete analyses of four margarine cheeses are given in the original paper.

M. J. S.

Some Properties of Rosin, with Special Reference to the Analysis of the Fatty Matter of Soap. By ALFRED SMETHAM and F. ROBERTSON DODD (*J. Soc. Chem. Ind.*, 1900, 19, 101—103).—It is shown that the iodine number of rosin is much reduced by the saponification process, although the saponification and acid values are not much affected thereby; this is of some importance when dealing with saponified rosins in the analysis of the mixed fatty acids of soap. But the fact that the iodine number is so high, that it much depends on the process employed (Hübl's, Wijs's), and that it is after all very uncertain, renders its direct application to soap analysis of doubtful value.

L. DE K.

Detection of "Saccharin" in Articles of Food. By R. TRUCHON (*Chem. Centr.*, 1900, i, 691; from *Ann. Chim. anal. appl.*, 5, 48—49).—The following modification of Schmitt's process is used in the Paris official laboratory: 200 c.c. of the liquid to be tested are acidified with phosphoric acid and shaken three times in succession with 35—40 c.c. of a mixture of ether and light petroleum; the ethereal liquid is washed with water and then evaporated in a platinum dish. 5—6 drops of aqueous sodium hydroxide are added to the residue and the whole gently fused over a small flame of a Bunsen burner until no more gas bubbles are noticed. The fused mass is dissolved in water,

acidified with sulphuric acid, and extracted twice in succession with 30 c.c. of benzene; this is allowed to evaporate in a porcelain dish and the residue is then tested for salicylic acid with ferric chloride.

L. DE K.

Technical Analysis of Liquorice Pastes. By M. TRUBECK (*J. Amer. Chem. Soc.*, 1900, 22, 19—21).—Hager's process, in which ammonia and alcohol are used, gives quite erroneous results when liquorice paste contains added glucose, as the percentage of glycyrrhizin so found may then be as much as 10 per cent. in excess of the truth. The following process is recommended: 2 grams of the sample are well stirred with 5 c.c. of warm water, and 20 c.c. of alcohol are added; the liquid is filtered, and the residue washed with dilute alcohol (1:4) until the washings are colourless. The residue is then dried at 105° and weighed; it represents the gummy matter, starch, &c. The filtrate is evaporated, finally in a small beaker, to 1 or 1.5 c.c., then dissolved in 2 c.c. of glacial acetic acid and mixed with 30 c.c. of absolute alcohol. The crude glycyrrhizic acid is then collected on a weighed filter, washed with absolute alcohol, dried at 105° for 3 hours and weighed, then incinerated, finally heating over the blow-pipe, and any ash so obtained weighed, and 0.7 of its weight deducted from the weight of the acid.

The filtrate from the glycyrrhizin is evaporated, the residue is moistened a few times with water, and finally dried for 3 hours at 105° and weighed; this represents saccharin matters, tannins, resins, &c.

The estimation of water, ash, matters soluble in cold water, and saccharin matters is effected in the usual manner.

L. DE K.

Colour Reaction for Tyrosine. By GEORGES DENIGÈS (*Compt. rend.*, 1900, 130, 583—585).—2 c.c. of sulphuric acid are very carefully mixed with 3 to 5 drops of a solution of aldehyde in twice its volume of alcohol of 90°, care being taken that the liquid remains colourless. A few drops of a solution of tyrosine are then added, and the liquid rapidly acquires a gooseberry-red colour, the intensity of which is proportional, within certain limits, to the quantity of tyrosine present. In this way, it is possible to recognise tyrosine in a solution containing only 1 part in 10,000, if 0.1 c.c. of the solution is taken. By using solutions of tyrosine of known strength, the quantity of tyrosine in the liquid under examination may be rapidly estimated colorimetrically. The reagent is not affected by proteids and peptones, but is affected by certain phenolic compounds.

A solution of commercial formalin in 50 vols. of sulphuric acid gives with tyrosine a brown coloration which eventually becomes reddish. This colour changes to green if the liquid is mixed with twice its volume of glacial acetic acid and boiled.

C. H. B.

Detection of Phenetidine in Urine. By G. EDLEFSEN (*Chem. Centr.*, 1900, i, 573; from *Centr. inn. Med.*, 21, 2).—According to Müller (*Therap. Monatsh.*, 12, 357), phenetidine can be detected in the urine after doses of phenacetine by diazotising and adding an alkaline solution of α -naphthol. The author finds that Müller's alkaline ether extract of the urine does not always give the reaction, the phenetidine

being present as an ethyl sulphonate, which requires to be boiled with hydrochloric acid before it will give Müller's indonaphthol reaction. The cooled liquid is shaken with 1—2 drops of a 1 per cent. nitrite solution. One-half of the mixture is treated with a drop or two of 4—5 per cent. alcoholic α -naphthol and then made alkaline. In presence of phenetidine, a pure red coloration is produced, which becomes a deep cherry-red on acidifying with hydrochloric acid. The other half is treated with 1 to 2 c.c. of a 3 per cent. phenol solution and sodium hydroxide; a yellow coloration is obtained, passing into pale red on acidifying. Müller's method is only suitable when a larger amount of phenetidine is present.

M. J. S.

Reactions of Antipyrine, Tolpyrine, Aminoantipyrine and Pyramidone. By PAUL HOFFMANN (*Chem. Centr.*, 1900, i, 519; from *Arch. intern. Pharm. Therap.*, 1899, 171).—The reactions of these compounds are described with auric chloride, ferric chloride, the Brouardel-Boutmy reagent, silver nitrate, potassium dichromate, Wagner's reagent, nitrous acid, bromine water, and blood solution with hydrogen peroxide. Aminoantipyrine and pyramidone being more oxidisable than antipyrine and tolpyrine, reduce auric chloride in the cold, the two latter only on boiling. The two former give also blue or violet colours with nitrous acid, bromine water, blood, ferric chloride, and the Brouardel-Boutmy reagent, whilst the two latter either give no reaction or one of another colour. Aminoantipyrine and pyramidone may be distinguished by the last three of these reagents.

M. J. S.

Coffee Extracts, their Composition and Analysis. By CRESACRE G. MOOR and MARTIN PRIEST (*Analyst*, 1899, 24, 281—283).—The percentage of extract, ash, total nitrogen, and caffeine is given for 10 samples of commercial coffee extracts, including 4 samples which also contained chicory extract. The figures representing the percentage of caffeine are in fair agreement with those obtained by the analytical sanitary commission of the *Lancet* in 1894.

Attention is called to the difficulty of making a proper division of the sample into three parts for the purpose of official analysis, as most of the caffeine may be at the bottom of the bottle as a sparingly soluble tannate; if the sample is warmed, this will completely redissolve.

L. DE K.

Estimation of the Alkaloids of the Leaves of Datura Stramonium, Hyoscyamus Niger, and Atropa Belladonna. By ERNST SCHMIDT (*Chem. Centr.*, 1900, i, 376—377; from *Apoth. Zeit.*, 15, 13—14).—10 grams of the dried and powdered leaves are shaken with 90 grams of ether and 30 grams of chloroform, 10 c.c. of a 10 per cent. solution of sodium hydroxide added, and the whole frequently shaken for 3 hours; 10 c.c. of water are then added, and after an hour 60 grams of the clear chloroform-ether solution (= 5 grams of the leaves) are filtered. This is distilled to about one-half, and the residue shaken in a separating funnel with 10 c.c. *N*/100 hydrochloric acid. This is collected, and the chloroform is washed thrice with 10 c.c. of water. The acid solution is filtered,

the washings being also passed through the same filter, which is finally washed until the total filtrate measures 100 c.c. The liquid is covered with 1 cm. layer of ether, 5 drops of alcoholic solution of iodococsin (1:500) added, and the excess of acid titrated with *N*/100 potassium hydroxide until the aqueous layer turns pale rose-red. A blank experiment is then made in the same manner, and the amount of alkaloid is calculated from the hydrochloric acid used for its neutralisation.

L. DE K.

Detection of Nicotine. By IWAN SCHINDELMEISER (*Chem. Centr.*, 1900, i, 67; from *Pharm. Centralhalle*, 40, 703).—When treated with a drop of 30 per cent. formaldehyde (free from formic acid) and a drop of concentrated nitric acid, nicotine gives a rose-red solution. It is better to leave the mixture of nicotine and formaldehyde for some hours before adding the nitric acid. As little as 0.5 mg. of nicotine will show the reaction, which is not interfered with by coniine, piperidine, trimethylamine, pyridine, quinoline, picoline, or aniline. The reaction was not obtained with extracts of decomposing horse-flesh, or the intestines of animals poisoned by tin, mercury, or arsenic, extracted by the Stas-Otto process. Too much formaldehyde must not be added, nor must the mixture be warmed, as in either case explosive decomposition will occur.

M. J. S.

Ullmann's Tests for Tanning Materials and Basic Colours used in Dyeing. By ADOLF HEINEMANN (*Chem. Zeit.*, 1900, 24, 58).—The colorimetric tests by means of basic colours, proposed by Ullmann, are stated to give untrustworthy results, as they do not sufficiently distinguish between tannic acid and gallic acid, which is of no use as a mordant.

L. DE K.

Distinguishing Between Hops and Quassia. By ALFRED C. CHAPMAN (*Analyst*, 1900, 25, 35—37).—The process is based on the fact that hop bitter yields valeric acid when oxidised with an alkaline solution of potassium permanganate, whilst quassia and chiretta do not yield any; camomile extract, however, behaves in a similar manner to hops.

The beverage to be tested, beer, for instance, is evaporated to dryness with some sand; the mass is then dried in an air-bath, powdered and extracted with ether. The ether is filtered into a flask, and after recovering the bulk by distillation, the last traces are driven off by warming the flask on the water-bath. A solution containing 40 grams of potassium permanganate and 10 grams of potassium hydroxide per litre is now added in small portions until the permanganate ceases to be readily reduced; warming and shaking promote the action. The excess of permanganate is then reduced by adding a sufficiency of oxalic acid, and the filtered liquid evaporated in a glass dish. If now the residue is moistened with dilute sulphuric acid, the odour of valeric acid will at once become apparent if hop bitter is present; in the case of quassia, a faint odour of acetic acid will be noticed.

L. DE K.

General and Physical Chemistry.

Spectra of Metals in the Electric Arc. V. Spectrum of Vanadium. By H. HASSELBERG (*K. sv. vet. Akad. Handl.*, 1900, 32, 2).—After careful comparison with the spectra of iron, titanium, chromium, manganese, cobalt, and nickel, the author gives a full list of the lines he regards as belonging to vanadium. His results agree in the main with those of Rowland. J. C. P.

Transparency of Aluminium to Radiations from Radium. By HENRI BECQUEREL (*Compt. rend.*, 1900, 130, 1154—1157. Compare Abstr., 1899, ii, 393; this vol., ii, 126, 182).—A series of experiments which confirm the author's previous statements that when radiations from radium fall on an aluminium screen, some are absorbed, some diffused, and others transmitted; the last have properties identical with those of the incident radiations. Of the secondary radiations which are also emitted, some are deviated by the magnetic field, whereas others are not (compare Villard, *Compt. rend.*, 1900, 130, 1012). H. R. LE S.

Radiations from Radium. By P. VILLARD (*Compt. rend.*, 1900, 130, 1178—1179).—When the radiations from radium fall on a glass plate 1 cm. in thickness, or on a sheet of lead 0.3 mm. in thickness, practically all the radiations which are deviated by a magnetic field are absorbed, whereas the others (those not so deviated) are transmitted almost completely. H. R. LE S.

Theory of the Latent Image. By EUGEN ENGLISH (*Chem. Centr.*, 1900, i, 706; from *Arch. wiss. Phot.*, 2, 50—52).—According to Schaum, the small lateral extension of the darkening compared with its depth points to the capability of development being due to the action of chemically active rays, and not to that of silver germs. This fact, however, must not be quoted against the contact theory, as is done by Eder. The subhaloid theory is to be rejected because, according to it, the undeveloped fixed image should be twice as strong as the developed fixed image. It appears that an appreciable part of the silver bromide is altered in the light, and thus prepared for development. If this can be proved, both the silver germ and subhaloid theories must be given up (compare Abegg; Luther, this vol., ii, 253). J. C. P.

Reversibility of Voltaic Cells. By T. SIDNEY MOORE (*Phil. Mag.*, 1900, [v], 49, 491—496).—Experiments were made to test the reversibility of the following voltaic cells; copper and zinc in solutions of their sulphates and of their chlorides, copper and cadmium in solutions of sulphates or chlorides, and the Clark cell. The experimental method is described and the results indicate that all the cells examined were reversible, the slight differences in the E.M.F.'s observed being within the limits of experimental errors. L. M. J.

Alleged Identity of Red and Yellow Mercuric Oxides. II. By ERNST COHEN (*Proc. K. Akad. Wetensch. Amsterdam*, 1900, 2, 458—460. Compare this vol., ii, 184).—The E.M.F. of the mercuric

oxide cell previously described increases from 0.685 millivolt at 25° to 0.773 millivolt at 35°, so that the temperature coefficient is 0.0088 millivolt. When this value is introduced in the equation

$$\pi = E/n\epsilon_0 + T.d\pi/dT,$$

E , the heat of transformation of the yellow into the red oxide, is calculated to be -89.4 cal. Varet found the heat of reaction of the red oxide with hydrocyanic acid to be 31550 cal., whilst Berthelot found 31600 cal. for the heat of reaction of the yellow oxide with the same acid. The difference of -50 cal. is of the same order as the value calculated above.

J. C. P.

Electrical Conductivity of Liquid Ammonia Solutions. By EDWARD C. FRANKLIN and CHARLES A. KRAUS (*Amer. Chem. J.*, 1900, 23, 277—313. Compare Abstr., 1899, ii, 202, 208, 284).—The authors regard the work of Cady (Abstr., 1898, ii, 203) and Goodwin and Thompson (*Phys. Rev.*, 1899, 8, 38) as being of a merely qualitative nature, and accordingly describe a complicated apparatus in which liquid ammonia can be purified, and isolated for a length of time. Numerous compounds have been used as solutes, and the conductivity of the resulting solutions has been determined by Kohlrausch's method. The molecular conductivity at infinite dilution for solutions of binary salts in ammonia at -38° ranges from 290—340 Kohlrausch units; a much greater value than that for the corresponding aqueous solutions at 18°, probably owing to the greater ionic velocities in ammonia solutions. The dissociation of binary salts, however, is, as a rule, less than in aqueous solutions, and Ostwald's dilution law holds approximately for solutions of these salts in ammonia. Silver iodide is dissociated in ammonia, although to a less extent than other binary salts; mercuric cyanide and silver cyanide both give conducting solutions, but the molecular conductivity of the former falls slightly, that of the latter rises slightly, with dilution. The only ternary salt fully examined, strontium nitrate, has a high molecular conductivity, and, as in aqueous solution, it approaches its maximum more slowly than the binary salts. Many nitro-compounds are good conductors when dissolved in ammonia; so are generally acid and basic amides. These latter are regarded as acids and bases, derived from ammonia in the same way as oxygen acids and bases are derived from water; this analogy is borne out by the chemical behaviour of ammonia solutions of the amides and by their action on indicators. In agreement with Cady, the authors find that ammonia solutions of the alkali metals conduct electricity without polarisation at the electrodes. The molecular conductivity of these solutions changes but slightly with the concentration; the temperature coefficient is positive.

J. C. P.

Electrolysis of Sodium Chloride. By C. G. L. WOLF (*J. Physical Chem.*, 1900, 4, 200—206).—The author describes a form of U-tube, fitted with a stirrer, which he used for the electrolysis of sodium chloride and the examinations of the gases liberated at each electrode. The solution of sodium chloride contained about 300 grams per litre, with 1.8 grams of potassium chromate added, and the current employed was about 1 ampère. The percentage inefficiency

at the cathode was but slight, being seldom over 1 per cent.; but at the anode it varied more, being usually about 20 per cent., and during the experiment of 7.4 ampère hours, 12.7 per cent. of the sodium chloride had been oxidised to chlorate. It was found that variations of temperature had a great effect on the efficiency, and that efficient stirring is necessary.

L. M. J.

Application of Faraday's Law to the Electrolysis of Fused Salts. By A. HELFENSTEIN (*Zeit. anorg. Chem.*, 1900, 23, 255—316. Compare Lorenz, this vol., ii, 333).—The author has electrolysed the chlorides of lead, zinc, tin, cadmium, and silver, and lead bromide and iodide, and has studied the influence of varying conditions on the current yield. Neither in a V-tube, nor in any simple apparatus which allows direct contact of the anode and cathode liquids, can a decomposition be effected equal to that required by Faraday's law. Rise of temperature, decrease of current strength, decrease of the distance between the electrodes, and prolongation of the electrolysis have the effect of diminishing the current yield; in the case of lead iodide, however, the yield increases for a certain interval, 600—800°, with rise of temperature, probably owing to the formation of periodide. The chief cause of the imperfect yields obtained is the solubility of the metal in its fused halogen compounds, and a consequent diffusion to the anode and to the surface of the electrolyte, where the metal is oxidised or goes off as vapour. Special experiments, in which a regulus of the metal was kept in contact with its fused halogen compound, showed that the solubility and rate of diffusion increase with rise of temperature. The diffusion of the halogen from the anode, although of less account than the diffusion of the metal from the cathode, is also responsible for a diminution of the yield; this influence of the halogen increases from chlorine to iodine.

An approximately theoretical yield is obtained when the disturbing factors enumerated above are removed. The anode and cathode are separated from each other, either by being enclosed in tubes with lateral openings, or by the interposition of a diaphragm. As is to be expected, the enclosing of the cathode is much more essential than the enclosing of the anode. Further, the electrolyte is allowed to solidify on the surface, so as to prevent diffusion of metallic vapour into the atmosphere, and the temperature is kept as low as possible—just above the melting point of the salt. With these precautions, a yield is obtained which is independent of temperature, current strength, and duration of the experiment.

J. C. P.

Electrolytic Conductivity of Saturated Solutions. By HARRY M. DAWSON and P. WILLIAMS (*Zeit. Elektrochem.*, 1899, 6, 141).—Apparatus is described in which the saturated solution may be filtered and transferred to the vessel in which the conductivity is to be measured without change of temperature and without exposure to the air.

The conductivity of supersaturated solutions of some readily soluble salts, such as magnesium sulphate, potassium carbonate, calcium chloride, decreases as the concentration increases. In the

case of salts having a transition point, this may be determined by making a series of determinations of the conductivities of solutions saturated at different temperatures. When the results are plotted in a diagram, curves are obtained which intersect at the transition temperature. The method is especially applicable to salts which are not readily soluble in water. The transition temperature of the hydrates of thorium sulphate, $\text{Th}(\text{SO}_4)_2 \cdot 9\text{H}_2\text{O}$ and $\text{Th}(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$, was found in this way to be 48° . Determinations with the dilatometer and tensimeter gave respectively 46.5° and 47.8° .

T. E.

Reducing Action of Electrolytically Deposited Metals. By A. BINZ and A. HAGENBACH (*Zeit. Elektrochem.*, 1899, 6, 261—271).—When indigotin is suspended (a) in a solution of sodium hydroxide, (b) in a solution of zinc oxide in sodium hydroxide, and the two liquids are placed in the cathode compartments of two electrolytic cells with zinc cathodes through which the same current is passed, then the indigotin in solution (b) is more rapidly reduced than that in solution (a). The deposition of zinc at the cathode would thus appear to exercise a more vigorous reducing action than the evolution of hydrogen. Indigotin is not a very suitable substance, however, since it is insoluble in the liquids used. Subsequent experiments were made with solutions of diamine-pure-blue, Ponceau R, and patent blue N. The influence of the cathode metal was first investigated. The solution was placed in the cathode compartments of two cells which differed only in the nature of the cathode metal, and through which the same current was passed. The colouring matters were dissolved in solutions of potassium hydroxide or of potassium or sodium acetate. The metals used were copper, platinum, zinc, and mercury, and in the case of the latter no amalgam was formed, the alkali metal being redissolved as fast as it separated. Practically no difference was found in the rate of reduction with the different cathodes. By using a concentrated solution of pure potassium hydroxide, an amalgam of potassium is obtained at a mercury cathode which is acted on very slowly by the solution. With a dilute solution of potassium hydroxide, the potassium is dissolved out of the amalgam much more rapidly. By using a concentrated and a dilute solution of potassium hydroxide, it is therefore possible to have evolution of hydrogen in one cell, and formation of amalgam in another. In this way, it is shown that, when hydrogen is evolved, the reduction of the colouring matters takes place very much more slowly than when an amalgam is produced. These experiments point to the alkali metal being the real reducing agent, and not the hydrogen liberated by the action of the metal on water. To test this further, zinc is caused to separate at a mercury cathode from a saturated solution of zinc oxide in sodium hydroxide in one cell, and hydrogen to separate from a solution of sodium hydroxide at a copper electrode in the other, both cells containing the same colouring matter. No hydrogen is evolved by the contact of the zinc amalgam with the solution, so that any reduction which occurs must be due to zinc. As a matter of fact, it is found that the reduction always takes place more rapidly in the cell with the zinc than in that in which the equivalent quantity of hydrogen is liberated. The

authors conclude that many cases of supposed reduction by nascent hydrogen are really cases of direct reduction by a metal. T. E.

Theory of Solution Pressure. By S. ROSLINGTON MILNER (*Phil. Mag.*, 1900, [v], 49, 417—423).—The author regards the proof given by Nernst for the expression representing the difference of potential between a metal and the solution of an electrolyte containing the metal in the ion state to be unsatisfactory, as the possibility of actually carrying out the individual process of the cycle is not apparent. He therefore deduces similar expressions by a slightly different method of consideration which is free from these objections. When the value of the solution pressure is excessively large, as in the case of zinc (10^9 atmos.), the author considers it to be due to the inapplicability of the gas laws over such a great range of pressure, and in this case P is merely a constant, such that $RT \log P$ represents the value of $\int v dp$ of the ions between unit pressure and the actual solution pressure. L. M. J.

Determination of some Coefficients of Magnetic Susceptibility. By STEFAN MEYER (*Ann. Phys.*, 1900, [iv], 1, 664—667. Compare this vol., ii, 7).—The magnetic susceptibility of solutions of vanadium chloride is independent of the dissociation, and the molecular susceptibility of this compound is found to be 1.25×10^{-6} . This value stands in a simple relation to those obtained for the iron group [$V : Ni : Cr : Fe : Co : Fe : Mn = \frac{1}{2} : 2 : 2\frac{1}{2} : 3 : 4 : 5 : 6$].

A higher value is found for the susceptibility of gadolinium oxide than that previously obtained; it is supposed, on the ground of spectroscopic investigation, that the old preparation contained more or less of a strongly magnetic element. From samarium sulphate, a value is found for the atomic susceptibility agreeing well with earlier determinations. J. C. P.

Atomic and Molecular Magnetism. By STEFAN MEYER (*Ann. Phys.*, 1900, [iv], 1, 668—672. Compare this vol., ii, 7).—The results previously recorded are supplemented by an investigation of the magnetic susceptibility of copper compounds. The fundamental difference in the magnetic behaviour of cupric and cuprous salts, suggested by Wiedemann, is not borne out by the experiments; cupric and cuprous sulphides are about equally diamagnetic.

The molecular volume and molecular magnetism are compared with the sum of the atomic volumes and atomic magnetisms respectively, and it is seen that when contraction takes place in the formation of the compound, the molecular magnetism is increased; when an increase of volume takes place, the diamagnetic character becomes more marked. Hence it is permissible to calculate the atomic magnetism of an element from the molecular magnetism of its compounds only when the molecular volume of the compound is equal to the sum of the atomic volumes.

The author points out the advantages of his method of determining magnetic susceptibility over that of du Bois and Liebknecht (this vol., ii, 127). J. C. P.

Deduction of Reaction Isotherms and Isochors for Systems involving Dissociation. By KIKUNAYE IKEDA (*Zeit. physikal. Chem.*, 1900, 33, 287—294).—A theoretical paper, not suitable for abstraction.

J. C. P.

Overflowing Thermocalorimeter. By GUSTAVE MASSOL (*Compt. rend.*, 1900, 130, 1126—1128).—Regnault's thermocalorimeter can only be used for small ranges of temperature below 40—50°. The instrument may be employed at temperatures of 250° and 300° if concentrated sulphuric acid is employed as the expanding liquid instead of alcohol; it also becomes possible to work through considerable ranges of temperature by adopting an overflow principle as in Walferdin's maximum weight thermometer. By means of this form of thermocalorimeter, the author has determined the specific heats of salt solutions at temperatures near their boiling and freezing points.

G. T. M.

Critical Temperatures of some Organic Sulphur Compounds. By L. FERRETTO (*Gazzetta*, 1900, 30, i, 296—302).—Using Altschul's method and apparatus (Abstr., 1893, ii, 446), the author has determined the following critical temperatures: ethyl mercaptan, 228°; methyl sulphide, 231·2°; ethyl sulphide, 284·67°; methyl ethyl sulphide, 259·66°; isoamyl mercaptan, 334° (?). The following compounds show decomposition below their critical temperatures, which were hence determined in ethereal solution, Pawlewski's formula for mixtures being employed: isoamyl mercaptan, 320·92°; isoamyl sulphide, 391·25°; allyl sulphide, 380·38°; ethyl disulphide, 368·93°. The following are the differences between the critical temperatures and the boiling points at ordinary pressures: ethyl mercaptan, 191·8°; methyl sulphide, 193·9°; ethyl sulphide, 191·77°; ethyl methyl sulphide, 193·76°; isoamyl mercaptan, 200·92°; isoamyl sulphide, 176·25°; allyl sulphide, 241·0°; ethyl disulphide, 216·13°. Thus Pawlewski's law, that for comparable substances there is a constant difference between the critical temperature and the boiling point, holds well amongst the first group of four of the above compounds, whilst for isoamyl mercaptan and isoamyl sulphide, the critical temperatures of which were determined in ether, the agreement with the law is less good. Guldberg's law of the constancy of the ratio between the absolute critical and boiling points is obeyed well by all the above compounds except isoamyl sulphide, the value for which, 1·38, differs considerably from Guldberg's number (1·55). The difference between the critical temperatures of two homologous compounds of the above series is roughly proportional to the difference in composition. The following table shows the differences between the critical temperatures of these sulphur derivatives and those of the corresponding oxygen compounds:

				Difference.
EtSH	228°	EtOH	244°	— 16
C ₅ H ₁₁ ·SH	320·92	C ₅ H ₁₁ ·OH	306·6	— 14·32
SMe ₂	231·2	Me ₂ O	129·6	+ 101·6
SEt ₂	284·67	Et ₂ O	191	+ 93·67
SMeEt	259·66	OMeEt	167·7	+ 91·96
S ₂ Et ₂	372·76	Et ₂ O ₂	191	+ 181·76

Thus in the ethers, the substitution of an atom of sulphur for one of oxygen raises the critical temperature by about 90° to 100° , whilst with the alcohols, the difference is much smaller and in the opposite direction.

T. H. P.

Heats of Combustion and Formation of Iodine Compounds. By MARCELLIN P. E. BERTHELOT (*Compt. rend.*, 1900, 130, 1094—1101).—Iodine compounds are completely burnt in the calorimetric bomb by the use of compressed oxygen and a priming of gun-cotton, the whole of the halogen being liberated. The following thermochemical constants are recorded :

	Molecular heat of combustion.		Molecular heat of formation.
	Constant vol.	Constant pressure.	
Methyl iodide.....	196.1 Cal.	196.5 Cal.	+ 1.3 Cal.
Methylene „	178.1	178.4	- 14.9
Iodoform	161.8	161.9	- 33.1
Ethyl iodide	355.4	356.0	- 24.0
<i>n</i> -Propyl „	512.3	514.3	+ 10.2
<i>iso</i> -Propyl „	507.4	509.1	+ 15.0
Allyl „	476.85	478.33	- 22.9
Iodobenzene	770.0	770.7	- 32.3
<i>o</i> -Iodobenzoic acid	769.4	769.6	+ 63.1
<i>o</i> -Iodosalicylic „	706.5	706.4	+ 126.3
Diiodosalicylic „	700.2	699.9	+ 98.3
Ethylene iodide.....	324.3	324.9	+ 1.7
Tetrioethylene	261.6	261.6	- 73.0
Iodopyrrole (iodole), C_4HNI_4 ...	503.3	503.1	- 91.4

The substitution of solid iodine for gaseous hydrogen in methane is always attended by an absorption of heat, the values for the introduction of successive atoms of the halogen being -17.6 , -17.0 , and -18.2 Cal. The difference between the heats of formation of allyl and propyl iodides has the same value as that for the corresponding alcohols, namely, -33.1 Cal. The heat absorbed by the substitution of iodine for hydrogen in benzene is -28.2 Cal., whilst in the case of benzoic acid it is -31.1 Cal. The introduction of the first atom of iodine into salicylic acid is accompanied by a thermal change of -12.5 Cal., whilst that of the second produces an absorption of -28.0 Cal. These results explain the non-formation of aromatic iodo-derivatives by direct substitution. The addition of iodine (1 mol.) to ethylene produces a heat change of 16.3 Cal., whilst the substitution of the four hydrogen atoms of this olefine by iodine is accompanied by an absorption of heat, namely, -58.4 Cal. The thermal effect of introducing four iodine atoms into the pyrrole ring is -73.4 Cal.

G. T. M.

Apparatus for determining Molecular Weights by the Boiling Point Method. By HERBERT N. MCCOY (*Amer. Chem. J.*, 23, 353—360).—In applying Walker and Lumsden's modification of Landsberger's method (see *Abstr.*, 1898, ii, 283 ; *Trans.*, 1898, 73, 502),

the author has combined the functions of the jacket and the boiling flask, as shown in the accompanying sketch.

Suitable quantities of the pure solvent are introduced into the outer tube, *B*, and the inner tube, *A*. The solvent in *B* is boiled, and if the side tube, *d*, be closed, the vapour passes through the tube *a*, which has five small perforations at its lower extremity, *b*, into the solvent in *A*. The latter is thus raised to its boiling point, and the excess vapour passes through the tube *c* to a Liebig's condenser. When the constant temperature of the boiling solvent has been ascertained, the side tube, *d*, is opened, and the boiling interrupted until a weighed quantity of the solute has been introduced into the inner tube; as in Walker and Lumsden's apparatus, the inner tube is graduated, so that the volume of the solution can be read off. Test experiments, in which various substances were dissolved in alcohol, benzene, ether, or water, gave very satisfactory results.

J. C. P.

A Manostat. By A. SMITS (*Zeit. physikal. Chem.*, 1900, 33, 39—46).—An apparatus has been devised to secure a steady pressure during boiling point experiments, the deviations not exceeding 1 mm. of

water. The space in which the pressure is to be kept constant is connected (1) with the shorter limb of a mercury manometer, (2) with a suction pump. If the latter is working to begin with, then the mercury in the shorter limb of the manometer rises, and at a certain point touches a copper rod, thereby completing a circuit containing an electromagnet; the first circuit is so combined with a second circuit with a second electromagnet that the suction pump is shut off, and is connected again only when the mercury has fallen below the point of the copper rod. The pressure in such an apparatus increases very slightly with a rise of the external temperature, and is independent of the variations of the atmospheric pressure.

J. C. P.

Disturbing Influences at the Critical Point of Pure Liquids and Mixtures. By RUDOLF VON HIRSCH (*Ann. Phys.*, 1900, [iv], 1, 655—663).—The influence of gravity on the critical phenomena is discussed. It is also pointed out that the appearance or disappearance of the meniscus lags behind the temperature, and experiments with ether show that the extent of this lag depends very much on the rate of change of temperature. As the mean of a number of determinations with different tubes, 194.7° is given as the critical temperature of ether.

The author considers that the above influences are sufficient to account for many of the anomalies observed at the critical point, and that there is no need to replace van der Waals' theory by newer ones.

J. C. P.

Determination of the Decrease in the Vapour Tension of Solutions by means of the determination of the Increase in the Boiling Point. By A. SMITS (*Proc. K. Akad. Wetensch. Amsterdam*, 1900, 2, 469—477).—The boiling vessels used were made of silver, and could be connected with the manostat devised by the author (see this vol., ii, 388). Enamel grains and silver tetrahedra were employed to induce regular boiling, and the condensed vapour flowed back through a tube with outlets turned away from the thermometer. With a steady pressure, the boiling point of water remained constant to 0.002° ; but it was noticed that a 1 cm. vertical displacement of the thermometer caused a difference of 0.01 — 0.03° in its indications.

Two such silver vessels, *A* and *B*, containing distilled water, were connected with the manostat, and the temperature of boiling recorded. A weighed quantity of solute was introduced into *A*, and the pressure was adjusted so that the boiling point of the solution was the same as that of the pure water under the original pressure. The thermometer immersed in the boiling water in *B* had now fallen, and the difference between the readings of the two thermometers corresponded with the decrease of vapour tension due to the dissolved substance. The results of the investigation are to be communicated later. J. C. P.

Theory of Vapour Pressure. By R. GAHL (*Zeit. physikal. Chem.*, 1900, 33, 178—214).—A method is described for the measurement of the partial pressures of electrolytes dissolved in water, and especially applicable to very small pressures; it consists essentially in the aspiration of a known volume of air through (1) the solution and (2) a flask of perfectly pure water, the partial pressure being estimated from the increase of conductivity of the water in this flask. As is evident, many precautions are necessary to ensure accuracy with a method of this nature, and of these a full account is given. The author investigates theoretically, from the thermodynamical basis, the relations between partial pressure and cryoscopic depression, and calculates the former, in the case of hydrogen chloride, from Roloff's freezing point determinations (*Abstr.*, 1896, ii, 291). The values so obtained are compared with direct determinations by the above method, the agreement being satisfactory, as, for example, 6.74 per cent. acid, found 0.0094 mm. mercury, calc. 0.0094 ; 3.5 per cent., found 0.00117 mm., calc. 0.00116 . From the values of the partial pressure of hydrochloric acid, the decomposition tension in salts of organic bases may be determined in the case of the insoluble salts of insoluble bases by finding the strength of the acid with which the salt is in equilibrium. If a solution of ammonium chloride be boiled, owing to dissociation and the greater partial pressure of ammonia, the distillate is alkaline and the residue acid, but the author finds that air passed over solid ammonium chloride causes no increase of conductivity in the water; the salt is hence not dissociated, and possesses but a very small vapour pressure. Equations similar to those previously deduced also hold for mixtures of two or three components, and the author discusses the cases of sulphuric acid hydrates and of hydrated crystals. The partial

pressure of sulphuric acid in solution could not be determined by this method, however, owing to the fact that the acid sufficiently concentrated to give a measurable pressure showed also a partial dissociation with formation of sulphur dioxide.

L. M. J.

Liquefaction of Gaseous Mixtures of Carbon Dioxide and Sulphur Dioxide. By F. CAUBET (*Compt. rend.*, 1900, 130, 828—829).—The experiments previously recorded (this vol., ii, 191) are extended to mixtures of carbon dioxide and sulphur dioxide, eight different mixtures being examined, and the critical line obtained. Retrograde condensation is obtained at all compositions, and, for the most favourable mixtures, is observed between wide limits of temperature and pressure, namely, 7° and 30 atmos., whilst the ratio of the maximum volume of the liquid to the total volume is also great, reaching 0.2.

L. M. J.

Relative Rates of Effusion of Argon, Helium, and some other Gases. By FREDERICK G. DONNAN (*Phil. Mag.*, 1900, [v], 49, 423—446).—The rate of effusion, that is, efflux through a small hole in a thin-walled partition, is theoretically considered; assuming that viscosity effects are eliminated, that the ideal gas laws hold, that the efflux is adiabatic, and that the motion is steady, the rates of effusion of two gases are still not simply proportional to the square roots of the densities, but are also dependent on the ratios of the two specific heats for the two gases. Considerable difficulty was experienced in obtaining apertures for which the viscosity effect was negligible, and a correction for viscosity is given, but is in most cases very small. The results show that, when compared with oxygen, the rate of effusion of argon is $3\frac{1}{2}$ per cent. faster than that calculated merely from the densities, and this is in qualitative accord with the theoretical deduction, or may be regarded as an additional proof of a high specific heat ratio. Hydrogen, oxygen, and carbon monoxide have rates of effusion in accord with those calculated, the specific heat ratios being also approximately equal for these gases; the effusion of carbon dioxide is, however, about 1 per cent. faster than that calculated from the density, and this is not ascribable to a high specific heat ratio. With helium, a relatively large viscosity correction has to be introduced, but the results are still not in accord with theory, the rate being slower than that calculated from the density. The author hence concludes that some factor has been omitted in the theoretical consideration, and that this is probably to be found in the Joule-Thomson effect. It is shown that a gas will effuse more slowly or more rapidly than an ideal gas, according as the Joule-Thomson effect is negative or positive. As for all the gases which Joule and Thomson examined, the constant was positive except for hydrogen, where the sign is uncertain, and as helium is even more "perfect" than hydrogen, it is probable that the sign is here negative, and that the anomalies of effusion are hence explicable.

L. M. J.

Dissociation in Dilute Solutions at 0°. By W. C. DAMPIER WHETHAM (*Proc. Roy. Soc.*, 1900, 66, 192—203).—The degree of dissociation in dilute solutions, as determined by the conductivity at

18° or 25°, is not directly comparable with the value arrived at from freezing point experiments. The author has accordingly measured the conductivity at 0° of solutions of sulphuric acid, potassium chloride, barium chloride, copper sulphate, potassium permanganate, potassium ferricyanide, and potassium dichromate. The results are contained in a number of tables, and curves are drawn showing how α , the degree of dissociation, varies with the concentration. At 0°, α falls less rapidly with increasing concentration than at higher temperatures. The curve for sulphuric acid shows a maximum, in agreement with other observations at higher temperatures. The curve for potassium permanganate likewise shows a fall in the value of α for the most dilute solutions; this the author attributes to the action of the salt on the impurities left in the solvent.

It may be noted that the solvent and solutions were not allowed to come in contact with anything except platinum. J. C. P.

Relation of Taste of Acids to their Degree of Dissociation.

II. By THEODORE W. RICHARDS (*J. Physical Chem.*, 1900, 4, 207—211).—Owing to the fact that the sour taste of acid salts is stronger than would be expected from the concentration of the hydrogen ions, Kahlenberg considered the explanation of the sour taste from the standpoint of the dissociation theory to be unsatisfactory (this vol., ii, 271). If, however, the sensation of taste is due to a chemical action between the substance and some constituent of the tongue surface, then the sensation may be accompanied by a removal of hydrogen ions, and hence further dissociation would occur in accord with the mass action law. It follows, therefore, that although the order of dissociation is correctly found, yet no quantitative connection can be obtained from the taste, and this is in accord with experiment. The above explanation is also in agreement with the paralysis of the sense of taste by concentrated solutions, and the author points out that hydrogen and hydroxyl ions, which are those possessing the most marked taste (Höber and Kiesow, *Abstr.*, 1899, ii, 206), are also those most capable of causing reactions in substances likely to be present in the tongue. Observed phenomena are hence not opposed to the dissociation theory (compare *Abstr.*, 1898, ii, 209).

L. M. J.

Simple Proof of van't Hoff's Osmotic Pressure Law. By KIKUNAYE IKEDA (*Zeit. physikal. Chem.*, 1900, 33, 280—286).—A siphon barometer tube, whose longer limb is of small bore, has its short wider limb closed by a moistened piece of bladder. The space in the wider limb unoccupied by mercury is filled with some gas, such as nitrogen, which is insoluble in water. When the whole is surrounded by a gas, for example, ammonia, which is soluble in water, the mercury rises in the longer limb owing to the diffusion of ammonia through the bladder, which thus acts as a semipermeable membrane. If A be the gas for which the membrane is permeable, and B the gas for which it is not permeable, it can be shown that the partial pressure (p) of B is independent of the concentration of A ; when this concentration is small, the relation $p = RTC$ holds, and from the above it must also hold when the concentration of A is great: in this way, the law can

be extended to the case of a solution, where A becomes the solvent and B the solute.

From the law $p = RTC$, Henry's law is deduced; the supposition that the absorption coefficient varies with the concentration of the gas is shown to be contrary to thermodynamical laws. J. C. P.

Hardness of Elementary Substances. By JOHANNES R. RYDBERG (*Zeit. physikal. Chem.*, 1900, 33, 353—359).—On the basis of Mohs' scale, and with the help of the existing data, an attempt is made to assign a numerical value for the hardness of the elements. The numbers obtained show that the hardness is a periodic function of the atomic weight. J. C. P.

Limited Chemical Reactions in Homogeneous Systems: Modulus Law. By A. PONSOT (*Compt. rend.*, 1900, 130, 829—832).

A theoretical paper in which the author deduces that in a system in equilibrium, the latter is independent of the pressure or of the presence of foreign substances, that if equilibrium is established at constant pressure, the volume is a minimum, and if at constant volume the pressure is a minimum. Thus the interaction of two salts in solution leads to a minimum volume, and hence at equilibrium $\sum dv/dm = 0$, where dv/dm is the coefficient of volume increase by addition of equivalents of the salts, and from this, as an immediate consequence, follows the additive effect of each radicle in causing change of volume in aqueous solution, and hence also change of density. That is, the coefficient of increase of density by the substitution of one radicle for another is independent of the radicle to which they are combined, and there is thus obtained what is termed the density modulus. Similarly, could be obtained modulus of vapour pressure, osmotic pressure, cryoscopic depression, &c. The author points out that these deductions are established without any presumption of dissociation. L. M. J.

Physical Reactions and the Mass Law. By AZARIAH T. LINCOLN (*J. Physical Chem.*, 1900, 4, 161—187).—Bancroft has shown that the relations between the compounds in certain cases of physical equilibrium may be represented by a modification of the usual mass-action formula, in which the exponential factors are not necessarily integers. Thus the relation between the concentrations x, y of two non-miscible liquids in a third consolute liquid of concentration z may be represented by the equation $x^{\alpha}y^{\beta}/z^{\alpha+\beta} = c$, and in this expression the concentrations may be expressed in units of any nature. If the liquids are mutually soluble, the equilibrium formula becomes $(x - s_2y)^{\alpha}(y - s_1x)^{\beta}/z^{\alpha+\beta} = c$, where s_1 and s_2 are the mutual solubilities (Bancroft, Abstr., 1895, ii, 157). Experimental work has shown that these equations represent the facts with a fair degree of accuracy (Taylor, Abstr., ii, 1898, 66, 213; Bathrick, Abstr., 1897, ii, 135), and the author has examined the system water, benzene, alcohol, using pure compounds and employing great precautions to ensure accuracy in the equilibrium determinations. He finds the results to be in almost perfect accord with those given by the above expression, the differences being far smaller than in previous less accurate experiments and seldom reaching $\frac{1}{2}$ per cent., and he considers that if the

experimental difficulties could be more completely overcome, the accord would be still more perfect. Under these circumstances, he holds that the formula is not merely empirical, but represents the facts absolutely, and is hence the expression of an actual natural law.

L. M. J.

Equilibria in the System : Water, Phenol, and *d*-Tartaric or Racemic Acid. By FRANS A. H. SCHREINEMAKERS (*Zeit. physikal. Chem.*, 1900, 33, 74—77. Compare Abstr., 1899, ii, 739).—The influence of these two acids in raising the critical mixture temperature of water and phenol is equal, and much less than that of sodium chloride (*loc. cit.*). The critical mixture temperature of a water-phenol system containing 40.9 per cent. of tartaric acid (referred to water + tartaric acid) is about 30° higher than that of the water-phenol mixture alone. It appears that the elevation of the critical mixture temperature by a third substance is not only a function of the molecular weight of this substance, but depends also on other factors.

J. C. P.

Equilibria in the System : Water, Phenol, and Acetone. By FRANS A. H. SCHREINEMAKERS (*Zeit. physikal. Chem.*, 1900, 33, 78—98).—Mixtures of water and acetone of known composition were put in glass tubes, and known weights of phenol added; the tubes were closed and the temperatures observed at which the contents became homogeneous. A number of tables are thus obtained, and the corresponding curves drawn, showing how this temperature varies with the composition of the ternary mixture. The results are represented also by means of the triangular system, and the binodal curves are drawn for various temperatures: those for higher temperatures are enclosed by those for lower temperatures, and ultimately shrink to a point corresponding with the temperature 92°, and the composition 59 per cent. of water, 12 per cent. of acetone, and 29 per cent. of phenol. The chief feature of interest is that whilst above 68° separation into two layers takes place in none of the three binary systems water-acetone, water-phenol, and phenol-acetone, yet such a separation can take place up to 92° in mixtures containing all three substances.

The paper contains also a review of the author's experimental work on ternary systems (compare Abstr., 1897, ii, 483; 1898, ii, 329, 424, 564; 1899, ii, 739; this vol., ii, 135).

J. C. P.

The System : Water, Phenol, and Hydrochloric Acid. By W. H. KRUG and FRANK K. CAMERON (*J. Physical Chem.*, 1900, 4, 188—192).—If hydrochloric acid be added to the partially consolute mixture of phenol and water, the temperatures at which solid phenol can exist are altered. Since the system containing the solid phenol and two liquid phases is still monovariant, there is no definite melting point, but if the quantity of water is great compared with that of the phenol, the range of temperatures in which the solid phase persists becomes very small and a freezing point may be obtained. These values were determined for solutions containing from 0 to 130 grams of hydrochloric acid per litre, and a curve for temperatures against acid concentration is given; the temperature in water was found to

be $1\cdot365^{\circ}$, and in the most concentrated solution $17\cdot195^{\circ}$. The author suggests that from this curve the concentration of a hydrochloric acid solution may be quickly determined approximately from the freezing point of phenol in it.

L. M. J.

Velocity of Reaction of Acids in Organic Solvents. By M. GEIGER (*Gazzetta*, 1900, 30, i, 225—233).—The action of methyl alcoholic solutions of various acids on marble has been studied. For solutions of hydrogen chloride, the action is much slower than that of the aqueous acid; the initial velocity of reaction increases with the concentration of the solution, but less rapidly than the latter, so that the ratio of velocity to concentration shows a considerable diminution, owing to the decreasing dissociation of the acid in concentrated solutions. The reaction is greatly influenced by changes of pressure, an increase of 8 cm. of mercury above the atmospheric pressure serving to completely stop the action. Methyl alcoholic solution of hydrogen bromide attacks marble slightly more energetically than the chloride solution does, whilst with hydrogen iodide the reaction is a little slower. The initial velocities with which marble is attacked by these acids and by nitric acid, calculated for 1 c.c. of gas evolved per minute and per sq. cm. of surface, are given in the following table:

	4-Normal.	2-Normal.	Normal.	0·5-Normal.
HCl.....	0·26	0·20	0·16	0·12
HBr	0·31	0·22	0·17	—
HI	—	0·19	0·15	—
HNO ₃	—	0·25	0·14	—

[T] From these values, it is seen that molecular solutions of these acids in methyl alcohol, when not too concentrated, give the same velocity of reaction with marble. Calcium sulphate being insoluble in methyl alcohol, the action of a methyl alcoholic solution of sulphuric acid on malachite was studied, and it was found that no action takes place; the same is the case if blocks of fused sodium carbonate are employed, although hydrogen chloride dissolved in methyl alcohol reacts readily with both these substances. Formic, acetic, and the chloroacetic acids are not dissociated in methyl alcohol solution and, as would hence be expected, do not attack marble or other carbonates. Zinc and magnesium are attacked much more readily than marble by a methyl alcoholic solution of hydrogen chloride.

T. H. P.

[F] **Hydrolysis in Organic Solvents.** By A. CAJOLA and A. CAPPELLINI (*Gazzetta*, 1900, 30, i, 233—240. Compare Gennari, *Abstr.*, 1896, ii, 413).—The velocity with which methyl acetate is hydrolysed by caustic soda or potash, when dissolved in various alcohols, has been measured. The mean hydrolysis constants are given in the following table:

	Propyl alcohol.	isoButyl alcohol.	isoAmyl alcohol
Soda.....	0·004371	0·00941	0·0117
Potash.....	0·004279	0·008285	0·01107

Thus the action is least energetic in propyl alcohol; this confirms the observations of Gennari (*loc. cit.*), who found that sodium hydroxide and

methoxide have a stronger hydrolysing action in ethyl alcohol than in methyl alcohol. In these alcohols, sodium hydroxide acts more energetically than potassium hydroxide. The hydrolysis of methyl acetate by means of methyl alcoholic solutions of sodium, potassium, barium, strontium, ammonium, and tetramethylammonium hydroxides has also been studied. Contrary to what would be expected on the dissociation hypothesis, sodium hydroxide has a hydrolysing effect less energetic than barium or strontium hydroxides. T. H. P.

Energy of Acids Dissolved in Mixtures of Organic Solvents and Water. By ANTONIO MORELLO (*Gazzetta*, 1900, 30, i, 257—284).—The inversion of cane sugar by means of hydrochloric and the chloroacetic acids has been measured in aqueous methyl alcohol (about 86 per cent.) and in aqueous acetone (about 70 per cent.) at the dilution $V=10$. The constants are as follows :

	86 per cent. methyl alcohol.	70 per cent. acetone.
HCl	0.00102	0.00122
$\text{CCl}_3\cdot\text{CO}_2\text{H}$	0.000136	0.000121
$\text{CHCl}_2\cdot\text{CO}_2\text{H}$	0.0000404	0.0000306
$\text{CH}_2\text{Cl}\cdot\text{CO}_2\text{H}$	—	0.00000416

The dissociation constants for hydrochloric and trichloroacetic acids, as deduced from the electrical conductivities, are for the aqueous methyl alcohol, 0.522 and 0.241, and for the aqueous acetone, 0.183 and 0.516 respectively. These results show that trichloroacetic acid, which in acetone is almost completely undissociated, in aqueous acetone suffers dissociation to a greater extent than does hydrochloric acid. Further, the values obtained from the electrical conductivities for hydrochloric and trichloroacetic acids differ both absolutely and relatively from those given by the inversion method. T. H. P.

Hydrolysis of Polysaccharides and Decomposition of Esters; Catalytic Action of some Metals. By OTTO KAR ŠULC (*Zeit. physikal. Chem.*, 1900, 33, 47—56).—Experiments, supplementary to those already described (*Abstr.*, 1897, ii, 136), show that the inversion of sucrose is accelerated by silver, and specially by copper, both in the spongy form. Palladium is found to retard the hydrolysis by dilute acids of sucrose, maltose, and raffinose.

The decomposition of amyl acetate by water is very much slower in the presence of palladium, osmium, rhodium, iridium, copper, and silver; mercury is practically without effect. With isobutyl acetate, qualitatively similar results have been obtained. In view of the difficulty of securing uniform conditions, no attempt has been made to compare quantitatively the catalytic effect of the metals named. J. C. P.

Chemical Dynamics of the Condensation of Acetone. By KARL KOELICHEN (*Zeit. physikal. Chem.*, 1900, 33, 129—177).—In the presence of sodium hydroxide, acetone undergoes condensation with the formation of diacetonolalcohol, and the author shows that this reaction is reversible, and that the final state is an equilibrium between the two products. In solutions, not too concentrated, it is shown that,

in accord with the mass action law, the equilibrium is expressed by the equation $(1-x)v/x^2=k$.

Although the velocity of the reaction is greatly influenced by the concentration of the catalyser, yet this has no effect on the final equilibrium, the velocity in either sense being equally affected. The velocity is approximately proportional to the concentration of the hydroxyl ions, and although for very weak bases the concordance is very imperfect, yet it is sufficient to indicate that the hydroxyl ion is the actual catalyser, and the discrepancies may be ascribed to the effect of the medium on the dissociation of the base, and to secondary reactions. The velocity of the reaction hence affords a means for the determination of the hydrolysis of sodium salts of weak acids, and the values so obtained for sodium carbonate are compared with those found by Shields (Abstr., 1893, ii, 418), with which, however, they are not in good accord, no explanation being given of the discrepancies. Normal salts have a marked action on the velocity, sodium chloride, nitrate, and thiosulphate causing a decrease, sodium sulphate an increase. The effect of temperature was also investigated; at low temperatures, the equilibrium is disturbed with increase of the alcohol. From the values of the equilibrium constants at 25.2° and 0° , the value $-77.4K$ is calculated for the heat of reaction. L. M. J.

Solubility of a Mixture of Salts having one Common Ion. By CHARLES TOUREN (*Compt. rend.*, 1900, 130, 908—911).—The solubility of a salt is diminished by the addition of another containing a similar ion, and in the case of slightly soluble salts, numerous experiments by Noyes with others have proved this diminution to be in accord with that predicted theoretically. The author extends the experimental work to very soluble salts, and has determined the solubility field for potassium nitrate and chloride, and nitrate and bromide. The experiments were made at temperatures of 14.5° and 25.2° , and in each case the results are shown by two curves, the first showing the decrease of solubility of nitrate by addition of the chloride or bromide, the second the decrease of solubility of the chloride or bromide by addition of nitrate; the intersection of these curves gives the composition of the solution in equilibrium with the two solid phases. It is seen that the first of these curves is identical for the two halogen salts, when the concentrations are expressed in molecular quantities, so that the molecules of chloride and bromide have equal effects in lowering the solubility of the nitrate, and are hence, even at high concentrations, equally dissociated. L. M. J.

Mechanism of Gelation in Reversible Colloidal Systems. By W. B. HARDY (*Proc. Roy. Soc.*, 1900, 66, 95—109).—The properties of the ternary system alcohol-gelatin-water have been studied. Below a certain temperature there are two phases, separated by a well-defined surface. The temperature of separation is raised by an increase in the proportion of alcohol or gelatin, and lowered by an increase in the proportion of water. Both phases are at first liquid, but with fall of temperature one becomes solid. The solid solution phase forms on the concave side of the surface of separation when the proportion of gelatin is small, on the convex side when the proportion

of gelatin is large. The more slowly the two phases are established, the less is the surface of separation, both in extent and curvature.

The system agar-water was also studied. A hydrogel of agar consists of a solid and a liquid part; each of these phases is a mixture of agar and water, but their composition depends on the ratio of agar to water in the whole mass, and more especially on the temperature. Taking the gaseous phase also into account, the hydrogel of agar is a system of three phases. The equilibrium is determined by the chemical potential of the components in the various phases, by two pressures and by temperature, other operating variables being capillary tension and the energy of the surface between the fluid and solid phases.

J. C. P.

Nature of so-called Colloidal Metallic Solutions. By RICHARD ZSIGMONDY (*Zeit. physikal. Chem.*, 1900, 33, 63—73).—A criticism of the conclusions of Stoeckl and Vanino (this vol., ii, 11). The author maintains that the gold solutions previously described by him (*Abstr.*, 1898, ii, 522) are really colloidal solutions, and not merely suspensions. The general characteristics of these two classes of liquids are discussed, and the tests applied by Stoeckl and Vanino are regarded as quite inadequate and inconclusive.

J. C. P.

Representation of the Periodic System of the Elements. By KARL SCHIRMEISEN (*Zeit. physikal. Chem.*, 1900, 33, 223—236).—The elements are represented in a system of circles, the angular displacement, in a clockwise direction, from the highest point of the circle, being proportional to the excess of the atomic weight above the initial value. The first circle embraces values from 3.96 (helium) to 20, so that lithium is situated at 68.8°, fluorine at 337.7°, &c.; the second circle is from 20 to 37.1; the third and fourth form a figure of eight, the upper circle embracing values between 37.1 and 48.3 and 72.7 and 83.9, the lower values between 48.3 and 72.7. A similar double set occurs for the fifth and sixth groups, 83.9 to 131.4, and for the eighth and ninth, 163 to 227, the tenth circle containing only two elements. The properties of elements may be deduced from their positions on these circles, and the author claims that his arrangement gives a better insight into the relations of the elements than any previously published, indicating more clearly the transition of properties of the elements of each group, and the properties of the different elements; that it locates the sub-groups more perfectly, connects coloured ions with the chemical properties, and indicates those places in the Mendeléeff system which it is probable will, or will not, be filled.

L. M. J.

Calibration of Glass Tubes, and some Compressibility Coefficients. By GEORGE A. HULETT (*Zeit. physikal. Chem.*, 1900, 33, 237—244).—The glass tube employed for compressibility determinations was calibrated by filling with mercury, and withdrawing equal quantities by means of a small capillary pipette, the tube being immersed horizontally in a specially constructed thermostat, and the position of the end of the mercury read by a microscope. The accuracy of the calibration was seen by the concordance of the corrected lengths

of a mercury thread in different parts of the tube. The apparent compressibility of mercury in this tube was found to be 0.78 cubic millimetres per c.c. per 100 atmospheres, and, accepting Amagat's value of 0.039 for the absolute compressibility, this leads to the value of 0.39 cubic mm. per c.c. for the expansion of the glass tube per 100 atmospheres, which agrees well with the value 0.40, calculated from the dimensions of the tube. The compressibility of pure distilled water, containing dissolved air, was found to be 0.0453 at 9°, 0.0446 at 17°, and 0.0419 at 50°; and the compressibility of *p*-toluidine at 45° was found to be 0.0512.

L. M. J.

Inorganic Chemistry.

Vapour Density of Bromine at High Temperatures. By EDGAR P. PERMAN and G. A. S. ATKINSON (*Zeit. physikal. Chem.*, 1900, 33, 215—222).—A porcelain flask of about 1 litre capacity was heated in a muffle furnace, exhausted by a pump until the pressure was reduced to about one-sixth of an atmosphere, and then filled with bromine vapour, this process being repeated six times. The bromine vapour was then withdrawn by aid of the pump through absorption tubes, the flask filled with air, and the withdrawal repeated six times, the weight of the bromine being then found. Temperatures were determined by means of a thermo-electric junction calibrated by boiling selenium and melting potassium sulphate. The vapour densities so obtained were: 650°, 80.0; 830°, 79.7; 900°, 78.6; 950°, 77.5; 1015°, 76.7; 1050°, 74.3. At temperatures about 1040°, it was found that the density decreased from 76 at a pressure of 755 mm., to 71.8 at 47.3 mm., and curves are given showing these variations of density with temperature and pressure. The ratio of the velocities of dissociation and association are calculated for temperatures from 800° to 1050°, the ratio increasing over a hundred-fold within this range.

L. M. J.

Preparation of Hydrogen Sulphide and of its Solution. By CLEMENS WINKLER (*Ber.*, 1900, 33, 1040—1043).—The apparatus for the generation of hydrogen sulphide is the same as that previously described (*Zeit. anal. Chem.*, 1882, 21, 386). The gas is first passed through a leaden wash-cylinder, and then into a flat leaden vessel half filled with distilled water. When the water is saturated, a given volume may be withdrawn and replaced by pouring the same amount of distilled water through a funnel attached to the top of the vessel. The apparatus is thus kept filled with a saturated solution of hydrogen sulphide, which, for most qualitative purposes, is better than the gas.

J. J. S.

Combination of Metallic Iodides with Sulphur Dioxide. By E. PÉCHARD (*Compt. rend.*, 1900, 130, 1188—1189).—Sulphur dioxide is absorbed by an aqueous solution of potassium iodide, the

solution turning yellow, and finally orange, but this coloration is not due to free iodine. When sulphur dioxide is passed over solid potassium iodide at 0° , the salt turns yellow, and absorption of the gas readily takes place, with formation of the compound SO_2KI , which, on heating to 100° , readily parts with its sulphur dioxide. The following values (in cm. of mercury) were obtained for the vapour tension of this compound: 60 at 0° , 93 at 10° , 146 at 20° , 238 at 30° .

Similar compounds are formed with sodium, ammonium, barium, calcium, and silver iodides, the compound formed with the last being of a brick-red colour.

Hydriodic acid also readily absorbs sulphur dioxide, giving an orange-yellow solution from which free iodine is absent.

H. R. LE S.

Compounds of Telluric Acid with the Iodates. By RUDOLPH F. WEINLAND and H. PRAUSE (*Ber.*, 1900, 33, 1015—1018). The alkali iodates unite with telluric acid to produce compounds analogous to those formed with sulphuric, chromic, molybdic, and tungstic acids. *Potassium telluriiodate*, $\text{K}_2\text{O}, \text{I}_2\text{O}_5, 2\text{TeO}_3, 6\text{H}_2\text{O}$, crystallises from a concentrated solution of its components in colourless prisms. The *rubidium* salt has a similar composition, whilst the *ammonium* salt has the formula $(\text{NH}_4)_2\text{O}, \text{I}_2\text{O}_5, 2\text{TeO}_3, 8\text{H}_2\text{O}$, and crystallises in irregular, six-sided plates. *Potassium telluridiiodate*, $\text{K}_2\text{O}, \text{I}_2\text{O}_5, \text{TeO}_3, 3\text{H}_2\text{O}$, crystallises from a solution of its components containing very slight excess of potassium hydroxide in vitreous, rhombohedral crystals. When recrystallised from water, a certain amount of the telluriiodate is formed.

It has been found impossible to prepare sodium salts of similar composition. From analogy with the molybdoiodates, it seems probable that the two potassium salts have the constitutional formulæ $\text{KO} \cdot \text{IO}(\text{OH}) \cdot \text{O} \cdot \text{TeO}_2 \cdot \text{OH}$ and $\text{KO} \cdot \text{IO}(\text{OH}) \cdot \text{O} \cdot \text{TeO}_2 \cdot \text{O} \cdot \text{IO}(\text{OH}) \cdot \text{OK}$.

A. H.

Preparation and Properties of so-called Nitrogen Iodide. By FREDERICK D. CHATTAWAY and KENNEDY J. P. ORTON (*Amer. Chem. J.*, 1900, 23, 363—368. See *Proc.*, 1899, 15, 17).

Action of Reducing Agents on Nitrogen Iodide. By FREDERICK D. CHATTAWAY and HENRY P. STEVENS (*Amer. Chem. J.*, 1900, 23, 369—376. See *Proc.*, 1899, 15, 17).

Preparation of Phosphorus Trisulphide. By EDM. SPRINGER (*Chem. Centr.*, 1900, i, 712; from *Pharm. Zeit.*, 45, 164).—The loss due to the burning of the mixture of red phosphorus and sulphur in the preparation of phosphorus trisulphide is avoided by at first only heating a small portion of the mixture in a Hessian crucible until combination takes place, removing the burner and then adding the rest of the mixture in small portions at a time. If the first charge takes fire, it is extinguished by means of sand, and after each subsequent addition the lid is replaced on the crucible. The action takes place quietly, causing only a slight puff and formation of fume.

E. W. W.

Electrolysis of Solutions of Alkali Chlorides. By HEINRICH WOHLWILL (*Zeit. Elektrochem.*, 1899, 6, 227). By FRITZ FOERSTER (*ibid.*, 253).—A criticism of Foerster's results relating to the electrolytic formation of chlorates (*Abstr.*, 1899, 88, 278; this vol., ii, 72) and a reply thereto. T. E.

Decomposition of Sodium Thiosulphate by Acids. By HELMUTH VON OETTINGEN (*Zeit. physikal. Chem.*, 1900, 33, 1—38).—According to the ionic theory, the decomposition is represented by the equation $\text{S}_2\text{O}_3 + \text{H}^+ = \text{HSO}_3 + \text{S}$, so that the concentration (x) of the hydrogen ions should have an influence on the progress of the reaction. If y be the time that elapses between the acidification of a dilute sodium thiosulphate solution and the appearance of turbidity, experiments show that for hydrochloric acid $y = 1/[A \log. (1 + bx)]$, where A and b are constants. When, instead of hydrochloric acid, solutions of oxalic, dichloroacetic, or trichloroacetic acid, with an equal concentration of hydrogen ions, are employed, the value of y remains unchanged. This result is regarded as a confirmation of the electrolytic dissociation theory. The initial presence of sodium sulphite hinders the appearance of turbidity, but in this case also the above logarithmic equation is found to be satisfied, provided allowance be made for the appropriation of H^+ ions by the SO_3^- ions, to form either HSO_3 ions or undissociated molecules of sulphurous acid. The point of equilibrium of the reversible reaction—thiosulphate=sulphite+sulphur—cannot be determined, owing to the interaction of thio-sulphate and sulphite (Colefax, *Trans.*, 1892, 61, 176).

Conductivity experiments show that not only in the appearance of turbidity, but also in the further progress of the reaction, the concentration of the hydrogen ions is the determining factor; isohydric acid solutions have an equal effect on the velocity of decomposition.

J. C. P.

Solubility of Sodium Tungstate in Water and the Density and Refractive Indices of its Solutions. By BRONISLAW PAWLEWSKI (*Ber.*, 1900, 33, 1223—1224).—A table is given of densities and refractive indices at 20° of solutions containing from 2.21—38.43 per cent. of sodium tungstate, Na_2WO_4 (corresponding with a range of 2.48—43.14 per cent. of $\text{Na}_2\text{WO}_4 + 2\text{H}_2\text{O}$). W. A. D.

Change of Volume accompanying Fusion of Rubidium. By MORITZ ECKARDT (*Ann. Phys.*, 1900, [iv], 1, 790—792).—By means of a dilatometer, the increase of volume on fusion was found to be 0.01657 c.c. for 1 gram of rubidium. The melting point was 37.8°, and 5 to 6 grams were used in the experiments. The corresponding increase of volume for caesium is 0.01393 c.c. for 1 gram of the metal.

J. C. P.

Electrolysis of the Bromides of the Alkaline Earth Metals. By JON SARGHEL (*Zeit. Elektrochem.*, 1899, 6, 149 and 173).—Solutions of the bromides of calcium, magnesium, and barium (10 and 20 per cent.) are electrolysed in a cell with platinum electrodes, and without

a diaphragm. The influence of temperature, current density, and the addition of alkalis to the solutions is investigated.

Calcium Bromide.—In neutral solutions, bromate and small quantities of hypobromite are formed. The highest current efficiency (90·8 per cent. of the theoretical amount) was obtained with a 10 per cent. solution at 75°; the electrodes were of equal size, and the current density 0·07 ampère per sq. cm. About 3 per cent. of the active bromine was present as hypobromite, the remainder as bromate. At higher temperatures, the yield is considerably smaller; at lower temperatures, it is slightly smaller. Increased concentration and increased current density both diminish the current efficiency. When lime is added to the solution, the efficiency also falls, owing to the increased formation of hypobromite and its subsequent reduction at the cathode. If a cathode with a smooth surface is used (instead of one with a rough surface), the calcium hydroxide, instead of adhering to the metal, passes into the solution, giving rise to the formation of hypobromite, and a consequent diminution of efficiency.

Magnesium Bromide.—More hypobromite and less bromate are formed when solutions of magnesium bromide are electrolysed than is the case with CaBr_2 . The total current efficiency is also less since, owing to the smaller solubility of magnesia, a considerable quantity of bromine escapes conversion into hypobromite. The best result (89·1 per cent. of the theoretical amount) was obtained with a 10 per cent. solution, current density at the cathode 0·07 ampère per sq. cm., at the anode 0·007 ampère per sq. cm., temperature 50°, E.M.F. 5·5 to 12·5 volts. In this experiment, 10·7 per cent. of the active bromine was present as hypobromite; the remainder as bromate. The influence of temperature is the same as in the case of calcium bromide. The efficiency is improved by an increase of the current density or by adding small quantities of magnesia to the solution.

Barium Bromide.—Owing to the ready solubility of barium hydroxide, considerable quantities of hypobromite are formed, and owing to the ease with which this substance is again reduced at the cathode, the total current efficiency is low.

T. E.

Hydrated Calcium Peroxides. By ROBERT DE FORCAND (*Compt. rend.*, 1900, 130, 1308—1311. Compare this vol., ii, 129, 277, 344).—Hydrated calcium peroxides are precipitated on adding hydrogen peroxide to saturated solutions of calcium hydroxide, just as in the preparation of the corresponding strontium and barium compounds.

When hydrogen peroxide ($\frac{1}{2}$ mol.) reacts with calcium hydroxide (1 mol.) in dilute solutions, the heat developed is 6·877 Cal.; the product is a fine, light powder which, when dried on porous plates, gives numbers corresponding with $\text{CaO}_{1\cdot842}\cdot 2\cdot 31\text{H}_2\text{O}$; it differs from the strontium and barium compounds both in composition and in heat of formation. A similar result is obtained when 1 or 2 mols. of hydrogen peroxide are employed. When 3 or 4 mols. of this reagent are added at 13—14°, the compound $\text{CaO}_{2\cdot06}\cdot 8\cdot 57\text{H}_2\text{O}$ is obtained, the heat of formation being 24·666 Cal.; this product is therefore an analogue of the hydrated strontium and barium peroxides, which have a similar

heat of formation and contain approximately the same amount of water; at 20° , the reaction takes a slightly different course, the substance produced being more pulverulent, and having the following composition, $\text{CaO}_{1.91}, 2\text{H}_2\text{O}$. G. T. M.

Radio-active Barium. By BÉLA VON LENGYEL (*Ber.*, 1900, 33, 1237—1240).—Uranium nitrate was fused with 2—3 per cent. of barium nitrate, subsequently converted by heat into the oxide, and the latter fused in an electric arc; the mass was then dissolved in nitric acid, most of the barium nitrate allowed to separate, and the decanted clear solution precipitated with sulphuric acid. The barium sulphate so obtained was strongly radio-active, and this was also the case with the barium carbonate and chloride obtained therefrom. In the author's opinion, this "synthesis" of radio-active substances, although merely preliminary, renders the existence of radium and polonium doubtful (compare P. and S. Curie, this vol., ii, 81—83, 126, 254). W. A. D.

Action of Chlorine on Cupric Hydroxide suspended in Potassium Hydroxide. By F. MAWBOW (*Zeit. anorg. Chem.*, 1900, 23, 233—235).—Hydrated cupric oxide, $6\text{CuO}, \text{H}_2\text{O}$, is obtained by the action of chlorine on cupric hydroxide suspended in potassium hydroxide. The product is a dark brown powder, and a complete conversion of the cupric hydroxide is only obtained by employing a large amount of potassium hydroxide, an excess of chlorine, and heating the mixture at 50 — 60° . No indication was observed of the formation of the red solution described by Krüger (*Zeit. anorg. Chem.*, 2, 658), which is supposed to contain a salt of cupric acid.

E. C. R.

Lead Selenides and Chloroselenides. By HENRI FONZES-DIACON (*Compt. rend.*, 1900, 130, 1131—1133).—Crystalline lead selenide, PbSe , was first obtained by Margottet, who prepared it by heating the amorphous compound in a current of hydrogen. It may also be produced by the following methods: (1) reduction of lead selenate by hydrogen at a bright red heat; (2) reduction of the selenate by carbon in the electric furnace; (3) action of hydrogen selenide on the vapour of lead chloride. The compound crystallises in cubes or in needles composed of rectangular lamellæ, is easily friable, and has a sp. gr. 8.10 at 15° . The selenide is decomposed by heated hydrogen chloride, oxygen, chlorine, steam, and the vapour of phosphorus trichloride. It is readily attacked by nitric and sulphuric acids, but only slowly decomposed by concentrated hydrochloric acid.

Lead chloroselenide, produced by the action of hydrogen selenide on a solution of lead acetate containing hydrochloric acid, is obtained as a red precipitate; it may also be prepared by passing the vapour of phosphorus trichloride over gently warmed amorphous lead selenide. This substance is converted into the selenide by the action of heat, boiling water, hydrogen selenide, sodium thiosulphate, and concentrated solutions of potassium hydroxide. G. T. M.

Formation and Transformation of the Double Salts of Thallium and Silver Nitrates. By C. VAN EIJK (*Proc. K. Akad. Wetensch. Amsterdam*, 1900, 2, 480—484).—Fused mixtures of thallium and silver nitrates were examined in order to ascertain whether a double salt separates out on cooling. Although such a substance was not isolated, yet the melting point determinations showed that, when fused mixtures containing 47—53 per cent. of silver nitrate were cooled down to 80—85°, a double salt separates out, the separation being most rapid at 82·8°. The discontinuity in the melting point curve corresponding with the formation of the double salt, is represented by a horizontal line connecting the portion of the curve representing the separation of solid thallium nitrate from that indicating the crystallisation of the silver salt.

Silver and thallium nitrates are rhombic at the ordinary temperature, but, at 159° and 142° respectively, undergo a structural change and become rhombohedral; if the crystals of either contain any impurity, the transition temperature is either raised or depressed, and this phenomenon is utilised in testing the purity of the solid separating from the fused mixtures of the two salts. Crystals taken from mixtures containing excess of silver nitrate undergo transformation at 160°, and appear to contain 80—100 per cent. of the silver salt; the solid separating from mixtures containing excess of thallium nitrate is transformed at 142°, and is therefore pure thallium salt.

It follows from this that mixed crystals are scarcely formed at all, and that the solidified mixtures are conglomerates of the double salt with excess of silver nitrate or thallium nitrate. At 26—27°, the double salt undergoes a transformation, the precise nature of which is not understood; this change proceeds very slowly, and is detected by dilatometric experiments; the volume of the admixed substance greatly diminishes, whilst that of the admixed silver or thallium salt remains unaltered.

G. T. M.

The Cerite Earths. By OTTO N. WITT and WALTER THEEL (*Ber.*, 1900, 33, 1315—1324).—Cerium can readily be separated from the other metals which usually accompany it in the cerite earths by means of ammonium persulphate. When a solution of a normal cerous salt is boiled with ammonium persulphate, oxidation occurs and a ceric salt is formed, which is at once decomposed by the water present into a basic ceric sulphate and free acid. If this acid is neutralised as fast as it is produced, the reaction becomes quantitative, and the whole of the cerium present is precipitated as basic ceric sulphate, whilst the other earths remain in solution. The normal salts of the cerite earths have a faintly acid reaction to litmus paper, but do not react with Congo paper, and the boiling liquid must therefore be maintained faintly acid to litmus, but neutral to Congo paper by the cautious addition of sodium carbonate solution or finely powdered calcium carbonate until the reaction is complete. The precipitate can readily be washed and the filtrate is quite free from cerium. The method is of special value for use in conjunction with Schéele's method of fractionation of the cerite earths, according to which the cerium is retained in the mixture of nitrates, whilst the lanthanum is gradually

removed, the result being solutions of neodymium and praseodymium mixed with cerium, from which the latter can then be removed by the persulphate process.

Microchemical Researches on Yttrium, Erbium, and Didymium. By M. E. Pozzi-Escot and H. C. Couquet (*Compt. rend.*, 1900, 130, 1136).—When treated with ammonium chromate, yttrium salts yield a chromate separating in elongated, hexagonal crystals having a violet tint; the corresponding didymium salt is obtained in orange, prismatic crystals exhibiting twinning, whilst the erbium compound crystallises with great difficulty and is usually amorphous.

With a solution of chromium trioxide in concentrated sulphuric acid, filiform crystals are obtained from yttrium salts, large, ill-defined crystals from erbium compounds, and amorphous precipitates gradually becoming crystalline from didymium derivatives.

These rare earth metals also form characteristic double chlorides with palladium chloride.

G. T. M.

Samarium. By EUGÈNE DEMARÇAY (*Compt. rend.*, 1900, 130, 1185—1188. Compare this vol., ii, 347).—The intermediate fractions obtained in the separation of neodymium and samarium show no indication of the presence of a third element.

A nitric acid solution of the samarium salts shows the following bands: λ 559 (feeble), 529 (very feeble, narrow), 498 (feeble, rather narrow), 476 (strong, diffused), 463 (very strong, rather wide), 453 (very feeble, narrow), 443 (very wide and diffused), 417 (very strong, wide), 407 (feeble, narrow and joining the next), 402 (very strong, wide), 390 (feeble, very wide and diffused), 375 (strong, wide), 362 (strong, wide).

The reversion spectra of the salts either in hydrochloric or nitric acid solution gave the three following bands: λ 644 (wide), 600 (middle of the principal band which extends from 610 to 593), and 564 (middle of the third band). No fourth band corresponding with the 614.4 band of Lecoq de Boisbaudran could be detected in the pure samarium examined.

Analyses of samarium sulphate gave numbers varying between 148 and 147.2 (O = 16) for the atomic weight of the metal; the author is, however, not satisfied with the method employed.

The *double nitrate*, $\text{Sm}(\text{NO}_3)_8 \cdot 3\text{Mg}(\text{NO}_3)_2 \cdot 24\text{H}_2\text{O}$, forms large, pale yellow, rhombohedral crystals melting at 94.5—93.5°. The *nitrate*, $\text{Sm}(\text{NO}_3)_8 \cdot 6\text{H}_2\text{O}$, forms thick, orange-yellow crystals which are very hygroscopic and melt at 78—79°.

Nature of the Process which occurs at the Aluminium Anode. By KONRAD NORDEN (*Zeit. Elektrochem.*, 1899, 6, 159 and 188).—When aluminium is used as anode in the electrolysis of dilute sulphuric acid, it becomes coated with a substance possessing a high resistance which gives rise to an apparent polarisation of some 20 to 30 volts. The author shows that when an aluminium wire is used alternately as anode and as cathode, the skin formed when the wire is anode is detached from the metal when it is used as cathode, and that when it is again used as anode a fresh coating forms under the old one.

By many repetitions of the process, the skins peel off and a quantity sufficient for an analysis may be collected. Analyses of the coatings formed with different current densities and different concentrations of acid agree well with each other, the average result being: Al_2O_3 , 69.8 per cent.; SO_3 , 13.2 per cent.; H_2O , 14.8 per cent.; SiO_2 , 2.2 per cent. The silica is doubtless due to oxidation of the silicon contained in the aluminium used. In the remaining substance, some of the aluminium is present in the form of small particles of metal. A mixture of a compound, $\text{Al}_2\text{O}(\text{SO}_4)_2 \cdot \text{H}_2\text{O} + 5\text{Al}_2(\text{OH})_6$, with 9.25 per cent. of metallic aluminium would have the composition indicated by the analyses.

T. E.

Preparation of Aluminium [Sulphide, Selenide, Phosphide, and Arsenide]. By HENRI FONZES-DIACON (*Compt. rend.*, 1900, 130, 1314—1316).—Aluminium sulphide, Al_2S_3 , is readily prepared when a mixture containing equivalent proportions of precipitated sulphur and fine aluminium powder is ignited by means of burning magnesium; the combustion is propagated throughout the mass, and a compact, yellowish-grey product is obtained, which is decomposed by water, yielding hydrogen sulphide. A mixture of antimony sulphide and aluminium, when treated in this way, yields aluminium sulphide and metallic antimony.

Aluminium selenide, Al_2Se_3 , is obtained in a precisely similar manner as a yellowish-grey, fibrous mass, which evolves hydrogen selenide when treated with water.

Aluminium phosphide, Al_2P_3 , is prepared by igniting an intimate mixture of aluminium and red phosphorus; when moistened, it evolves non-inflammable hydrogen phosphide, the yield of this gas being practically theoretical.

Aluminium arsenide is a black, friable mass, produced from a mixture of aluminium and metallic arsenic; the hydrogen arsenide liberated from this compound by the action of water is almost wholly absorbed by copper sulphate, and the decomposition is quantitative.

A mixture of antimony and aluminium is not ignited by a fuse of magnesium or an aluminium cartridge (a mixture of aluminium and barium dioxide fastened to a strip of magnesium); its combustion may, however, be effected by adding a small quantity of sodium peroxide; the product is a black, friable mass, which, when treated with water, evolves a considerable amount of hydrogen antimonide. G. T. M.

Manganous Fluoride. By HENRI MOISSAN and VENTURI (*Compt. rend.*, 1900, 130, 1158—1162).—*Manganous fluoride*, MnF_2 , is best prepared by dissolving manganese in dilute hydrofluoric acid contained in a silver basin, which is kept cool by a rapid current of cold water; on boiling the resulting solution, the manganous fluoride is precipitated as a white, crystalline powder, which is collected and dried at 120° .

Manganese is readily attacked by hydrogen fluoride with the development of much heat, and manganous fluoride is thus obtained as a rose-coloured, fused mass. Pure manganous fluoride may also be formed by heating hydrated manganese silicofluoride to 1000° in a current of hydrogen fluoride. When manganous carbonate is dissolved

in dilute hydrofluoric acid, the resulting solution contains the hydrated fluoride; when the solution is boiled, a certain amount of the anhydrous salt is deposited.

Manganous fluoride may be recrystallised from fused manganous chloride, when it is obtained as rose-coloured prisms of sp. gr. 3.98, and melting at 856° . Manganous fluoride is completely reduced by hydrogen at 1000° , but only very slowly at 500° ; it is only slowly decomposed by fluorine in the cold, but readily on heating, manganese trifluoride being formed (this vol., ii, 280).

It is not attacked by chlorine in the cold; but at 1200° partial decomposition occurs, manganous chloride being formed. Dry oxygen acts only slowly on manganous fluoride at 400° , but at 1000° it is completely decomposed, and manganese tetroxide is formed; when heated to 1000° in an atmosphere of sulphur, it is rapidly converted into green manganous sulphide. It is not decomposed by carbon at 1200° , but at 1000° both silicon and boron readily decompose it, with formation, in the first case, of manganese silicide, and in the second, of boron fluoride and manganese boride. When manganous fluoride is boiled with water, manganese oxyfluoride and hydrofluoric acid are first produced; if the boiling is continued, then a mixture of hydrated manganese fluoride and oxyfluoride is deposited. At 1200 — 1300° , manganous fluoride is converted by steam into manganous oxide, and by hydrogen sulphide into green manganous sulphide. It is sparingly soluble in liquid ammonia, a crystalline powder being produced, probably of the composition $3\text{MnF}_2 \cdot 2\text{NH}_3$, which slowly evolves ammonia. When heated at 1200° in an atmosphere of ammonia, the fluoride is partially reduced.

Sodium, potassium, aluminium, and magnesium reduce manganous fluoride below a red heat, cold concentrated nitric acid and hydrochloric acid dissolve it readily, and dilute hydrochloric acid and acetic acid only slowly; but hydrofluoric acid is without action on it, and sulphuric acid decomposes it with evolution of hydrogen fluoride. It is decomposed by fused alkali carbonates, potassium hydroxide, potassium nitrate, and potassium chlorate, and with chlorine or bromine water manganese dioxide and hydrofluoric acid are produced. Manganous fluoride is practically insoluble in water, alcohol, or ether.

H. R. LE S.

Cause of the Evolution of Oxygen when Oxidisable Gases are Absorbed by Permanganic Acid. By HARMON N. MORSE and H. G. BYERS (*Amer. Chem. J.*, 1900, 23, 313—322. Compare Morse and Reese, *Abstr.*, 1898, ii, 588).—It is shown that no oxygen is liberated, either during the absorption of carbon monoxide by neutral aqueous potassium permanganate, or during subsequent prolonged agitation of the neutral solution with the manganese dioxide thus precipitated; if, however, the solution is acidified with sulphuric acid immediately after the absorption, there is a liberation of oxygen just as when the gas is absorbed by an acid solution. The amount of oxygen liberated within a given period increases with the concentration of the solution, and the rate of evolution in any given case diminishes with time, the decrease being most marked in the more

concentrated solutions. With a fixed quantity of carbon monoxide, the quantity of oxygen liberated during absorption with initially acid solutions of potassium permanganate increases with the concentration of the solutions; the same is true of the amount liberated in a given period after the absorption is complete, and the rate of evolution diminishes with time just as in the foregoing case of solutions initially neutral and subsequently acidified. The authors therefore conclude that in acid solution the liberation of oxygen is due to the reduction of the permanganic acid by the precipitated manganese dioxide, rendered active by the sulphuric acid present; the fact that no oxygen is liberated in neutral solutions may be due to either potassium permanganate being more stable than permanganic acid, or to the precipitated manganese dioxide being "saturated" with alkali, or to both causes combined. The falling off with time of the reducing power of the manganese dioxide in acid solution is explained by assuming the initial activity of the manganese dioxide molecules to be due to their simplicity; as the molecules become more complex owing to polymerisation, so do they lose their power of reduction. It is noteworthy that whilst the oxide formed in acidified solutions is, in general (especially in the more concentrated solutions), more active during the first 24 hours than that formed in neutral solutions, the converse is true after 150 hours.

W. A. D.

Revision of the Atomic Weight of Iron. By THEODORE W. RICHARDS and GREGORY P. BAXTER (*Zeit. anorg. Chem.*, 1900, 23, 245—254).—The method employed is the reduction of ferric oxide to iron in a current of hydrogen. The operation is carried out in a porcelain tube at 900°, and a considerable time is required to effect complete reduction. In the first series of experiments, the iron, purified by electrolytic deposition, was dissolved in nitric acid, the solution precipitated with ammonia, and the precipitate of hydroxide washed with water and converted into oxide by heating at 900° to a constant weight. Two experiments with this oxide gave the mean value $\text{Fe} = 55.900$ ($\text{O} = 16$). In the second series, the ferric oxide was prepared by heating the carefully purified nitrate at 900° to a constant weight. The mean of five experiments gave the value $\text{Fe} = 55.883$.

The ferric oxide prepared from the nitrate was more easily reduced than that prepared from the hydroxide. A careful examination of the ferric oxide showed that it contained only a very minute quantity of included gases, chiefly nitrogen, and also a very minute quantity of platinum, derived from the vessel employed, the total impurities being such as to increase the results by only 0.01 per cent.

E. C. R.

Thermochemistry of Iron and Steel. By EDWARD D. CAMPBELL (*J. Amer. Chem. Soc.*, 1900, 22, 205—206).—The author now finds that the heat of solution of steel in slightly acid ammonium copper chloride solution does not depend to any considerable extent on the heat or mechanical treatment to which the metal has been subjected, or on its chemical composition, the extreme variation being less than

2 per cent. He therefore withdraws his previous paper on this subject (Campbell and Thompson, *Abstr.*, 1898, ii, 323). E. G.

Allotropic Transformations of Iron and Nickel Alloys. By L. DUMAS (*Compt. rend.*, 1900, 130, 1311—1314. Compare *Abstr.*, 1899, ii, 352, 630).—The paper contains the diagrams and tabulated results of experiments on the transformation points of alloys of iron and nickel containing traces of carbon and manganese, and in one case chromium. The diagrams indicate that the curves of the transformation points of iron (non-reversible transformation) are distinct from those of nickel (reversible transformation), and there is therefore no minimum transformation temperature corresponding with the existence of a eutectic alloy. Nickel lowers the transformation points of iron, and iron lowers those of nickel, although at first it raises them. The magnetism of alloys, containing less than 25 per cent. of nickel, which have not been cooled below 0°, is entirely due to the iron present; when the percentage is greater than 26, the magnetic properties are wholly derived from the nickel; the alloys containing intermediate amounts of nickel are almost non-magnetic at ordinary temperatures, owing to the simultaneous depression of the transformation points of both their constituents. G. T. M.

Electro-deposition of Chromium. By SHERARD COWPER-COLES (*Chem. News*, 1900, 81, 16—18).—Electro-deposited chromium is comparatively soft, and tarnishes; a bright deposit can be obtained from a solution of 25 parts of chromium chloride in 75 parts of water, working at 190° F. with a current of 40 to 50 ampères per square foot. In the cold, gas is evolved at both electrodes, but no metallic deposit is obtained until excess of hydrochloric acid is added. A solution of 100 parts of chrome alum in 100 parts of water with 12 parts of barium sulphate does not yield a metallic deposit by electrolysis.

D. A. L.

Enantiotropy of Tin. IV. By ERNST COHEN (*Proc. K. Akad. Wetensch. Amsterdam*, 1900, 2, 464—467. Compare this vol., ii, 83 and 212).—Another case of 'tin plague' infection is noticed, and emphasis is laid on the fact that the corrosion of tin is independent of the mode of preparation of the metal. The occurrence of 'tin plague' in organ pipes suggested that the conversion of the white into the grey modification below 20° might be accelerated by mechanical vibration, but a test experiment gave a negative result. J. C. P.

Hydrolysis of some Chlorine Compounds of Platinum, Gold, and Tin on Standing, and under the Influence of Light. By FRIEDRICH KOHLRAUSCH (*Zeit. physikal. Chem.*, 1900, 33, 257—279).—Platinic chloride crystallises with 5H₂O, but the fifth molecule cannot be removed without decomposition of the chloride. Hittorf and Salkowski (*Abstr.*, 1899, ii, 398), and Dittenberger and Dietz (*Abstr.*, 1899, ii, 629), have shown that in the electrolysis of this compound the platinum goes to the anode. These facts point to the existence of an oxy-acid, PtCl₄OH₂. The author finds that even in the dark the conductivity of solutions of this compound increases, especially when they are left in contact with the electrodes; the conductivity rises

rapidly when the solutions are exposed to sunlight; red, yellow, blue and white light are increasingly efficient in producing the hydrolysis that this increase of conductivity points to. When the limit of hydrolysis in dilute solutions is reached, it seems as if all the chlorine were present as hydrogen chloride; in more concentrated solutions, the hydrolysis does not go so far. The numbers obtained for the molecular conductivity of freshly prepared solutions agree fairly well with the supposition that PtCl_4OH_2 is a moderately dissociated monobasic acid. The hydrolysis is accompanied by a change in colour from an almost greenish-yellow to a bright orange, and in the more dilute solutions a sort of fluorescence is observed, which the author attributes to the separation of finely divided particles, possibly of platinum hydroxide. Similar changes of conductivity take place in solutions of chloroplatinic acid of less than 1/10th normal strength; stronger solutions are stable and not affected by light. For a freshly-prepared solution containing 0.0002 gram-equivalents per litre, $\mu = 380$; when hydrolysed by light, μ for the same solution = 1048; here again, it seems as if all chlorine were present as hydrogen chloride.

In solutions of gold chloride, light causes no hydrolysis; a slight increase in conductivity with time is set down to the action of the electrodes.

The change in conductivity of stannic chloride solutions with time has been accurately traced; the change becomes less rapid as hydrolysis proceeds, and light is found to have no hydrolysing influence. At higher temperatures, the rate of hydrolysis is much increased. Comparison of the results for platinum and stannic chlorides show that the two compounds are essentially different in type.

The temperature coefficient of the conductivity has been determined for the above solutions, and found to agree approximately with the value obtained in the case of acids generally. J. C. P.

[Similar experiments on the hydrolysis of stannic chloride solutions have been made by Kowalewsky (this vol., ii, 256).—ABTRACTOR.]

Mineralogical Chemistry.

Magnetic Iron-Ores from Eastern Ontario. By FREDERICK J. POPE. (*Trans. Amer. Inst. Mining Eng.*, California Meeting, Oct. 1899, 34 pp.).—These ores occur in gneisses and schists, or at the contacts of these with crystalline limestone, and also in gabbros and anorthosites. Descriptions and twelve detailed analyses are given of the ores from several mines. The magnetites occurring in the gabbro differ from the others in being titaniferous and in containing small amounts of vanadium (up to 0.63 per cent. V_2O_5) and of nickel and cobalt (compare Abstr., 1899, ii, 109; this vol., ii, 283).

Details are given of the methods used in estimating titanium and vanadium, and also for the preparation of pure vanadic oxide from these ores. L. J. S.

Minerals from Narsarsuk, S. Greenland. By GUSTAV FLINK (*Meddelelser om Grönland*, 1899, [1900], 24, 7—180).—A detailed description is given of 34 mineral species, of which 9 are new, collected by the author in 1897 on the plateau of Narsarsuk, near Julianehaab, S. Greenland. The minerals occur in drusy cavities bounded by large crystals of microcline and *agirite*, which locally form pegmatite masses in the syenite of the region; this on weathering leaves the minerals in the coarse gravel on the surface. Analyses, several of which were made by R. Mauzelius, are given of the following minerals.

Rhodochrosite occurs as small rhombohedra, and is frequently altered to a black, powdery substance. Analyses of the least altered material gave:

MnO.	FeO.	CaO.	O, CO ₂ , H ₂ O.	Total.	Sp. gr.
57.06	15.76	2.68	[24.50]	100.00	3.666

Parisite (compare Abstr., 1895, ii, 401).—The *parisite* from Greenland differs from the original *parisite* from Colombia in several of its most important characters. The former has a rhombohedral instead of hexagonal development, and although several crystal forms are present few are common to both occurrences; it is also frequently twinned on (111) and has no cleavage, but there is sometimes a parting parallel to (111). The sp. gr. (3.902 Greenland, 4.3915 Colombia) and refractive indices also differ. Formula, $\text{CeFCa}(\text{CO}_3)_2$. The Colombian mineral has the formula $(\text{CeF})_2\text{Ca}(\text{CO}_3)_3$ (Abstr., 1899, ii, 600), but there is, however, not sufficient reason to consider that these are two distinct minerals. Analysis:

CO ₂ .	Ce ₂ O ₃ .	(La, Di) ₂ O ₃ .	Y ₂ O ₃ .	CaO.	Na ₂ O.	K ₂ O.	F.	Total, less O for F.
26.54	28.14	22.88	1.23	17.13	0.19	0.12	5.82	99.60

Cordylite (*barium-parisite*).—This new mineral occurs as small, hexagonal, club-shaped crystals, with $[a:c = 1:3.3865]$; for *parisite*, $a:c = 1:3.3645$. The crystals are pale wax-yellow, clear and transparent, and there is a distinct basal cleavage. Optically uniaxial and negative. Sp. gr., 4.31. Formula, $(\text{CeF})_2\text{Ba}(\text{CO}_3)_2$, which is the same as that of the Colombian *parisite* with barium in place of calcium. Analysis:

CO ₂ .	ThO ₂ .	Ce ₂ O ₃ .	(La, Di, &c.) ₂ O ₃ .	Y ₂ O ₃ .	FeO.	BaO.	CaO.	H ₂ O.	F.	Insol.
23.47	0.30	23.72	25.67	trace	1.43	17.30	1.91	0.80	[4.87]	2.68

Ancylite.—The orthorhombic crystals of this new mineral are octahedral in habit, with markedly curved faces of the forms {101} and {011}; $[a:b:c = 0.916:1:0.9174]$. The colour is light yellow inclining to orange, but also brownish or greyish. Sp. gr. 3.95. Formula, $4\text{Ce}(\text{OH})\text{CO}_3, 3\text{SrCO}_3, 3\text{H}_2\text{O}$. Traces of Y_2O_3 , MnO and fluorine are also present. The mineral is somewhat allied to the Norwegian *weibeyite*. Analysis:

CO ₂ .	ThO ₂ .	Ce ₂ O ₃ .	(La, Di, &c.) ₂ O ₃ .	FeO.	SrO.	CaO.	H ₂ O.	Insol.	Total.
23.28	0.20	22.22	24.04	0.35	21.03	1.52	6.52	0.60	99.76

Spodiophyllite.—This new mineral occurs as rough, hexagonal prisms or sometimes as thin, trigonal plates; it is optically uniaxial and

negative. There is a perfect basal cleavage with pearly lustre. Colour, ash-grey; very brittle; sp. gr. 2·633. Formula

The mineral resembles the micas and chlorites in its physical characters, but differs from them in containing no water; it is a meta-silicate related in composition to *segitrite* and *arfvedsonite*. Analysis:

SiO_2	Fe_2O_3	Al_2O_3	FeO	MnO	MgO	Na_2O	K_2O	Total.
53·61	11·24	4·27	4·13	0·64	10·16	8·55	7·80	100·40

Catapleiite.—Three types of crystals are distinguished: the one analysed when considered as hexagonal has $[a:c=1:1\cdot3509]$. Basal sections are in part uniaxial and in part biaxial with $2E=30^\circ$. When a crystal of this type is heated to 30° , or even when held in the warm hand, the twin lamellæ seen in a basal section disappear, and the whole becomes optically uniaxial. It has the usual formula, $\text{Na}_2\text{SiO}_3\cdot\text{H}_4\text{Zr}(\text{SiO}_4)_2$. Analysis:

SiO_2	ZrO_2	FeO	Na_2O	H_2O	Total.	Sp. gr.
44·70	30·85	0·71	14·09	9·07	99·38	2·781

Polyolithionite.—This agrees with *zinnwaldite* in the optical characters and crystal angles, but differs from it in containing more alkalis and silica. Sp. gr., 2·701. Formula, $(\text{Al,Fe})_4(\text{Li},\text{K},\text{Na})_7\text{F}_2\text{Si}_{16}\text{O}_{46}$. The mineral from Narsarsuk contains more potassium and less sodium than *Lorenzen's* original polyolithionite from the neighbouring locality, *Kangerdluarsuk* (Abstr., 1886, 677). Analysis:

SiO_2	Al_2O_3	Fe_2O_3	MnO	Li_2O	K_2O	Na_2O	F.	Total, less O for F.
58·68	10·24	4·02	0·31	8·24	11·05	1·61	8·16	98·87

Tainiolite.—This new mineral is a member of the mica group; it has the form of strips or bands and so differs in habit from other micas. The colourless crystals are monoclinic, with angles very near those of *biotite*. There is a perfect basal cleavage; it is optically biaxial and negative; $2E=50^\circ$; sp. gr., 2·86. Assuming the deficiency in the analysis to be water, the formula is given as

This composition distinguishes *tainiolite* from all other micas.

SiO_2	Al_2O_3	FeO	MgO	K_2O	Na_2O	Li_2O	Total.
52·2	2·7	0·6	19·1	11·5	1·8	3·8	91·3

Lorenzenite.—The small, acicular crystals of this new mineral are orthorhombic $[a:b:c=0\cdot6042:1:0\cdot3592]$. They have a high adamantine lustre, and are colourless to brownish, with sometimes black ends, they then resemble lucifer matches in appearance; sp. gr., 3·42. Formula, $\text{Na}_2(\text{TiO})_2\text{Si}_2\text{O}_7$. Analysis:

SiO_2	TiO_2	ZrO_2	Na_2O	K_2O	H_2O	Total.
34·26	35·15	11·92	17·12	0·37	0·77	99·59

Leucosphenite.—The white crystals of this new mineral are monoclinic, with a prismatic habit and wedge-shaped terminations $[a:b:c=0\cdot5813:1:0\cdot8501; \beta=93^\circ23']$. Sp. gr., 3·05. Formula, $\text{BaNa}_4(\text{TiO})_2(\text{Si}_2\text{O}_5)_5$. Like *petalite*, this is a dimetasilicate. The

mineral shows certain crystallographic and chemical relations to eudidymite ($\text{BeSiO}_3, \text{HNaSi}_2\text{O}_6$). Analysis :

SiO_2	TiO_2	ZrO_2	BaO	Na_2O	K_2O	H_2O	Total.
56.94	13.20	3.50	13.75	11.14	0.56	0.31	99.40

Elpidite.—This is very abundant at Narsarsuk, but it is usually much altered and has the appearance of sticks of decayed wood. Fresh, clear, and transparent crystals are very rare; these give $[a:b:c=0.51008:1:0.97813]$. The material analysed by Lindström (Abstr., 1895, ii, 401) was not fresh, and the whole of the water is probably due to alteration, in which case the formula of the mineral would be $\text{Na}_2\text{Si}_2\text{O}_5, \text{Zr}(\text{Si}_2\text{O}_5)_2$.

Narsarsukite.—This new mineral occurs plentifully at Narsarsuk as tabular or cube-shaped, tetragonal crystals with $[a:c=1:0.52352]$. They are honey-yellow, and have a perfect prismatic cleavage. Sp. gr. 2.751. Formula, $12\text{SiO}_2, 2\text{TiO}_2, 3\text{Na}_2\text{O}, \text{FeF}$. Analysis by Christensen :

SiO_2	TiO_2	Fe_2O_3	Al_2O_3	MnO	MgO	Na_2O
61.63	14.00	6.30	0.28	0.47	0.24	16.12
F. H ₂ O. Total less O for F.						
0.71 0.29 99.74.						

Chalcolamprite.—This is a new member of the pyrochlore group. It is found as small, regular octahedra on crystals of *ægirite*. The name *chalcolamprite* alludes to the metallic, coppery lustre on the faces of the crystals. Thin sections of the mineral are translucent, straw-yellow, and isotropic. Sp. gr. 3.77. Formula, $\text{R}''\text{Nb}_2\text{O}_6\text{F}_2 + \text{R}'\text{SiO}_3$. Analyses: I. *Chalcolamprite*. II. *Endeiolite*.

	Nb_2O_5	SiO_2	TiO_2	ZrO_2	Ca_2O_3	Fe_2O_3	MnO	CaO	K_2O
I.	59.65	10.86	0.52	5.71	3.41	1.87	0.44	9.08	0.38
II.	59.93	[11.48]	0.76	3.78	4.43	2.81	0.37	7.89	0.43

	Na_2O	H_2O	F.	Total less O for F.
I.	3.99	1.79	5.06	100.63
II.	3.58	4.14	0.69	100.00

Endeiolite.—This is also a new member of the pyrochlore group; it occurs as small, brown octahedra, which are remarkable in being sometimes twinned on the spinel law. Sp. gr. 3.44. Formula, $\text{R}''\text{Nb}_2\text{O}_6(\text{OH})_2 + \text{R}'\text{SiO}_3$. *Endeiolite* differs from *chalcolamprite* in having hydroxyl in place of fluorine, and both minerals differ from *pyrochlore* in having $\text{R}'\text{SiO}_3$ in place of $\text{R}''(\text{Ti}, \text{Th}, \text{Zr})\text{O}_3$. *Microelite* ($\text{Ca}_2\text{Ta}_2\text{O}_7$) also occurs at Narsarsuk (Abstr., 1895, ii, 401).

Yttrium-apatite.—This forms small, short, hexagonal prisms, which are opaque, with an enamel white colour and a metallic lustre on the surface. Sp. gr. 3.24. The results of the analysis agree with those required for the apatite formula, but part of the lime is replaced by rare earths. The insoluble portion consists of *ægirite* and *neptunite*.

P ₂ O ₅ .	CaO.	Y ₂ O ₃ , &c.	Ce ₂ O ₃ , &c.	MgO.	MnO, FeO.	H ₂ O.
41.12	47.67	3.36	1.52	0.79	traces	0.22
		F.	Insol.	Total less O for F.		
		3.59	2.63	99.37		

Another type of apatite occurring as clear, colourless, hexagonal prisms also contains rare earths.

Detailed descriptions are given of the crystallographic and optical characters and modes of occurrence of each of the above minerals, and also of epididymite, eudidymite, ægirite, arfvedsonite, eudialyte, neptunite, &c. The paper is illustrated by nine plates. L. J. S.

Britholite, a New Mineral. By CHR. WINTHER (*Meddelelser om Grønland*, 1899 [1900], 24, 190—196).—This is found in the pegmatites in the nepheline-syenite at Nauyasakik, near Julianehaab, Greenland. The opaque, brown crystals are apparently hexagonal prisms with pyramids, but really consist of biaxial orthorhombic individuals twinned together as in aragonite; $[a:b:c=0.620:1:0.423]$. $H=5\frac{1}{2}$; sp. gr. 4.446. Formula,

Analysis by C. Christensen:

Steenstrupine. By O. B. BOEGGILD (*Meddelelser om Grønland*, 1899 [1900], 24, 203—213).—Besides on the Frith of Kangerdluarsuk, steenstrupine has now been found at other localities in the nepheline-syenite district about Julianehaab, Greenland. The mineral usually occurs as isolated crystals, of which three types are distinguished. Crystals from one of the new localities, namely Tutop Agdlerkofsa, are of a different type from those analysed by Blomstrand (Abstr., 1898, ii, 296); they are brownish-black, contain fewer enclosures, and are less altered; the birefringence and dichroism are uniform throughout each crystal; streak colourless; sp. gr. 3.5122; analysis by C. Christensen gave:

SiO ₂ .	Nb ₂ O ₅ .	P ₂ O ₅ .	ThO ₂ .	(Ca, La, Di) ₂ O ₃ .	Y ₂ O ₃ .	Fe ₂ O ₃ .

The formula is written as

L. J. S.

Schizolite, a New Mineral. By CHR. WINTHER (*Meddelelser om Grønland*, 1899 [1900], 24, 196—203).—This is found as pink prisms or radiated groups in granular albite, and also rarely in pegmatite, in the nepheline-syenite near Julianehaab, Greenland. The habit, cleavage

and axial ratios [$a:b:c = 1.1496:1:1.0343$; $\beta = 85^\circ 32'$] of the monoclinic crystals closely resemble those of pectolite, of which the mineral may be considered to be a manganese variety, like manganopectolite (Abstr., 1891, 407). Sp gr., 3.089. Formula,

$15(\text{Si,Ti})\text{O}_2, 10(\text{Ca,Mn,Fe,Ce})\text{O}, 4(\text{Na,H})_2\text{O}$,
from analysis I, by C. Christensen; the formula of pectolite being $3\text{SiO}_2, 2\text{CaO}, (\text{Na,H})_2\text{O}$.

	SiO ₂ .	TiO ₂ .	CaO.	Y ₂ O ₃ .	FeO.	MnO.	CaO.	MgO.	Na ₂ O.	H ₂ O.	Total.
I.	51.06	0.68	1.47	—	2.79	12.90	19.48	—	10.71	1.36	100.45
II.	51.44	—	—	2.40	2.01	11.69	20.53	0.13	9.50	2.25	99.95

A variety of schizolite occurs in pegmatite at another locality near Julianehaab as very small and indistinct cube-like crystals and plates. Sp. gr., 3.084. Formula, $3\text{SiO}_2, 2(\text{Ca,Mn,Fe,Mg,Y})\text{O}, (\text{Na,H})_2\text{O}$, from analysis II, by C. Christensen. L. J. S.

Action of Ammonium Chloride on Natrolite, Scolecite, Prehnite, and Pectolite. By FRANK W. CLARKE and GEORGE STEIGER (*Amer. J. Sci.*, 1900, [iv], 9, 345—351. Compare this vol., ii, 24, 219).—Natrolite (from Bergen Hill, New Jersey, anal. I) and scolecite (from Whale Cove, Grand Manan Island, New Brunswick, anal. II) when heated at 350° with ammonium chloride in a sealed tube, both give the product $(\text{NH}_4)_2\text{Al}_2\text{Si}_3\text{O}_{10}$. No soluble silica is liberated when the original minerals or this ammonium natrolite are ignited. The formulae of natrolite and scolecite are therefore written as $\text{Na}_2\text{Al}_2\text{Si}_3\text{O}_{10} + 2\text{H}_2\text{O}$ and $\text{CaAl}_2\text{Si}_3\text{O}_{10} + 3\text{H}_2\text{O}$ respectively, by which they are represented as salts of the acid $\text{H}_8\text{Si}_3\text{O}_{10}$.

Prehnite (from Paterson, New Jersey, anal. III) behaves quite differently, ammonium chloride having very little action at 350° ; very little soluble silica is liberated on ignition. These results support the orthosilicate formula $\text{H}_2\text{Ca}_2\text{Al}_2(\text{SiO}_3)_3$ for prehnite.

Further experiments made on pectolite (this vol., ii, 24) do not lead to any definite results; the ammonium chloride reaction varies in different experiments and is never complete.

	SiO ₂ .	Al ₂ O ₃ .	Fe ₂ O ₃ .	CaO.	Na ₂ O.	H ₂ O at 100°	H ₂ O above 100° .	Total.
I.	46.62	26.04	—	1.48	15.69	0.39	10.18	100.38
II.	45.86	25.78	—	13.92	0.41	0.40	13.65	100.02
III.	42.31	19.95	6.20	26.63	—	5.02		100.11

L. J. S.

Epistolite, a New Mineral. By O. B. BOGGILD (*Meddelelser om Grönland*, 1899, [1900], 24, 183—190).—Epistolite was found as large, thin, rectangular plates in pegmatite veins and in granular albite at four localities in the nepheline-syenite region about Julianehaab, S. Greenland. Crystals are rare; they are monoclinic with approximately [$a:b:c = 0.803:1:1.206$; $\beta = 74^\circ 45'$]. The colour is greyish or brownish, but on the perfect basal cleavage it is silver-white, with a strong pearly lustre, $H = 1-1\frac{1}{2}$, very brittle; sp. gr. 2.885. Analysis by C. Christensen gave:

SiO ₂	Nb ₂ O ₅	TiO ₂	FeO.	MnO.	CaO.	MgO.
27.59	33.56	7.22	0.20	0.30	0.77	0.13
				Total less O for F.		
	Na ₂ O.	H ₂ O.	F.			
	17.59	11.01	1.98	99.52		

There is also a trace of potassium, but no tantalum or zirconium; 1.75 per cent. of the water is lost below 100°, and is omitted from the formula, which is given as

Epistolite contains more niobium than any other silicate. L. J. S.

Meteorite from Quesa, Spain. By EDUARDO BOSCÁ Y CASANOVES (*Actas Soc. Española Hist. Nat.*, 1899, 53—56).—This iron fell at Quesa, in Valencia, on August 1st, 1898; it weighs 10670 grams, and has the fine grained structure of an ataxite (compare following abstract). Sp. gr. 6.48. Analyses by Peset gave I for the oxidised outer portion, and II for the interior of the mass.

	Fe.	Ni.	Co, Mn, &c.	O.	Total.
I.	79.07	17.95	traces	2.98	100.00
II.	81.35	18.35	0.30	—	100.00

L. J. S.

Meteoric Iron from Quesa, Spain. By EMIL W. COHEN (*Mitth. naturwiss. ver. f. Neu-Vorpommern Rügen, Berlin*, 1900, 31, 63—66. Compare preceding abstract).—A new examination of a larger piece of this iron shows the structure to be octahedral with lamellæ of medium width. A new analysis (I) has been made, since the previous analysis by Peset shows much more nickel than any other known octahedrite. The previous determination of the fine-grained structure was based on the examination of small fragments from the external part of the mass; this is much poorer in nickel (anal. II) than the interior.

	Fe.	Ni+Co.	P.	Total.

II.	95.56	4.40	—	99.96

L. J. S.

Gases Evolved by the Springs of Mont-Dore. By F. PARMENTIER and A. HURION (*Compt. rend.*, 1900, 130, 1190—1191).—The gas evolved by the spring water of Mont-Dore has the following percentage composition: Carbon dioxide, 99.50; nitrogen, 0.49; argon, 0.01.

H. R. LE S.

Combustible Gases of Salsomaggiore. By RAFFAELE NASINI and ROBERTO SALVADORI (*Gazzetta*, 1900, 30, i, 281—296).—Analyses are given of the various gases which are evolved, together with the saline waters and petroleum, from the springs of Salsomaggiore. The gases, which burn with a luminosity about equal to that of ordinary coal gas, consist for the most part of methane and ethane, with varying and, in general, small proportions of unsaturated hydrocarbons, nitrogen and carbon dioxide.

T. H. P.

Physiological Chemistry.

The Percentage Oxygen Capacity and Total Oxygen Capacity and the Total Mass of Blood in Man. By JOHN S. HALDANE and J. LORRAIN SMITH (*Proc. Physiol. Soc.*, 1900, v—vi; *J. Physiol.*, 25).—The oxygen capacity of the hæmoglobin in ox-blood was first determined by the ferricyanide method. A small volume of human blood was then compared colorimetrically with the ox-blood, and its percentage oxygen capacity calculated, for the colour of the blood runs parallel to its power of absorbing oxygen. In healthy human blood, the percentage oxygen capacity is between 16 and 21. The total oxygen capacity was determined by allowing the subject of the experiment to breathe and absorb a known volume of carbon monoxide. The percentage saturation of the hæmoglobin was determined in a drop of the blood by the carmine method, and from the result the total capacity of the blood for absorbing carbon monoxide or oxygen could easily be calculated. The total volume of the blood was then calculated from the two preceding numbers, and its mass by multiplying the volume by the specific gravity. The commonly accepted estimate that the weight of the blood is equal to about a twelfth of the body weight is much too high; the average amount is only a twentieth of the body weight.

W. D. H.

The Volume, Total Oxygen Capacity, and Percentage Oxygen Capacity of the Blood in Chlorosis and Pernicious Anæmia. By J. LORRAIN SMITH (*Proc. Physiol. Soc.*, 1900, vi—vii; *J. Physiol.*, 25).—In chlorosis, the total oxygen capacity is approximately normal, but the percentage oxygen capacity is markedly diminished (often below 50 per cent.); the volume of the blood is markedly increased. The decrease in the number of red corpuscles and in the amount of hæmoglobin cannot be regarded as due simply to increase in the plasma. In pernicious anæmia, both percentage and total oxygen capacity are greatly diminished, but the volume of the blood is increased. The decrease in the number of the red corpuscles, and in the amount of hæmoglobin, is greater than can be explained by the increase in the volume of the blood.

W. D. H.

Relationship of Iron to Blood-formation. By EMIL ABDERHALDEN (*Zeit. Biol.*, 1900, 39, 487—523).—Previous portions of the research have shown that inorganic iron, hæmoglobin, and hæmatin in the food are absorbed, and lead to an increase of body weight, and of the blood-pigment. The most important fact now added is that animals on their normal diet assimilate more iron than those kept on a diet poor in iron, to which inorganic iron salts, hæmoglobin, or hæmatin has been added.

W. D. H.

Effect of Ingestion of Alcohol on the Blood of Mother and Fœtus, and on the Milk. By MAURICE NICLOUX (*Compt. rend.*, 1900, 130, 855—858).—Experiments were made on dog, sheep, and guinea-pig. Ingested alcohol passes into the milk. The amounts of

alcohol in the blood and milk of the mother and the blood of the fetus are approximately equal.
W. D. H.

Chemical Changes in the Blood produced by Feeding with Ammonium Sulphate. By THEODOR RUMPF and O. SCHUMM (*Zeit. physiol. Chem.*, 1900, 29, 249—255).—After the administration of ammonium sulphate, the amount of alkali in the blood is diminished; this is chiefly due to a lessening of organic sodium compounds. The sodium chloride and the amount of calcium in the blood are increased; the water is lessened.
W. D. H.

Hæmorrhage and Transfusion in Dogs. By PERCY M. DAWSON (*Amer. J. Physiol.*, 1900, 4, 1—24).—A full account of experiments concerning which a preliminary communication has already been made (this vol., ii, 291). An important new point is that transfusion of Ringer's fluid containing more than 0.026 per cent. of calcium chloride is dangerous. More than this appears to overstimulate the heart; and several cases of death in dogs occurred.
W. D. H.

Gaseous Metabolism of the Submaxillary Gland. By JOSEPH BARCROFT (*J. Physiol.*, 1900, 25, 265—282).—This preliminary paper treats mainly of methods. The form of gas pump used is described in full with illustrations; it is a modification of Töpler's. Haldane's method of gas analysis was employed. Incoagulability of the blood is best brought about in dogs, which were the animals used, by injection of leech extract: this is not absolutely certain to produce incoagulability, but it has the advantage of not influencing the flow of saliva. The amount of oxygen and carbon dioxide in the blood is, however, increased. The anæsthetics found most suitable were morphine and chloroform; the effect of these anæsthetics on the blood gases is inconstant, but the most marked feature is a gradual increase in the carbon dioxide.
W. D. H.

Influence of Asparagine and Ammonia on Proteid Metabolism in Ruminants. By OSCAR KELLNER, A. KÖHLER, F. BARNSTEIN, W. ZIELSTORFF, R. EWERT, and K. WEDEMEYER (*Zeit. Biol.*, 1900, 39, 313—376).—The experiments recorded with full details were performed on four sheep. In two, the amount of proteid in the food was small, in the other two, medium. In the first case, the addition of asparagine furthers the putting on of proteid; ammonium acetate has the same action. In the second case, asparagine has no action in influencing either the digestion or the assimilation of proteid.
W. D. H.

Nuclein Metabolism. By OTTO LOEWI (*Chem. Centr.*, 1900, i, 871; from *Arch. exp. Path. Pharm.*, 44, 1—23).—The quantity of phosphoric and uric acids in the urine largely depends on the amount of nuclein in the food. Allantoin does not occur. After feeding on allantoin, only a small amount of it is found in the urine.
W. D. H.

Energy-value of Flesh and Proteids. By EDOUARD PFLÜGER (*Pflüger's Archiv*, 1900, 79, 537—596).—The article is mainly a

critical review of our knowledge of the subject, and the numerous errors which must be avoided in a study of the metabolism of proteid material. Considerable space is devoted to a criticism of Rübner's methods and results. The urine, after flesh diet, receives contributions from the metabolism of fat, and cannot be considered a purely 'flesh urine.' Rübner's assumption that meat extract takes no part in metabolism is questioned, at any rate in regard to those extractives which do not pass unchanged into the urine. W. D. H.

Influence of Alcohol on Muscular Work. By J. C. TH. SCHEFFER (*Chem. Centr.*, 1900, i, 870—871; from *Arch. exp. Path. Pharm.*, 44, 24—58).—From experiments made with Mosso's ergograph, it appears that alcohol causes first an increase of muscular work, and later a decrease. The irritability passes through corresponding phases. If the peripheral motor nerve apparatus is eliminated in animals by curare, alcohol has no effect. W. D. H.

Transformation of Fat into Glycogen. By CHARLES BOUCHARD and ALEXANDRE DESGREZ (*Compt. rend.*, 1900, 130, 816—822).—In a starving animal, the copious administration of fat does not increase the glycogen of the liver, but there is a rise in that of the muscles. Fat is therefore regarded as one source of the muscular glycogen; another source is the sugar of the blood that leaves the liver. On oxidation, muscular glycogen is stated to pass into the condition of lactic acid, and not into that of sugar. W. D. H.

Action of Soaps in the Body. By IMMANUEL MUNK (*Chem. Centr.*, 1900, i, 676; from *Centr. Physiol.*, 13, 657—661).—When soaps are introduced into the blood, the heart is affected, and the blood pressure sinks. In the case of sodium soaps, Bottazzi (*Arch. Ital. Biol.*, 32, 176) attributes this action to the sodium. This cannot be the case, since to produce such a fall of pressure a quantity of sodium hydroxide is necessary much larger than that which can be formed by dissociation from the soap injected. W. D. H.

Absorption of Fats and Soaps in the Large Intestine. By HARTOG J. HAMBURGER (*Archiv Anat. Physiol. Physiol. Abth.*, 1900, 433—464).—The experiments on dogs which are here recorded show that the large intestine is capable of absorbing fats, this property not being confined, as hitherto thought, to the small intestine. In order to obtain marked absorption, it is necessary to take an emulsion and leave it a long time in the intestine. Admixture with sodium carbonate is unnecessary; sodium chloride, which is rapidly absorbed, will do as well. Admixture with *sapo medicatus* also suffices. Soaps are absorbed, but during absorption are partly converted into fats. This is brought about by the mucous membrane; it can be proved after the removal of the intestine from the body, and is also brought about by the 'surviving' membrane after it is finely minced. Heating the mucous membrane to 80° destroys this property. W. D. H.

Fixation of Alkaline Bases in the Fœtal Body during the last Five Months of Intrauterine Life. By LOUIS HUGOUNENQ (*Compt. rend.*, 1900, 130, 941—942).—The proportion of potassium

and sodium in the ash of fœtuses of different ages was determined. As growth takes place, both bases increase in amount, but the sodium increases more rapidly on account of the richness of cartilage in sodium chloride. The potassium is a predominant element of red blood corpuscles, and in well nourished subjects increases more rapidly than in the cases of malnutrition. W. D. H.

Absorption of Iodides by the Skin. By F. GALLARD (*Compt. rend.*, 1900, 130, 858—861. Compare Abstr., 1899, ii, 503).—The skin of man and animals can absorb aqueous solutions of iodides. The elimination by the urine is slow, so that some accumulation occurs in the tissues. The respiratory mucous membrane only permits the entrance of a very small amount of iodine. W. D. H.

Variations of the Iodine of the Thyroid of New Born Children under various Pathological Influences. By ALBERT CHARRIN and BOURCET (*Compt. rend.*, 1900, 130, 945—948).—In various cachectic conditions of the mother, the new born child is feeble, and often suffers no harm from injections of thyroid extract. There are frequently histological changes in the thyroid of these infants. The present paper records the examination of the thyroid in 32 cases of the kind. In 18 of these, no iodine was found; the maladies of the mother and the child were very different. In the remaining 14 cases, the pathological conditions being here equally variable, the percentage of iodine in the dry gland varied from 0.001 to 0.006. W. D. H.

Hüfner's Method of preparing Pure Glycocholic Acid. By W. A. OSBORNE (*Proc. Physiol. Soc.*, 1900, xi—xii; *J. Physiol.*, 25).—Hüfner (*J. prakt. Chem.* [ii], 1874, 10, and 1879, 19) described an effective method of obtaining glycocholic acid from ox-bile. The main points in the method are that bile is shaken up with ether and hydrochloric acid. In a short time, crystals of glycocholic acid separate out so abundantly as to render the bile almost solid, and may be purified by washing and recrystallisation. Certain observers have cast doubt on the method, and in some districts of Germany success was generally not obtained. In America, also, the separation of the crystals occurred in only 22 per cent. of the specimens of ox-bile examined. The present paper shows that the bile of English oxen and cows gives completely successful results. The method also succeeds with rabbits' bile. W. D. H.

The Maximum Production of Hippuric Acid in Rabbits. By F. H. PARKER and GRAHAM LUSE (*Amer. J. Physiol.*, 1900, 3, 472—484. Compare Abstr., 1899, ii, 312).—In a fasting rabbit fed with lithium benzoate, the amount of glycocine eliminated as hippuric acid in the urine indicates that 4 grams may be derived from the metabolism of every 100 grams of body proteid, and the excretion runs parallel to the proteid destroyed. Administration of carbohydrates has no effect. After gelatin, the number sinks to 3.1 from the combined metabolism of gelatin and proteid; after casein, it is 3.45. After phloridzin and benzoic acid in one experiment, the number was doubled, but this could not be repeated. In metabolism, the proteid

and gelatin molecule may yield glycocine to the amount of at least 3 to 4 per cent.

W. D. H.

Caseinogen of Human Milk. By ERWIN KOBRAK (*Pflüger's Archiv*, 1900, 80, 69—85).—The caseinogen was prepared from centrifugalised milk by the careful addition of acetic acid; various foreign substances were then removed by dialysis, and the product purified by means of alcohol and ether. It differs from the caseinogen of cows' milk, especially in its small degree of acidity; the casein formed from it by rennet is flocculent, not coherent. By repeated solution in alkali and precipitation by acid, a product is finally obtained, practically identical with cow-caseinogen. Human caseinogen is therefore probably a nucleo-proteid identical with that obtained from cows' milk, but containing an admixture of some basic, proteid-like material, possibly histon or protamine.

W. D. H.

[**Glycolytic Action of the Pancreas and of Urine.**] By G. PIERALLINI (*Chem. Centr.*, 1900, i, 828; from *Zeit. Klin. Med.*, 39, 26—31).—The urine, both in health and disease, has no glycolytic action. Search for a glycolytic ferment in the human pancreas removed after death gave uncertain results.

W. D. H.

Lipolytic Ferment in Human Ascitic Fluid. By HARTOG J. HAMBURGER (*Proc. K. Akad. Wetensch. Amsterdam*, 1900, 2, 428—436).—It is extremely probable that the lymph contains an agent which reduces the fat emulsion of the intestine to the extremely finely divided condition in which it is found as the 'molecular basis' of chyle. As the lymph of the villi is difficult to collect in quantity, advantage was taken of a case of ascitic fluid, supposed to be chylous. The opalescent character of this fluid was, however, found not to be due to fat, but to mucoid; nevertheless, it was found possible to make with this fluid, as well as with ordinary horse serum, a perfect "dust-like" emulsion. Possibly the continual movement of the lymph in the villi normally produces a like change. The same ascitic fluid contains also a lipolytic ferment, which acts on the finely divided fat; but for this action, the presence of blood corpuscles and access of air are also necessary. The ferment is a constituent of the chyle rather than of the blood, as Cohnstein and Michaelis consider.

W. D. H.

A Diastatic Ferment in Hen's Eggs. By JOHANNES MÜLLER and M. MASUYAMA (*Zeit. Biol.*, 1900, 39, 542—559).—The yolk of the hen's egg contains, in not unimportant quantities, an enzyme, which is capable of transforming starch into dextrin and sugar (isomaltose).

W. D. H.

Meningocele Fluid. By WLADIMIR VON GULEWITSCH (*Zeit. physiol. Chem.*, 1900, 29, 281—282).—Choline was sought for in a specimen of cerebro-spinal fluid removed from a meningocele, with negative results. This confirms the statement made by Mott and Halliburton (*Abstr.*, 1899, ii, 315) that normal cerebro-spinal fluid does not contain this base.

W. D. H.

The Crystalline Stalk of Acephalous Molluscs. By HENRI COUPIN (*Compt. rend.*, 1900, 130, 1214—1216).—The crystalline stalk

of acephalous molluscs has been regarded as a copulative organ, and as a manubrium to agitate the gastric contents. The present research, carried out on *Cardium edule*, shows that the weight of the organ is 0.03 gram, and it contains 87 per cent. of water. It is regarded as a digestive agent containing the ferments amylase with a little sucrase.

W. D. H.

Solution of Uric Acid by means of Nucleic Acid. By ALBRECHT KOSSEL and GOTO (*Sitzungber. Ges. gesamm. Naturwissensch. Marburg*, 1900, April 6).—It has been previously shown that nucleic acid will unite with certain quantities of purine bases. The present research shows that similar loose combinations are formed between nucleic acid and thymic acid on the one hand, and uric acid on the other, and in this way more uric acid is dissolved than in control specimens where the nucleic acid is absent. It is thus possible that the action of nucleic acid and its compounds in the body may be a factor in determining the solubility of uric acid there. Whether nucleic acid can be used as a therapeutic agent in assisting the solution of uric acid is another possibility.

W. D. H.

Investigation of Urine by a Combination of the Freezing Point and Blood Corpuscle Methods. By HARTOG J. HAMBURGER (*Centr. inn. Med.*, 1900, No. 12).—A combination of the two methods mentioned above affords a means of determining approximately the osmotic pressure due to inorganic constituents (such as sodium chloride) and organic constituents (such as urea). If Δ be determined for the urine, and then, by means of the blood corpuscle method, the osmotic pressure is found equal to that of a saline solution of a certain strength, of which the depression of freezing point is Δ' , then $\Delta - \Delta'$ gives the value to be assigned to urea and similar substances. Examples are given and the question discussed from the theoretical standpoint.

W. D. H.

Glycuronic Acid in Normal Urine. By PAUL MAYER and CARL NEUBERG (*Zeit. physiol. Chem.*, 1900, 29, 256—273).—The work recorded covers much the same ground as that in a paper previously published (this vol., ii, 155). The following additional fact of physiological importance is added, that glycuronic acid compounds are constituents of normal urine; the greatest part of the acid is combined with phenol, and smaller amounts with indoxyl and scatoxyl.

W. D. H.

Elimination of Nitrogen, Sulphates, and Phosphates after Ingestion of Proteid Food. By H. C. SHERMAN and P. B. HAWK (*Amer. J. Physiol.*, 1900, 4, 25—49).—The experiments were conducted by the authors on themselves. The urine was collected at three hour intervals; the rates of excretion of nitrogen and sulphates run closely parallel, and show a tendency to rise during the morning, reaching a maximum after the midday meal, with a slight fall in the following period, and another rise after the evening meal. A minimum is reached during the night. The excretion of phosphates describes a different curve, rising steadily from the middle of the morning until retiring, falling during sleep and continuing to fall for three hours

after rising, reaching a minimum after breakfast. When 64 grams of extra proteid was taken with breakfast, the output of nitrogen began to rise three hours later until the sixth to the ninth hour, when it declined at first rapidly, and then slowly, until it reached the normal in about 36 to 39 hours. The excretion of sulphates runs a similar course; the rise, however, begins a little later, and reaches the normal a little earlier. The increase in the rate of excretion of phosphates begins a little later still, reaches a maximum simultaneously with the nitrogen, and then regains the normal very rapidly in from 12 to 15 hours.

The increased heat of combustion of the urine was but little greater than would correspond with an amount of urea equivalent to the extra nitrogen eliminated. This indicates that the amount of less highly oxidised constituents of the urine was but little affected. The nature and extent of the changes in the urine seem to have been about the same when the proteid was simply added to the diet as when it was substituted for an isodynamic amount of fat. A moderate gain or loss of body nitrogen does not affect the changes noted. W. D. H.

Indicanuria Produced by Administration of Oxalates. By ERICH HARNAACK and ELSE VON DER LEYEN (*Zeit. physiol. Chem.*, 1900, 29, 205—221).—Indicanuria can be produced by poisoning with dilute sulphuric acid (2.5 to 6 per cent. solution), but much more readily and intensely by the administration of oxalic acid by the mouth or subcutaneously. In order to produce this effect, the best form to give is sodium oxalate, and non-toxic doses will accomplish the result; for instance, in a large dog, 0.06 gram given subcutaneously is enough. The indigotin does not apparently arise in the alimentary canal, but as a result of disordered tissue metabolism. W. D. H.

Comparative Investigation of the Fæces after Feeding on Meat and Plasmon. By KARL MICKO (*Zeit. Biol.*, 1900, 39, 430—450).—After feeding on plasmon, the fæces contain no unabsorbed proteids; absorption is stated to be even more complete than after a meat diet. W. D. H.

Organic Phosphorus in Fæces after Feeding on Milk. By PAUL MÜLLER (*Zeit. Biol.*, 1900, 39, 451—481).—By examining the fæces of children fed, some on human, some on cow's milk, no difference between them could be discovered. The N:P ratio was determined by two methods; but the results were practically identical in all cases. The statement made by Knöpfelmacher, that after feeding on cow's milk there is a considerable digestion residue rich in phosphorus in the fæces, was, therefore, not confirmed. W. D. H.

Composition of Urinary Calculi. By LEOPOLD SPIEGEL (*Chem. Centr.*, 1900, 1, 616—617; from *Ber. deutsch. pharm. Ges.*, 9, 318—326).—A large number of analyses of stones removed from various parts of the urinary tract are recorded. W. D. H.

Secretion of Pepsin in Gastric Disease. By ROTH (*Chem. Centr.*, 1900, i, 618; from *Zeit. klin. Med.*, 39, 1—12).—Mett's method (*Diss.*, Petersburg, 1899) is recommended for the clinical estimation of

pepsin in the stomach contents. From a consideration of numerous cases of disease, the estimation of pepsin is considered to have less value for diagnostic than for therapeutic purposes. W. D. H.

[Metabolism in Leucæmia.] By C. VON STEJSKAL and F. ERBEN (*Chem. Centr.*, 1900, i, 828—829; from *Zeit. klin. Med.*, 39, 151—170).—These are chiefly studies in metabolism in various forms of leucæmia. W. D. H.

Physiological Effects of Extracts of Nervous Tissues. By WILLIAM D. HALLIBURTON (*Proc. physiol. Soc.*, 1900, vii—ix; *J. Physiol.*, 25).—Saline extracts of various nervous tissues (fresh and dried) produce a temporary fall of blood pressure, partly by their effect on the heart, partly by causing a dilatation of splanchnic blood vessels. The effect is more marked the greater the proportion of grey matter in the tissue used. The effect is not abolished by section of both vagi, nor, as a rule, by the administration of atropine. The depressor substance is soluble in alcohol, and choline is always to be found in the alcoholic solution. Possibly lactic acid and other substances not yet identified are partly responsible for the effect; these substances will account for the fact that the effect is not always completely neutralised by atropine. It is not advisable to employ glycerol extracts, for glycerol itself has a depressor action. W. D. H.

Physiological Effects of Extracts of Nervous Tissues. By W. A. OSBORNE and SWALE VINCENT (*J. Physiol.*, 1900, 25, 283—294; *Proc. physiol. Soc.*, 1900, ix—x; *J. Physiol.*, 25).—The main results are the same as those recorded in the preceding abstract. The principal difference is the following: although choline is admittedly present in the extracts, its amount is not regarded as sufficient to account for the effect produced, and it is moreover stated that the depressor effect of the extracts is not abolished by atropine. The other substance or substances responsible for the fall of blood pressure were not identified; they are soluble in alcohol and in ether. W. D. H.

Anti-leucocytic Serum; its Action on the Coagulation of Blood. By C. DELEZENNE (*Compt. rend.*, 1900, 130, 938—940).—Certain products of bacterial agency in the blood-serum are believed to hinder coagulation by causing destruction of the leucocytes. Peptone is believed to act in a similar way. The anti-coagulating action of such serum can only be demonstrated by injecting it into the blood stream; *in vitro*, it accelerates coagulation. W. D. H.

Chemical Behaviour of Drugs and Poisons in the Organism. By SIGMUND FRÄNKEL (*Chem. Centr.*, 1900, i, 775—776; from *Pharm. Post*, 33, 109—111).—A discussion on general pharmacological questions, and of the work of others on the subject. W. D. H.

Action of some Aliphatic Compounds. By MÅRTEN ELFSTRAND (*Chem. Centr.*, 1900, i, 560; from *Arch. exp. Path. Pharm.*, 43, 435—455).—Valeraldehyde, pentane, and cyclopentadiene are narcotics like ether, but are not as powerful; cyclopentadiene acts also on muscles,

causing rigor. During the narcosis produced, stimulation of the vagus causes no inhibition of the heart.
W. D. H.

Physiological Action of Nitriles. By EDMOND FIQUET (*Compt. rend.*, 1900, 130, 942—945).—Acetonitrile is less toxic than generally supposed. In rabbits and guinea-pigs, 1.5 c.c. per kilo. of body weight are necessary to cause death rapidly. The higher nitriles are very toxic, and act like certain ptomaines; they produce loss of sensation and muscular paralysis, preceded by convulsions. Very similar effects follow the injection of urine. The influence of the CO_2H and SO_3H groups is to lessen the toxic power of nitriles.
W. D. H.

Action of Santonin and Amyl Nitrite on Vision. By WILHELM FILEHNE (*Pflüger's Archiv*, 1900, 80, 96—107).—In frogs poisoned by santonin and kept in the dark, no departure from the normal is noted in the retinal pigments; but if the animals are kept in the light, and then placed in darkness, there is little or no regeneration of the visual purple, and the melanin-laden epithelial cells show little activity. Amyl nitrite acts in the same way, except that the epithelial cells behave normally in conditions both of light and darkness.
W. D. H.

Action of Caffeine and Theobromine on the Heart. By JOHANNES BOCK (*Chem. Centr.*, 1900, i, 559; from *Arch. exp. Path. Pharm.*, 43, 367—399).—Both caffeine and theobromine cause the isolated mammalian heart to beat more quickly and lessen its elasticity. With large doses, the blood pressure sinks. In rabbits, small doses of caffeine when injected cause a lessening of the heart's rate; this is the result of stimulation of the vagus centre. The rise of blood pressure is due to stimulation of the vaso-motor centre.
W. D. H.

Physiological Action of 1- and 4-Methylxanthines. By MANFREDI ALBANESE (*Chem. Centr.*, 1900, i, 558—559; from *Arch. exp. Path. Pharm.*, 43, 305—310).—The two methylxanthines produce muscular rigor in frogs. 0.01 gram of heteroxanthine or of 1-methylxanthine is lethal; the same dose of 4-methylxanthine only causes slight stiffness. After the injection of methylxanthine, caffeine and theobromine produce little or no tetanus, as they usually do. The lethal dose of 4-methylxanthine in dogs is from 0.3 to 0.4 gram per kilo. of body weight. Smaller doses cause convulsions and affect the breathing, although the heart is still powerful and regular. Heteroxanthine produces no convulsions, but paralysis. With moderate doses of the two methylxanthines, the frequency of the pulse and the arterial pressure go up; with larger doses, although the pulse is still fast, the pressure goes down. In dogs, these substances cause no diuresis, but in rabbits they do. A small quantity of the methylxanthines appears unchanged in the urine.
W. D. H.

Action of Nicotine on Respiration and Circulation. By HEINRICH WINTERBERG (*Chem. Centr.*, 1900, i, 559—560; from *Arch. exp. Path. Pharm.*, 43, 400—434).—In mice and rabbits, nicotine is very fatal, and produces clonic spasms and cessation of respiration.

Smaller doses stimulate respiration. The blood pressure first sinks and then rises.

W. D. H.

Comparative Action of Veratrine Alkaloids on Muscle and Nerve. By AUGUSTUS D. WALLER (*Proc. Physiol. Soc.*, 1899; *J. Physiol.*, 1900, 25).—A frog poisoned by veratrine has muscles that give the well known protracted contraction and nerves that give normal electrical variations in activity. A frog poisoned by proto-veratrine has muscles that give a normal contraction and nerves that give a protracted negative variation.

W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

Production of Quinone by Streptothrix Chromogena and the Biology of this Microbe. By MARTINUS W. BEIJERINCK (*Arch. Neerl.*, 1900, iii, 2, 327—340).—The organism *Streptothrix chromogena*, which is peculiar on account of its capability of causing the formation of quinone, had been previously known to the author as *S. humifica* on account of its playing an active part in the formation of humus in soil; it is probable that both functions are intimately connected. As probably many species exist, the name *S. chromogena Gasperini* is given to the particular microbe examined, and of this, as well as of an allied species, *S. alba*, descriptions are given. It is a minute myceliform vegetation whose spores possess considerable powers of resistance, withstanding water at 80°, but being destroyed at 100°. It is found in soils to the depth of one or two metres, and is abundant in the soil adhering to roots. The author believes the organism to be important to plant life, not only on account of its rapidly converting nitrates into nitrites, and of producing humus, but also probably in aiding the accomplishment of vital processes of which the roots themselves are incapable. The tests are described by which the presence of quinone or of quinhydrone was determined, and the mode of its formation is discussed. It is probably formed from albumin or peptones, as a consequence of catalytic decompositions due to the organisms.

L. M. J.

Action of Fluorescent Substances on Infusoria. By OSCAR RAAB (*Zeit. Biol.*, 1900, 39, 524—546).—In researches on the action of acridine, phosphines, and eosin, daylight was found to increase the destructive influence on infusoria; this is evidently connected with the fluorescence of these compounds. The rays which act most in this way are those which most excite fluorescence, and it is probable that fluorescent substances are able to transform the energy of rays of light into chemical energy. It is also probable that fluorescence plays a part in the animal organism, but in a lesser degree.

W. D. H.

Reactions to Stimuli in Unicellular Organisms. By HERBERT S. JENNINGS (*Amer. J. Physiol.*, 1900, 3, 397—403).—The experiments previously described (this vol., ii, 158) are again discussed, and points

of disagreement with Garrey (*ibid.*) considered. These points are mainly those of nomenclature and interpretation of results.

W. D. H.

Root Nodules of Alder and *Elæagnus*. By LORENZ HILTNER (*Forsil. naturw. Zeit.*, 1898, 7, 415—423).—It was previously shown (*Landw. Versuchs-Stat.*, 46, 153) that, like the *Leguminosæ*, alder plants when provided with root nodules grow normally in absence of combined nitrogen. Some trees have now been growing for five years in sand without nitrogenous manure, and have attained a height of 1·5 metres. Young alder trees grown in ordinary soil continue to grow normally when planted in sand free from nitrogen.

The organism which produces the nodules, *Frankia subtilis*, forms a connecting link between bacteria and fungi. Unlike leguminous plants, alder plants develop normally in water cultures when the nodules remain covered with water (compare this vol., ii, 299). Nodules which seem to be produced by the same organism occur on all varieties of alder.

As regards *Elæagnus*, inoculated plants have grown for seven years without combined nitrogen. Probably all the varieties, such as *Hippophaë* and *Shepherdia*, are enabled, by symbiosis, to utilise free nitrogen (compare Frank, *Ber. deut. bot. Ges.*, 1891, 9, 224.) N. H. J. M.

Assimilation by Means of Chlorophyll. By GINO POLLACCI (*Chem. Centr.*, 1900, i, 822; from *Atti. Inst. Bot. Pavia*, 7, October, 1899. Compare this vol., ii, 160).—The green organs of plants grown in sunlight restore the colour of magenta which has been decolorised by sulphurous acid, whilst fungi or plants which have been kept for a long time in the dark or in an atmosphere free from carbon dioxide do not give this reaction. The distillate obtained by boiling the liquid expressed from plants which have grown in sunlight shows all the reactions of formaldehyde. E. W. W.

Chlorophyllous Assimilation in Indoor Plants. By ED. GRIFFON (*Compt. rend.*, 1900, 130, 1337—1340).—Plant species in general, whether indigenous or cultivated in hothouses, are quite incapable of decomposing carbon dioxide in dimly-lighted apartments; the minimum intensity of illumination at which chlorophyllous assimilation is possible varies for each species. The respiration of certain plants (heather, *Begonia* and *Selaginella*) is so feeble that it is counter-balanced by assimilation even in diffused daylight, and accordingly these species evolve oxygen when cultivated in partly darkened rooms (compare this vol., ii, 159). G. T. M.

Occurrence of Albumin, Albumose, and Peptone in the Vegetative Portions of Plants. By THOMAS BOKORNY (*Pflüger's Archiv*, 1900, 80, 48—68).—The principal references to the literature of this subject from Ritthausen onwards are given. The chief new point made out in an investigation of the soluble proteids in numerous portions of plants of different kinds is that, with the exception of fungi and seedlings, proteoses and peptone are almost altogether absent. W. D. H.

Occurrence of Dulcitol in the Bark of *Evonymus Artropurpureus*. By M. HOEHNEL (*Chem. Centr.*, 1900, i, 869; from *Pharm. Zeit.*, 45, 210—211).—The bark of *Evonymus artropurpureus* has been found to contain dulcitol, but not mannitol. The dulcitol was isolated and identified by its properties and behaviour. E. W. W.

Gummy Substance in Elm Galls. By NAPOLEONE PASSERINI (*Ricerche Esper. Istituto Agrar. Scandicci*, 1896—1897).—The galls of *Ulmus campestris* contain a dense, syrupy liquid which is colourless or slightly yellowish, or more rarely brown. The liquid is slightly alkaline, does not show the tannin reaction with ferric chloride, and is strongly dextrorotatory. Sp. gr. 1.06553 at 21°. It contains 18.94 per cent. of a gum, precipitated by alcohol, which resembles gum arabic in appearance. The gum does not yield mucic acid with nitric acid, or furfuraldehyde when distilled with hydrochloric acid; and it is not coloured by iodine. It is precipitated by lead acetate, and reduces copper salts readily. When oxidised with nitric acid, much tartaric and very little oxalic acid are formed. N. H. J. M.

Distribution of the Diastatic Enzyme in the Potato Plant. By ADOLF MAYER (*Chem. Centr.*, 1900, i, 823—824; from *J. Landw.*, 48, 67—70).—In order to ascertain the distribution of the diastatic enzyme, the amount of diastase in the following materials was approximately determined. (1) Old germinated potatoes, and (2) the sprouts from these potatoes; (3) old potatoes from the field; (4) the young tubers attached to these; (5) the stalks above the ground, and (6) the leaves on these stalks. (1) and (6) were found to contain by far the most diastase, (2) contained very much less, and (3), (4) and (5) were practically free from diastase. Thus, in accordance with the present theory, the organs from which the carbohydrate is sent throughout the plant are the richest in the diastatic enzyme. The old tubers from the field no longer contained diastase, but in this case, the plant being already completely developed and producing abundance of carbohydrate, a supply from the mother tuber was no longer necessary.

Similar experiments made with sugar beet showed that none of the organs contained any enzyme analogous to invertin. In this case, however, the monosaccharides passing through the leaves are not necessarily formed from sugar, and in fact the roots always contain more sugar than the leaves. Experiments with oats show that the ripe seed contains much larger quantities of the diastatic enzyme than the half-ripe ears. E. W. W.

Formation of Vanillin in Potato Parings and its Detection. By W. BRÄUTIGAM (*Chem. Centr.*, 1900, i, 728; from *Pharm. Zeit.*, 45, 164).—Vanillin does not occur in fresh potato parings, but is formed under the influence of warmth and atmospheric oxygen, its formation not being dependent on any bacteriological process. The amount of vanillin formed depends on the temperature, &c., and also on the kind of potato.

Fresh bark taken from a lime tree in summer was found to contain vanillin, but the bark of the same tree in winter was devoid of this substance. E. W. W.

Products in Tobacco Smoke. By HERMANN THOMS (*Chem. Centr.*, 1900, i, 826—827; from *Ber. Deutsch. Pharm. Ges.*, 10, 19—31).—Experiments on the products in tobacco smoke have led to the following conclusions: (1) Tobacco smoke contains the following bases which are injurious to health: nicotine and its decomposition products, pyridine and homologues, and a peculiar, poisonous, ethereal oil which is only formed during the combustion of the tobacco. (2) A solution of alkali not only extracts carbon dioxide and butyric acid from tobacco smoke, but also hydrocyanic acid. The quantity of the last is too small, however, to exercise any physiological influence. (3) The quantity of carbon monoxide in the smoke is also too small to have any deleterious effect. (4) A cigar end may contain as much as 3—4 times the amount of nicotine originally present in the tobacco. (5) Of the total nicotine contained in the smoke, 75 per cent. was isolated as such, whilst 25 per cent. was decomposed. The original paper contains a sketch of an apparatus by means of which products in the smoke of cigars may be examined, 10—15 cigars being sufficient for the test. The amount of nicotine in the cigars is first determined by Keller's method (*Abstr.*, 1899, ii, 193), or by the author's potassium bismuth iodide method. In the latter, which depends on the property of the iodide of precipitating nicotine and organic bases, but not ammonia, 10 grams of the sliced cigars are left in contact with 100 c.c. of 10 per cent. sulphuric acid in a closed vessel for 24 hours at a moderate temperature; to 50 c.c. of the filtered extract, 10 c.c. of potassium bismuth iodide solution (Kraut, *Abstr.*, 1882, 528) are added, the precipitate collected, washed with a little water, and then treated with 20 c.c. of a 15 per cent. sodium hydroxide solution; the alkaline liquid is shaken with 40 c.c. of a mixture of equal volumes of ether and light petroleum, and to 20 c.c. of this extract 10 c.c. of a mixture of equal volumes of alcohol and water and a drop of iodo-eosin solution are added, and the mixture is finally titrated by Keller's method. The percentage of nicotine is found by multiplying the c.c. of decinormal hydrochloric acid used by 0.6480. The pyridine bases are removed by distilling the acetic acid solution in steam, and the nicotine and ammonia left behind are separated by the above method.

E. W. W.

Experiments on the Physiological Phenomena which accompany Chlorosis in the Vine. By GEORGES CURTEL (*Compt. rend.*, 1900, 130, 1074—1076).—The effects of chlorosis are (1) a decided weakening of respiratory activity resulting in a diminution of the relation CO_2/O_2 , (2) a diminution followed by the cessation of the function of assimilation, and (3) a great reduction in transpiratory power. It has been found that the activity of transpiration may be affected by excess of lime in the soil, by excess of water, by unfavourable climatic conditions, &c.

The appearance of chlorosis and the alteration in transpiration seem to be inseparable, and anything capable of modifying the one would necessarily influence the other.

N. H. J. M.

Some Changes produced in Etiolated Plants. By GUSTAVE ANDRÉ (*Compt. rend.*, 1900, 130, 1198—1201).—The composition of

maize and lupin seeds is compared with that of normal and of etiolated plants about six weeks old. The carbon of the etiolated plants amounted to only about half the quantity present in the seeds, whilst there was a slight loss of total nitrogen. The maize seed contained 0.25 gram of asparagine in 100 seeds, and the etiolated plants 0.41 gram; in the case of lupins, the seeds contained 1.51 grams, and the etiolated plants 6.17 grams of asparagine. Amidic nitrogen (including nitrogen as asparagine) represents about half the total nitrogen in etiolated maize, and about nine-tenths the total nitrogen of lupins. These results, in conjunction with those relating to the carbohydrates soluble in water and the carbohydrates saccharifiable by dilute acids, indicate that the regeneration of proteids from asparagine and carbohydrates takes place more readily in maize than in lupins. In etiolated maize, there is a transformation of soluble carbohydrates into cellulose, whilst in the case of etiolated lupins the amount of cellulose remains stationary.

As regards ash constituents, it was found that silica was 30 times as abundant in etiolated maize as in the seed, and 15 times as abundant in the case of lupins. Etiolated maize contained 100 times as much lime as the seeds, but in etiolated lupins the amount of lime remained unchanged. The phosphoric acid both of etiolated maize and lupin plants remained about the same as in the seeds. Potash increased from 0.11 in maize seed to 0.72 in the etiolated plants and diminished from 0.46 in lupin seeds to 0.40 in the plants.

The relatively large amount of lime in etiolated maize plants is perhaps connected with the production of cellulose from soluble carbohydrates.

N. H. J. M.

Chemical Alteration of Rye and Wheat on becoming Mouldy. By R. SCHERPE (*Zeit. Unters. Nahr. Genussm.*, 1900, 3, 166).—With reference to the work of Dietrich, Hebebrand, and Welte, the author points out that grain, flour, and bread must not be regarded as identical media for the growth of micro-organisms.

M. J. S.

Manuring of Clover Hay. By J. R. CAMPBELL (*Rep. Tech. Instruct. Comm. Lancaster C.C.*, 1899, 11—13).—Sodium nitrate and ammonium sulphate applied alone gave almost the same results; but in conjunction with dung, or with a mixture of basic slag and potassium chloride, sodium nitrate gave a considerably greater increase than ammonium sulphate under the same conditions.

With sodium nitrate and basic slag, 1 cwt. of potassium chloride gave better results than half or twice the quantity.

Sodium nitrate, when applied with farmyard manure, produced an increase equal to that when applied alone.

N. H. J. M.

Manuring of Clover Hay. By J. R. CAMPBELL (*Rep. York. Coll. Leeds and E. and W. Ridings Joint Agric. Council*, No. 5, 1900, 8—12).—On chalk soil, potash manures had a decided effect in increasing the yield of red clover; the yellow trefoil was, consequently, largely suppressed. Basic slag alone did not increase the crop, but in conjunction with potassium chloride was decidedly beneficial; a

mixture of the two manures, 4 cwt. and 2 cwt. respectively, is recommended for clover-sick land.

Inoculation with nitragin had no appreciable effect.

N. H. J. M.

Experiments with Horse Beans on Soils of Various Origin under the same Climatic Conditions. By JOSEF SKISSL and EMANUEL GROSS (*Chem. Centr.*, 1900, i, 831; from *Zeit. landw. Versuchs-Wesen. Oesterr.*, 3, 153—162).—The results of pot experiments with six different soils: (1) clayey marl, (2) calcareous clay, (3) poor, red soil, (4) loose, humous loam, (5) sandy loam, rich in humus, and (6) loam poor in sand. No. 4 gave the best results, then 2, 5, 1, and 6 in the order given; No. 3 gave less than half the amount of produce obtained with No. 4.

As regards the plant constituents taken up from the soil, it was found that although the absolute amounts diminished, the relation in which they took part in production remained almost the same.

Analyses of the soil showed that in most cases a certain relation existed between the yield, the assimilation of phosphoric acid, and the proportions of phosphoric acid and sesquioxides on which the solubility of the phosphoric acid doubtless depends.

N. H. J. M.

Composition of the Very Rich Sugar-Beet of the Season 1898. By J. GRAFTIAU (*Ann. Science Agron.*, 1899, [ii], 5, ii, 173—178).—The analysis of a lot of twelve roots gave the following percentage results:

Water.	N.	Fat.	Sucrose.	N-free extract.	Cellulose.	Pure ash.
72.16	0.207	0.047	19.60	5.01	1.216	0.60

The ash contained K_2O , 31.7; CuO , 17.5; MgO , 9.83; and P_2O_5 , 10.17 per cent. The average weight of the roots was 400 grams, and they contained 93.21 per cent. of juice and 6.79 per cent. of marc. Comparing the results with those of previous years, it is seen that although the sugar was abnormally high in 1898 in the fresh roots, the results of this and other years do not differ much as regards sugar in dry matter. The nitrogen, the cellulose, and especially the pure ash, diminish as the sugar increases. As regards the ash constituents, the calcium increases slightly with the sugar, whilst the potassium and phosphoric acid greatly diminish in quantity as the percentage of sugar in the roots increase; and the magnesium remains fairly constant. This is in opposition to Corenwinder's theory that magnesium and phosphoric acid are absorbed in the form of ammonium magnesium phosphate.

N. H. J. M.

Experiments at Rothamsted on the Changes in the Composition of Mangels during Storage. By NORMAN H. J. MILLER (*Journ. Roy. Agric. Soc. Engl.*, 1900, [iii], 11, 57—64).—Samples of mangels from two plots of the permanent Root Crop Field were analysed as soon as possible after being taken up, and subsequently, at suitable intervals, until the end of June. Sugar, total nitrogen, and ash were determined at each date, and pentosans at the commencement

and in June. The results are calculated as percentages of the original weights of the roots (in October).

Series II, Plot I (manured with dung, basic slag, and potassium sulphate). Up to March 28, there was no decided change in composition, either as regards the amount or the nature of the sugar. But by June 20 there was a loss of about 1·4 per cent. of sugar, and about half the sugar had become inverted, whilst the loss of dry matter was about twice as great as that of the sugar; the pentosans diminished from 1·13 in October to 0·82 in June; whilst the total nitrogen at the two dates was nearly the same. There was a gain both of sugar and of nitrogen in the dry matter of the roots.

Series II, Plot II (same manures, with nitrate in addition). In these roots, loss of sugar (0·7 per cent.) had taken place early in January, and there was a further loss (0·66 per cent.) between January 6 and March 28; but from March to June the loss was less. The total loss of sugar in 8 months was 1·7 per cent., whilst the loss of total organic matter was 2·2 per cent. The inversion of the sugar began earlier, but was not so great as in Series II, Plot I. The percentage of pentosans was 0·97 in October, and 0·72 in June. The dry matter of the roots contained less sugar in June than in October, and rather more nitrogen.

In comparing the results obtained with the roots from the two plots, it is seen that the loss of sugar was greater and the loss of organic matter other than sugar much less under the influence of nitrate than without nitrate; in the one case, there was a tendency for the percentage of sugar in the dry matter to diminish and in the other to considerably increase.

As regards pentosans, the roots manured with nitrate contained rather less than the roots which received no nitrate (compare de Chalmont, *Ber.*, 1894, 27, 2722); and the loss was slightly less in the case of the nitrate plot.

Calculated in pounds per acre, it is seen that the loss of sugar was very considerable, especially in the case of the roots from Series II, Plot II. Owing, however, to the much greater yield of roots on this plot, the amount of sugar from the roots of an acre remained much in excess of the amount from Series II, Plot I. N. H. J. M.

Behaviour of Water-soluble Phosphoric Acid in Soils. By MARTIN ULLMANN and A. GRIMM (*Chem. Ind.*, 1900, 23, 61—69).—The results of numerous experiments with various soils showed that for months after the application of superphosphate, phosphoric acid soluble in water passed through a depth of soil equal to 25—27 cm. without being completely retained, either chemically or mechanically. It is not possible by determining the magnesia, lime, and sesquioxides in soil to estimate its absorptive power for phosphoric acid, as the results cannot show to what extent these substances are available. An artificial mixture of sand (300 grams) and freshly precipitated aluminium hydroxide (3 grams) completely absorbed 0·15 gram of soluble phosphoric acid at once, whilst with ferric hydroxide the absorption was complete in an hour. With soil (100 grams) containing 10·26 per cent. of ferric oxide and alumina, and 0·18 gram of

soluble phosphoric acid, 28.13 per cent. of the latter remained in solution after 66 hours, only a portion of the sesquioxides being available for fixing phosphoric acid.

In the case of soil containing 18.7 per cent. of lime as carbonate, in addition to 4.21 per cent. of ferric oxide and alumina, 20.24 per cent. of the soluble phosphoric acid remained dissolved after 66 hours, and 18.81 per cent. after 14 days.

The diffusion of water-soluble phosphoric acid in the soil depends on the amount and distribution of the rain. There is no evidence to show how far the fear of loss of soluble phosphoric acid in light, sandy soils is justified, but in the case of limed or marled sandy soil it has been shown that no loss takes place. The mechanical fixation of soluble phosphoric acid seems to depend on the amount of fine sand, and especially sand of the fineness of dust, in the soil.

Attention is called to the advantage of a supply of soluble phosphoric acid in the subsoil, and the conclusion is drawn that superphosphate is, in many cases, preferable to other phosphatic manures.

N. H. J. M.

Chemical Methods for ascertaining the Lime Requirement of Soils. By HENRY J. WHEELER, BURT L. HARTWELL, and C. L. SARGENT (*J. Amer. Chem. Soc.*, 1900, 22, 153—177).—The best method, of those tried, for ascertaining the lime requirement of upland acid soils in Rhode Island was found to be titration with ammonia. The soil (15 grams) is treated with about *N*/10 ammonia (100 c.c.) and distilled water (100 c.c.) and frequently agitated during about 42 hours. After being allowed to settle, a definite amount of the liquid is treated with hydrochloric acid (about *N*/2) at the rate of 5 c.c. to each 20 c.c. of solution, and made up to a definite volume. When the precipitated humus has settled, portions of 50 c.c. are titrated with ammonia, coralline being employed as indicator. The method is most suitable in the case of soils containing much humus. The gravimetric determination of humus in soils, without previous extraction with acid, also gave results more in accordance with the crop tests than the other methods.

Useful indications are obtained by observing the effect of the moistened soil on blue litmus paper, as compared with soil of known character; and (when the acidity is due to a great extent to organic matter) by treating the soil with dilute ammonia, and noting whether the liquid acquires a dark brown or black colour.

In the case of the upland acid soils, the methods of Hollemann (extracting the lime with water containing carbon dioxide, *Landw. Versuchs-Stat.*, 1892, 41, 38), and of Tacke (*Abstr.*, 1898, ii, 103), and extracting the lime with hot dilute hydrochloric acid, were found to be unsuitable. A new method, which it is thought may prove to be very useful when the most suitable conditions have been ascertained, is described, in which the soil is heated with calcium carbonate in presence of water and the carbon dioxide determined.

N. H. J. M.

Composition of the Soils of the Canton Redon as regards Lime, Magnesia, Potash, and Nitrogen. By G. LECHARTIER (*Compt. rend.*, 1900, 130, 1163—1166).—Analyses of soil samples re-

presenting the soils of different geological origin in the Canton of Redon, in the Department Ille-et-Vilaine, are given. The formations from which the various soils are derived are granite, pre-Cambrian, Silurian, Upper Silurian, and ancient and modern alluvium. The average amounts of lime and magnesia are 0.58—1.08 and 0.84—1.60 per thousand. In some cases, soils which produce 20—30 hectolitres of wheat per hectare contain only 0.26—0.28 per thousand of lime on the pre-Cambrian, and 0.67—0.80 per thousand on the Angers schists. The soils are rich in potash, and only on 6—7 per cent. of the whole area is the amount of potash in the soil less than 0.2 per cent.; the average amounts are 0.232—0.577 per cent.

The soils contain on the average 0.109—0.135 per cent. of nitrogen, and 2.37—4.18 per cent. of organic matter, determined by Raulin's method.

N. H. J. M.

Arable Soils of the Canton of Redon with respect to Phosphoric Acid. By G. LECHARTIER (*Compt. rend.*, 1900, 130, 1225—1229. Compare preceding abstract).—The cultivated soil of half the area of the Canton contains more than 0.1 per cent. of phosphoric acid. The average amounts of phosphoric acid in the soils derived from the different geological formations are as follows: granite, 0.87; pre-Cambrian, 0.90; Armorican sandstone, 0.57; Angers schist, 1.04; Poligné schist and sandstone, 1.05; and alluvium, 1.24 per cent.

Phosphatic manuring was found to be beneficial even in the case of soils containing more than 0.1 per cent. of phosphoric acid. Both the yield and the quality of wheat, grown in rotation, was benefited by phosphates; and fossil phosphates and basic slag had more effect than superphosphate.

N. H. J. M.

Analysis of Siberian Arable Soil. By A. SEMPOLOWSKI (*Chem. Centr.*, 1900, i, 831; from *Zeit. landw. Versuchs-Wesen Oester.*, 3, 163—164).—The sample of soil was obtained from the steppe near Omsk, where the land had been ploughed once. The soil contained: Stones, 0.014; coarse gravel, 0.046; fine gravel, 1.050; coarse sand, 1.362; fine sand, 13.630; sand as dust, 55.115; and clay, 28.773 per cent. The chemical composition of the dry soil was as follows: Humus, 11.57; N, 0.57; K₂O, 0.16; CaO, 0.93; and P₂O₅, 1.00 per cent. The absorptive power for water is 35.84 per cent.

Experiments with sugar beet gave unsatisfactory results; the roots were small, and the juice had a very low purity coefficient.

N. H. J. M.

Use of Nitragin and Alinit for the Growth of Beans and Oats respectively. By J. R. CAMPBELL (*Rep. Tech. Instruction Comm. Lancaster C.C.*, 1899, 36—37).—Experiments with beans and clover made in 1897 seemed to indicate that inoculation with nitragin was beneficial. In 1898, negative results were obtained.

Alinit had no apparent effect.

N. H. J. M.

Experiments with Alinit. By HJALMAR VON FEILITZEN (*Mitt. Ver. Förd. Moorkultur*, 1900, 18, 41—44).—Black Tartarian oats were

grown in peaty soil in zinc vessels having an area of 0.283 sq. m. All the vessels received slaked lime (6000 kilos.), basic slag (800 kilos.), and potash manure (96 kilos. per hectare); one set had no further manure, another had alinit, and a third set nitrogen as ammonium sulphate and sodium nitrate. The following yields were obtained (grams):

Kainit.			88 per cent. potash manure.		
Without N.	Alinit.	With N.	Without N.	Alinit.	With N.
167.5	156.0	434.0	133.5	123.5	369.0

Field experiments on peat land furnished similar results; both the yield of grain and of straw were much less under the influence of alinit than without alinit, whilst sodium nitrate very greatly increased the yield.

In field experiments on poor, sandy soil, the effect of inoculation with alinit was compared with that of different amounts of sodium nitrate. The smallest amount of nitrate (100 kilos.) produced considerably more grain and straw than was obtained on the alinit plot.

N. H. J. M.

Alinit. By BRUNO TACKE (*Mitt. Ver. Förd. Moorkultur* (1900, 18, 37—41).—Oats, barley, and summer rye were grown in peaty soil in pots, without nitrogenous manure, with sodium nitrate and with alinit respectively. Mineral manures were applied to all the pots. Similar experiments were also made on plots.

In the case of the pot experiment, the application of alinit resulted, on the whole, in a slightly diminished yield, owing possibly to denitrification. In the field experiments with rye, barley, and oats, the yield was considerably less under the influence of alinit than on the plots which were not inoculated, whilst nitrate, in every case, increased the yield. In the case of black oats, the yield of the alinit plot was greater than that of the plot which had no alinit, but much less than that of the nitrate plot. It is, however, not thought that the alinit had any beneficial effect.

N. H. J. M.

Analytical Chemistry.

Apparatus for Measuring Evolved Gases at Constant Volume. By ANDRÉ JOB (*Bull. Soc. Chim.*, 1900, [iii], 23, 288—291).—This apparatus is of use in the analysis of carbonates, carbides, sulphides, carbamide, &c., the gases evolved by the decomposition of these substances in a closed vessel being estimated by the increase in pressure observed. It consists of a bulb or flask, connected with a delicate mercurial manometer, into the neck of which fits a graduated pipette furnished with a stopper so arranged that the liquid run into the flask is replaced by the air in the apparatus itself. Before each experiment, the apparatus is brought to a known temperature by im-

mersion in water, and the pressure made equal to that of the atmosphere; the acid or other liquid in the pipette is then allowed to flow into the flask, which may be heated if necessary, and the apparatus finally brought to the original temperature and the manometer read. If h is the increase in pressure, V the capacity of the apparatus, and t the temperature, the volume of the gas evolved is $Vh/760(1 + \alpha t)$.

N. L.

Hydro-Gasometer and Urinometer. By E. BENOIT (*J. Pharm.*, 1900, [vi], 11, 454—458).—The apparatus consists of a bottle (A) closed with a cork through which a tube passes. This tube is connected to another tube which passes through a cork inserted in one neck of a three-necked Woulff's bottle. Through the cork in the second neck of the Woulff's bottle, a thistle funnel is inserted, to act as a safety tube, and through the cork in the third neck a tube bent twice at right angles is inserted; one end of this tube dips under the water contained in the Woulff's bottle. The gas evolved in the bottle (A) forces the water out of the Woulff's bottle, and by collecting this water in a graduated cylinder, the volume of the gas evolved is ascertained.

H. R. LÉ S.

New Electrodes for Electrolytic Estimations. By AUGUSTE HOLLARD (*Bull. Soc. Chim.*, 1900, [iii], 23, 291—292).—The electrode on which the element is to be deposited consists of a nearly cylindrical, truncated cone of platinum foil, whilst the other electrode consists of a spiral of platinum wire inside, and a wire cage outside, the cone. The advantages claimed are rapid and regular deposition, and an equable evolution of gas, whereby loss through spirting is avoided.

N. L.

A New Indicator. By JULIUS FORMÁNEK (*Zeit. anal. Chem.*, 1900, 39, 99—103).—Alizarin-green-B (Dahl and Co.) dissolves in water with a dirty green colour; in alcohol, more sparingly, with a flesh colour. Acids added to either of these solutions produce a carmine red colour, alkalis a pure green. It is affected by carbon dioxide as by an acid. In presence of ammonium salts, its indications are uncertain. Aluminium salts behave like free acids, even in presence of precipitated aluminium hydroxide. This indicator can be used by artificial light. M. J. S.

New Indicator for Acidimetry; Estimation of Boric Acid. By JULES WOLFF (*Compt. rend.*, 1900, 130, 1128—1131).—Ferric salicylate dissolved in a solution of sodium salicylate develops a violet coloration in dilute mineral acids, which changes to orange when the solutions are neutralised or rendered alkaline by sodium hydroxide; the acid reaction is, however, not produced by boric, phosphoric, or hydrofluoric acid, and the end point is not affected by the presence of ammonium sulphate. Similar reagents may be obtained from other aromatic ortho-hydroxy-acids.

In estimating the boric acid present in a borate, the solution of the salt is acidified with sulphuric acid, and the excess of mineral acid removed by means of standard alkali, the end point being determined by the above indicator. Glycerol and phenolphthalein are now

added to the solution, and the titration of the boric acid is effected in the usual manner (compare this vol., ii, 312).

G. T. M.

Iceland Spar as a Standard in Volumetric Analysis. By ORME MASSON (*Chem. News*, 1900, 81, 73—75).—Iceland spar in lumps of a gram to three grams in weight, freed from dust and sharp edges by treating with dilute hydrochloric acid, and then washing and drying, is used in quantities of about 3 grams; it is weighed in the beaker, which is covered with a glass. Twenty c.c. of the acid to be tested are run in, and when action has ceased, the sides and cover of the beaker are washed down, and the whole heated to and kept at boiling temperature for an hour. The calcium chloride solution is decanted off, the beaker and residual spar well washed, dried, and weighed. The strength of the acid is calculated from the loss in weight.

D. A. L.

Separation and Identification of Acids. By RICHARD ABEGG and W. HERZ (*Zeit. anorg. Chem.*, 1900, 23, 236—239).—The authors give a systematic method for the qualitative examination of the acids of a mixture, analogous to those in general use for the bases. The substance is (i) boiled with dilute hydrochloric or nitric acid, whereby carbon dioxide, sulphur dioxide, nitrogen trioxide, hydrogen cyanide, hydrogen sulphide, and acetic acid are evolved, and are identified by special tests. (ii) The substance is boiled with concentrated sodium carbonate solution, the filtrate treated with hydrochloric acid, made alkaline with ammonia, and treated with calcium chloride. A precipitate insoluble in acetic acid indicates the presence of a fluoride or oxalate; a precipitate soluble in acetic acid indicates the presence of a cyanide, succinate, arsenite, arsenate, or phosphate. (iii) The filtrate from (ii) is treated with barium chloride. A precipitate soluble in hydrochloric acid indicates the presence of a chromate or dichromate; a precipitate insoluble in hydrochloric acid indicates the presence of a sulphate or silicofluoride. (iv) The filtrate from (iii) is neutralised with hydrochloric acid and zinc chloride added. A brownish-yellow precipitate indicates the presence of a ferricyanide, and a white precipitate the presence of a ferrocyanide. (v) A small quantity of the filtrate from (iv) is treated with a small quantity of a ferric salt. A permanent red coloration indicates the presence of a thiocyanate, and a red coloration disappearing on boiling with the formation of a precipitate the presence of an acetate. (vi) In the absence of a thiocyanate, the filtrate from (iv) is treated with a solution of silver nitrate (nitric acid and nitrates being used in place of hydrochloric acid and chlorides in all previous operations). A precipitate indicates the presence of a chloride, bromide, or iodide. (vii) An aqueous solution of the original substance is tested for a nitrate by means of a ferrous salt. Oxyhalogen acids are indicated by the evolution of oxygen on igniting the original substance.

E. C. R.

Volumetric Estimation of Bromides in Presence of Iodides and Chlorides. By JULIUS VON WESZELSZKY (*Zeit. anal. Chem.*, 1900, 39, 81—91).—In moderately acidified solutions, hydriodic acid is converted into iodic acid by chlorine, whilst from hydrobromic acid

the bromine separates in the free state. In alkaline solutions, bromides are oxidised to bromates. A mixture, containing the three halogen salts, is therefore acidified, treated with chlorine water, and distilled in a stream of carbon dioxide into a solution of potassium hydroxide. The retort with a bulbous neck, employed by Bunsen and Fresenius for the absorption of chlorine, forms a suitable receiver; the still should consist entirely of glass. When the carbon dioxide is no longer absorbed, the contents of the receiver are boiled to dryness to expel chlorine and hypochlorous acid, and convert hypochlorite entirely into chlorate. The residue is dissolved, mixed with some potassium iodide and acidified, and the liberated iodine titrated with thiosulphate. The iodate in the still can also be estimated by adding potassium iodide and titrating the iodine. In the absence of iodides, potassium carbonate and chlorine are added to the original solution, which is then boiled down and treated as before. Arsenic and antimony must first be removed by hydrogen sulphide, and iron, by boiling with the alkaline carbonate and filtering before adding chlorine. M. J. S.

Estimation of Ozone. By NICOLAE TECLU (*Zeit. anal. Chem.*, 1900, 39, 103—105).—The gas in which ozone is to be estimated is enclosed in a glass tube of pipette form between two stopcocks. A solution of potassium iodide is forced into the tube by mercury pressure, and shaken with the gas for 5 minutes. It is then acidified with acetic acid to decompose any iodate which has been formed, and is titrated with thiosulphate. Any blue colour which is developed after its first disappearance is to be neglected. 1 c.c. of *N*/100 thiosulphate = 0.00008 gram of ozone. M. J. S.

Detection of Sulphates in Presence of Thiosulphates. By LEONARD DOBBIN (*Pharm. J.*, 1900, [iv], 10, 182).—Barium sulphate is perceptibly soluble in solution of sodium thiosulphate, especially in the presence of a little free nitric acid.

Salzer has recommended converting the thiosulphate into tetrathionate by means of iodine before testing for sulphate, but the author thinks that the detection of sulphate is best accomplished by using the method devised by Grossman. The liquid is heated in a current of carbon dioxide, hydrochloric acid is added, and the sulphur dioxide expelled by prolonged boiling. The remaining liquid is filtered and tested for sulphate with barium chloride. L. DE K.

Estimation of Nitric Nitrogen by Schlösing's Method. By C. DAVIDSON (*Chem. News*, 1900, 81, 97—98).—A modification of de Koninck's apparatus (*Abstr.*, 1894, ii, 296) is described; in it a descending tube, 800 mm. long and 2 mm. bore, is used to connect the distilling flask to the lower side tube of a modified Schiff's nitrometer, the lower part of which is charged with mercury nearly to the level of the other side tube, which is connected with an air-free water supply. The gas burette is furnished with a T-piece at the top, to the middle limb of which the top of the modified Schiff nitrometer is attached by means of a capillary tube, the other limb carrying a funnel with a clip at the connection. In use, air is driven out from the intermediate vessel and at this funnel by the air-free water; the

gas burette is charged from its reservoir with soda right into the funnel, and subsequently the intermediate vessel and the gas burette are put into connection for the transference of the nitric oxide produced.

D. A. L.

Detection of Nitrous Acid in Water by Means of Aminonaphthol-K-Acid [1-Amino-8-hydroxynaphthalene-4:6-disulphonic Acid]. By H. MENNICKE (*Zeit. angew. Chem.*, 1900, 235—236).—The author strongly recommends Erdmann's process (this vol., ii, 243) as affording the most delicate test as yet known for the detection of nitrites in drinking water. Nitrites do not interfere. It is possible to detect the presence of 1 part of sodium nitrite in 300,000,000 parts of water. The test is best made in daylight.

L. DE K.

Detection of Nitric Acid in Water and in Milk. By F. UTZ (*Chem. Centr.*, 1900, i, 875; from *Pharm. Zeit.*, 45, 229—230).—Cimmino's modified diphenylamine test is recommended if conducted in the following manner. The water or the milk serum is mixed with a little of the diphenylamine reagent, put into a test-tube, and strong sulphuric acid is carefully poured down the side. At the place of contact a more or less intense blue ring is formed. When milk is kept for a long time, the lactic acid bacteria destroy any nitrates.

L. DE K.

Hygienic Significance of Nitrites in Drinking Water. By EDUARD SCHAEER (*Ber.*, 1900, 33, 1232—1236).—A theoretical paper, in which the author discusses the origin of nitrites in drinking water, and endorses Spiegel's conclusion (this vol., ii, 318) as to their being of little value for hygienic diagnosis; no new facts are adduced.

W. A. D.

Connection Between the Chlorides and Nitrates in the Polluted Well Waters in Inhabited Localities. By JOSEF KÖNIG (*Zeit. Unters. Nahr.-Genussm.*, 1900, 3, 228—233).—Attention is directed to the already well-known fact that in well waters which have been contaminated with sewage there is generally an intimate relation between the chlorides, nitrates, and sulphates present. Waters which are unquestionably free from animal pollution may contain large amounts of one or other of these impurities, and even be very rich in bacterial life, but the simultaneous presence of large proportions of all of them, if the conditions as to locality are such that contamination is possible, point unmistakably to its occurrence.

M. J. S.

Estimation of Arsenic in Metals and Alloys. By AUGUSTE HOLLARD and L. BERTIAUX (*Bull. Soc. Chim.*, 1900, [iii], 23, 300—302).—The arsenic is separated by distillation with hydrochloric acid and ferric sulphate, and titrated with iodine solution in the usual manner. Antimony is retained by passing the vapours through a U-tube filled with glass beads and heated in an oil-bath at 150—175°. The process is inexact when applied to the estimation of arsenic in antimony, since about 0.03 per cent. of the latter passes over into the distillate.

N. L.

Detection of Boric Acid in Borates. By HUGO BORNTÄGER (*Zeit. anal. Chem.*, 1900, 39, 92).—When heated on platinum foil, boric acid colours a Bunsen flame green; borates do not. Borates when similarly heated with hydrofluoric acid or with ammonium nitrate and chloride, or with mixtures of sulphuric and hydrochloric acids, sulphuric and nitric acids, or hydrochloric and nitric acids (but not with one of the acids alone) give an instantaneous and intense green coloration. The reaction is more sensitive than that with sulphuric acid and alcohol. M. J. S.

Absorption Apparatus for Elementary Organic Analysis. By FRANCIS G. BENEDICT (*Amer. Chem. J.*, 1900, 23, 323—334).—The water formed during a combustion is absorbed by bubbling through concentrated sulphuric acid contained in the bend of a 5" U-tube, the second limb containing glass-wool moistened with the same acid to finally dry the gas; any condensed water is allowed to drop into a small vial supported in the first limb above the acid on a piece of glass rod flattened at one end. The carbon dioxide is absorbed in a U-tube by specially prepared moist soda-lime, whilst another U-tube acting as a guard tube, is one-third filled with soda lime and two-thirds with pumice moistened with concentrated sulphuric acid, a plug of glass wool separating the two. The advantage of this apparatus over that ordinarily employed is discussed; a description is appended of a modified calcium chloride jar, which serves to free the air or oxygen used in a combustion from both water and carbon dioxide in a single vessel. W. A. D.

Estimation of Carbon and Hydrogen by Combustion in Oxygen using Copper Oxide. By CHARLES F. MABERY and WILLIAM R. CLYMER (*J. Amer. Chem. Soc.*, 1900, 22, 213—218).—From the authors' experiments, it appears that the best results in the analysis of hydrocarbons are obtained when the combustion tube containing the copper oxide has been used a few times.

The water formed during the combustion is best absorbed in a U-tube containing 3 c.c. of strong sulphuric acid, a bulb being attached to condense the greater part of the water; the quantity of carbon dioxide retained by the acid is very trifling. The carbon dioxide is best absorbed in a Geissler apparatus containing aqueous potassium hydroxide of 33.3 per cent. strength, the usual calcium chloride tube being attached; no advantage is gained by using phosphoric oxide instead of fused calcium chloride.

The air and oxygen used in the experiment should be purified by passing through two long bent tubes containing broken glass moistened with 40 per cent. aqueous potassium hydroxide and strong sulphuric acid respectively. L. DE K.

Elementary Analysis of Organic Substances containing Nitrogen. By FRANCIS G. BENEDICT (*Amer. Chem. J.*, 1900, 23, 334—352).—When a substance containing nitrogen not directly combined with oxygen is first charred in the closed combustion tube (that is, without a current of air or oxygen), and the non-volatile residue subsequently oxidised by the admission of oxygen, no oxides of

nitrogen are produced; in the case, however, of nitro-compounds, and especially of nitrates of organic bases, the results are vitiated by the formation of these oxides. Instead of employing a copper spiral in the fore-part of the tube to reduce the oxides, the author mixes with the substance analysed a known weight of either pure cane sugar (in the form of powdered sugar-candy) benzoic acid, or naphthalene; the finely-divided copper produced in the reduction of the copper oxide by this excess of oxidisable material is sufficient to completely reduce any oxides of nitrogen formed. This method obviates the error usually introduced in a combustion owing to the presence of either hydrogen, water, or carbon dioxide in the copper spiral employed. In the case of explosive compounds, the combustion is rendered more regular by mixing the substance with 3 or 4 times its bulk of finely powdered, pure quartz. In the case of highly nitrated substances, it is noteworthy that this admixture has a direct influence on the reduction of nitrogen oxides; although not completely reduced, these are now present in much smaller quantities, so that without the addition of a reducing material such as cane sugar or benzoic acid, the results obtained for carbon are sufficiently accurate for most purposes, although the percentage of hydrogen is somewhat too high.

A large number of analyses are given showing the universal application of the method described, and the degree of accuracy of the results obtained.

W. A. D.

Repeated Use of Copper Potassium Chloride for the Solution of Steel or Iron in estimating Carbon. By GEORGE W. SARGENT (*J. Amer. Chem. Soc.*, 1900, 22, 210—213).—The solution of copper potassium chloride, when used in the estimation of carbon in steel or iron, gradually becomes converted into the cuprous state, but may be rendered again fit for use by passing a current of chlorine. In this way, it may be used over and over again until it becomes too saturated with iron.

L. DE K.

Direct Combustion of Metallic Alloys. By HARRY BREAULEY (*Chem. News*, 1900, 81, 91—92).—With regard to the direct estimation of carbon in alloys, &c., in the case of tungsten, ferro-tungsten (85 and 50 per cent.), ferro-silicon, 12 per cent. silicon-spiegel, ferro-silico-molybdenum, molybdenum, and 70 per cent. molybdenum-nickel, satisfactory decarbonisation has been achieved by 1 hour's combustion of the material passed through a 90-mesh sieve, in a current of oxygen at a high temperature, a porcelain tube supported on asbestos arches being employed. With 20 per cent. spiegel, 70 per cent. tungsten-nickel, 80 per cent. ferro-manganese, 60 per cent. ferrochromium, 70 per cent. chromium-nickel, and chromium, however, decarbonisation was imperfect under the same circumstances.

D. A. L.

Substitutes for Hydrochloric Acid in Testing Carbonates. By JOSEPH W. RICHARDS and NORMAN S. POWELL (*J. Amer. Chem. Soc.*, 1900, 22, 117—121).—For use in the field, the authors prefer using solid acids for the identification of native carbonates as being more easy to carry in a portable set of apparatus. Before use, they are dissolved in boiling water.

A 20 per cent. solution of tartaric acid is the best, citric acid coming next. A 10 per cent. solution of oxalic acid does not give such a plain effervescence as the others. A 20 per cent. solution of potassium hydrogen sulphate also gives a satisfactory result except in the case of witherite and phosgenite; it must be remembered that sulphides also give effervescence.

L. DE K.

Technical Estimation of Zinc. By ALBERT H. LOW (*J. Amer. Chem. Soc.*, 1900, 22, 198—202).—The author's process is devised for zinc ores from Colorado, but with suitable modifications it may no doubt be applied also to other zinc ores.

A solution of potassium ferrocyanide containing 22 grams of the crystallised salt per litre is standardised by dissolving 0.1 gram of pure zinc in 6 c.c. of strong hydrochloric acid, and adding 10 grams of ammonium chloride and 200 c.c. of boiling water. The ferrocyanide is then added until a drop of the liquid strikes a brownish colour with solution of uranium nitrate.

0.5 gram of the ore is boiled in a pear-shaped flask with 5 c.c. of nitric acid and 2 grams of potassium nitrate, 10 c.c. of a saturated solution of potassium chlorate in nitric acid are added, and the whole evaporated to complete dryness. When nearly cold, 30 c.c. of a solution containing 200 grams of ammonium chloride, 350 c.c. of water, and 500 c.c. of ammonia are added, and the contents boiled for 2 minutes; the solution is filtered and the undissolved matter washed with a hot solution of ammonium chloride containing 100 grams of the salt and 50 c.c. of ammonia to the litre. The filtrate is neutralised with hydrochloric acid, and 6 c.c. of the latter are then added in excess. After diluting to about 150 c.c., any copper, cadmium, and the bulk of the lead are precipitated by adding 50 c.c. of a saturated solution of hydrogen sulphide. After filtering, which is, however, only necessary if there is an abundant precipitate, the liquid is heated, and about one-third is poured into a beaker and set aside. The remainder is then titrated as described, and the greater part of the reserve liquid being added, the titration is continued; finally, the remainder of the reserve liquid is added and the titration cautiously finished. Both in this titration and in the "check," the true end-point is always slightly passed, as it always requires one or more drops of the ferrocyanide solution to get the uranium reaction, but this may be ascertained by a direct experiment.

Attention is called to the great importance of carefully following the directions as to the amount of free acid. Arsenic, when present in large amount, sometimes gives trouble by retaining iron in the ammoniacal solution. In this case, the ore should be subjected to a preliminary treatment. 0.5 gram of the sample is treated with 10 c.c. of strong hydrochloric acid and 1 c.c. of bromine, gently warmed for a few minutes, and finally boiled to dryness; the arsenic will thus be sufficiently expelled. Potassium nitrate and nitric acid are added, and the analysis proceeded with in the usual manner.

With some ores, it may be necessary to resort to a fusion before dissolving in acid.

L. DE K.

Volumetric Estimation of Red Lead. By JAMES F. TOCHER (*Pharm. J.*, 1900, 10, 310—312).—*1st Method.*—2.064 grams of the sample are heated with 50 c.c. of nitric acid of sp. gr. 1.2; 50 c.c. of *N/5* solution of oxalic acid are added, and when the lead peroxide has disappeared, the liquid is partly neutralised with barium hydroxide. Solution of sodium sulphate is now added to precipitate the lead and barium, and after adding some dilute sulphuric acid to decompose any barium oxalate, the excess of oxalic acid is titrated with *N/5* permanganate. One c.c. of oxalic acid decomposed by the lead peroxide represents 3.3 per cent. of red lead.

The matter may be simplified by treating the sample with 50 c.c. of nitric acid of sp. gr. 1.3 and adding the oxalic acid from a burette until the last trace of lead peroxide has disappeared.

2nd Method.—3.415 grams of the sample are heated with hydrochloric acid, the chlorine evolved is passed through a solution of potassium iodide, and the liberated iodine is titrated with *N/10* sodium thiosulphate; each c.c. represents 1 per cent. of red lead.

3rd Method.—1.032 gram of the sample is heated with 20 c.c. of *N/5* nitric acid and 20 c.c. of neutral hydrogen peroxide in a retort, the drawn-out neck of which dips into *N* soda, which should not be in excess. When the lead peroxide is decomposed, the flame is removed, and the soda solution allowed to enter the retort. Excess of sodium sulphate is added, then phenolphthalein, and the free nitric acid titrated with normal soda. Ten times 100 (representing 20 c.c. of *N/5* nitric acid) — number of c.c. of soda required for neutralisation, gives the percentage of total lead in the sample. If only the lead peroxide is to be estimated, the sample is first treated with dilute nitric acid, and the undissolved matter is collected on a filter; or the decomposed mixture is carefully poured on to a saturated solution of sodium and potassium nitrates, contained in a conical vessel, when the lead peroxide sinks to the bottom, and the acid liquid may be siphoned off; the deposit is then treated with hydrogen peroxide as directed.

L. DE K.

Estimation of Thallium. By VICTOR THOMAS (*Compt. rend.*, 1900, 130, 1316—1319).—Soluble thallous salts are oxidised to the thallic condition, by auric bromide (bromauric acid, HAuBr_3), an equivalent amount of gold being precipitated; the latter is collected and weighed. The amount of thallium present is obtained by multiplying the weight of this precipitate by the factor 1.5533. The quantity of thallous compound taken for analysis should correspond with 0.2—0.3 gram of the pure chloride.

The auric bromide is conveniently prepared by dissolving gold in a mixture of bromine and hydrobromic acid, and evaporating the solution to the crystallising point.

G. T. M.

Analysis of Commercial Copper. By AUGUSTE HOLLARD (*Bull. Soc. Chim.*, 1900, [iii], 23, 292—300).—A detailed scheme for the complete analysis of commercial copper is given. The metal is dissolved in a mixture of sulphuric and nitric acids, and the copper, together with silver, deposited electrolytically, using the author's

form of electrodes (this vol., ii, 435). Since arsenic and antimony are usually present in sufficient quantity to be deposited along with the last traces of copper, it is advisable to stop the electrolysis before the whole of the copper is deposited, and to estimate the remainder after removing arsenic and antimony. The arsenic is precipitated by hydrogen sulphide in concentrated hydrochloric acid solution, and the filtered liquid diluted with an aqueous solution of hydrogen sulphide, whereby the sulphides of copper and antimony are precipitated. The mixed sulphides are dissolved in potassium cyanide solution, and the antimony estimated electrolytically, whilst the residual copper is estimated colorimetrically or electrolytically after removal of the cyanide. In the liquid from which copper, arsenic, and antimony have been removed, the iron is precipitated by ammonia, and the precipitate dissolved in hydrochloric acid and titrated with iodine solution. The nickel and cobalt still remaining in solution are deposited electrolytically in presence of ammonium sulphate, according to Fresenius and Bergmann's process. For the estimation of lead a fresh quantity of the metal is dissolved in nitric acid, and the solution electrolysed, the lead being deposited as peroxide on the anode. The electrolytically deposited copper, or a fresh portion of the original metal, is dissolved in nitric acid, and the silver precipitated by hydrochloric acid; the precipitate is dissolved in potassium cyanide solution and the liquid electrolysed, the metal being either weighed as such, or dissolved in nitric acid and titrated with potassium thiocyanate solution. Arsenic is estimated by the Hollard and Bertiaux's process (this vol., ii, 438). Gold is determined by treating a large quantity of the metal with nitric acid and cupelling the insoluble residue. Sulphur is estimated as barium sulphate in the nitrohydrochloric acid solution of the metal. N. L.

Volumetric Estimation of Corrosive Sublimate in Dressing Materials. By MARTIN LEHMANN (*Chem. Centr.*, 1900, i, 876; from *Pharm. Zeit.*, 45, 209—210).—Twenty grams of the material are treated in a 500 c.c. stoppered flask with 200 c.c. of a 0.5 per cent. solution of sodium chloride at 70—80°, and left for 24 hours at 25—30°, with frequent shaking; 100 c.c. of the solution are then carefully evaporated to 10—15 c.c. A loss of mercuric chloride is not to be feared, as its double sodium salt is not volatilised with water vapour. The solution is now slowly poured into 20 c.c. of *N*/100 alkali, the mixture is gently warmed, and the excess of alkali titrated with *N*/100 hydrochloric acid, using phenolphthalein as indicator. L. DE K.

Estimation of Manganese as Pyrophosphate. By WILHELM BÖTTGER (*Ber.*, 1900, 33, 1019—1022).—Accurate results can be attained in the estimation of manganese as pyrophosphate by precipitating with ordinary sodium phosphate in a neutral solution to which 5—10 mol. of an ammonium salt have been added. The precipitate must be washed with cold water containing a little ammonia until no residue is left on evaporating the filtrate and igniting. A. H.

Estimation of Manganese as Sulphide. By JOHN PATTINSON and HUGH S. PATTINSON (*Chem. News*, 1900, 81, 193).—When the sul-

phide method of estimating manganese is employed, the sulphide precipitate should be examined for barium, cobalt, iron, silicon, calcium, magnesium, &c., and the filtrate should be acidified, treated with bromine to oxidise separated sulphur, then mixed with excess of ammonia and bromine, and any precipitate of manganese added to the main sulphide precipitate. D. A. L.

Electrolytic Estimation of Manganese in Manganese Ores. By ARTHUR HIORNS (*Chem. News*, 1900, 81, 15).—The solution, which should not contain more than 0.03 gram of manganese, should be made strongly acid with nitric acid, and be kept so during the operation. A tared platinum dish serves for the positive electrode, a spiral of platinum wire for the negative, and when the current is started the temperature is raised to, and maintained at, 60°. Twelve hours suffices for the deposition of all the manganese, which is washed, dried, ignited, and weighed as Mn_2O_3 . D. A. L.

Estimation of Manganese in Steel. By HORACE JERVIS (*Chem. News*, 1900, 81, 171—172).—In the method of estimating manganese by dissolving the sample in nitrosulphuric acid, oxidising with red lead, and titrating the filtrate with ferrous sulphate and permanganate, the quantity of the latter reagent consumed at first increases with the amount of manganese present, but when a maximum of 0.180 per cent. of manganese in the solution in the presence of iron, or 0.224 per cent. in the absence of iron, is attained, any further increase in the manganese causes a corresponding decrease in the consumption of permanganate. D. A. L.

Soluble Ferric Pyrophosphate. By W. E. RIDENOUR (*Chem. Centr.*, 1900, i, 834; from *Amer. J. Pharm.*, 72, 125—128).—The author has modified the orthophosphate test of the U.S. Pharmacopeia for the purity of soluble iron pyrophosphate as follows: 1 gram of the sample is boiled with 10 c.c. of aqueous potassium or sodium hydroxide to remove the iron, the filtrate is acidified with hydrochloric acid, ammonia is added in slight excess, and then magnesium mixture (10 grams of magnesium sulphate, 20 grams of ammonium chloride, dissolved to 120 c.c.) as long as a precipitate is formed; this precipitate should be soluble in a slight excess of acetic acid, and should not reappear on boiling the solution.

If the sodium pyrophosphate used in the preparation of the iron compound is free from orthophosphate, there is no fear of the latter containing any orthophosphate, no transformation occurring. L. DE K.

Analysis of Molybdenum Alloys. By HUGO BORNTRÄGER (*Zeit. anal. Chem.*, 1900, 39, 91).—About a gram of the alloy is dissolved in 50 c.c. of aqua regia, the solution evaporated to dryness, and the nitric acid expelled by hydrochloric acid. The residue is treated with 50 per cent. alcohol, when most of the molybdenum will remain undissolved as molybdic acid, but part dissolves as chloride. The solution is evaporated to dryness, and the residue again treated with 50 per cent. alcohol, when the remainder of the molybdenum is obtained as molybdic acid (compare Abstr., 1898, ii, 649). M. J. S.

Separation of Tungsten and Molybdenum. By FRED IBBOTSON and HARRY BREARLEY (*Chem. News*, 1900, 81, 13—15).—Heating mixtures of molybdic and tungstic oxide in a muffle is not adapted to the direct estimation of the molybdenum. In such mixtures, 90 per cent. of the molybdenum volatilises readily, but the remaining 10 per cent. requires prolonged and strong heating for its expulsion. The separation of these oxides by means of hydrochloric acid is imperfect, the molybdic anhydride not being absolutely soluble and the tungstic anhydride not absolutely insoluble. A procedure recommended is to precipitate the two together by means of lead acetate, wash slightly with hot, very dilute acetic acid, ignite, dissolve the residue by heating gently with concentrated hydrochloric acid, using 1 c.c. for each centigram of lead salt, then add two or three times the volume of boiling water, boil, redissolve the precipitate in hydrochloric acid, reprecipitate with water, and determine the molybdenum as lead molybdate. When the proportion of tungsten is small, the solution of the ignited lead salts is evaporated to a pasty consistency with a few drops of nitric acid, treated with 100 to 200 c.c. of dilute hydrochloric acid (3 : 1), and boiled.

D. A. L.

Test for Tin. By ALLEN ROGERS (*J. Amer. Chem. Soc.*, 1900, 22, 220—221).—The usual ammonium molybdate solution is stated to be a very delicate confirmatory test for stannous chloride, with which it produces a dark blue colour, even if the amount of stannous chloride does not exceed 0.000021 gram per c.c. Even when this solution is diluted five times, and consequently does not give any reaction with mercuric chloride, it still shows a faint blue tint with the molybdic reagent.

L. DE K.

Detection of small Quantities of Gold in Ores. By THEODOR DÖRING (*Chem. Centr.*, 1900, i, 734—735; from *Berg.-Hüttenm. Zeit.*, 59, 73—76, 97—99. Compare this vol., ii, 371).—The ore is treated with a volatile iodine compound, such as ammonium iodide containing free iodine, or preferably with a solution of bromine in ether. Into the solution is dipped, six times in succession, a strip of filter paper 10 cm. long and 2 c.c. wide; this is then burnt, when, if gold is present, it will leave an ash of a purple colour, or if the solution contained more than 0.007 per cent. of gold, the colour will be yellow or brownish-red. The reaction is interfered with by the presence of iron or platinum should these metals have passed into the solution. The filter paper is prepared by soaking ash-free filter paper into a solution of magnesium nitrate containing 0.1 per cent. of magnesium oxide, and then exposing it, when dry, to the fumes of ammonium carbonate. An alternative process is given, based on the formation of purple of Cassius, which is a modification of Ohly's method. 100 grams of the finely-powdered and roasted ore are treated in a glass-stoppered bottle with 2 c.c. of a mixture of equal volumes of bromine and ether, and the bottle is frequently shaken for two hours; during this time bromine fumes must be plainly visible. The mass is then digested for 2 hours with 50 c.c. of water, the solution is filtered and concentrated to one-fifth of its bulk, and a little bromine water and then an excess of stannous chloride added, which will then give the usual reaction. One part of gold in 2,000,000

parts of ore may be thus detected. Tellurium interferes with the test.

L. DE K.

Detection of Benzene in Denatured Alcohol. By GEORGES HALPHEN (*J. Pharm.*, 1900, [vi], 11, 373—375).—The alcohol is mixed with brine and extracted with carbon disulphide, which dissolves the benzene. The carbon disulphide extract is then treated with a mixture of Nordhausen sulphuric acid and fuming nitric acid. The acid layer which now contains the benzene as nitrobenzene, is separated, mixed with water, and extracted with ether. The ethereal extract is evaporated, and the residue reduced with zinc dust and dilute hydrochloric acid. The solution is next filtered, and a few drops of a solution of sodium nitrite added to the filtrate, which is then neutralised with sodium carbonate. An alkaline solution of α -naphthol is finally added, when, if benzene is present, an orange-red coloration will be produced.

H. R. LE S.

Hundertkräuter-Likör (Centerba). By GIULIO PARIS (*Zeit. Unters. Natur.-Genussm.*, 1900, 3, 153—158).—This liqueur, prepared in the Abruzzi, occurs mainly in two forms, the *potabile*, which is sweet, and the *semplice*, which is more strongly alcoholic and is not sweet. The author has estimated the alcohol, free acid, total solids, ash, esters, fusel oil, sucrose, and glucose in several specimens of each variety obtained direct from the factories. Of the *centerba semplice* there appear to exist two varieties, one of which is coloured green by chlorophyll, and is prepared by extracting aromatic herbs with alcohol; the other is coloured with artificial dyes. M. J. S.

Some Properties of Glycerol. By HEINRICH STRUVE (*Zeit. anal. Chem.*, 1900, 39, 95—99).—Commercial glycerol contains 6—8 per cent. of water. After drying over sulphuric acid in a partial vacuum, it still retains 1.52 per cent. of water. After drying in this manner, it gains slightly in weight if exposed in a platinum crucible in the water oven, but at the same time a small loss of glycerol takes place (compare Abstr., 1899, ii, 816). Glycerol also volatilises in small amount when its aqueous solution is distilled (see Abstr., 1895, ii, 537). Dehydrated glycerol absorbs about 17 per cent. of water on exposure to the atmosphere. Some of the author's conclusions are based on the sp. gr. of the glycerol (compare Abstr., 1899, ii, 64).

M. J. S.

[**Estimation of Pentoses in Urine.**] By SULEIMAN BEY (*Chem. Centr.*, 1900, i, 803—804; from *Zeit. klin. Med.*, 39, 305—312).—In order to determine the quantity of pentoses in urine, it is necessary to evaporate until the liquid contains 2—3 per cent., and then only 92 per cent. of the theoretical quantity is obtained by precipitating with twice the volume of alcohol. The barium dipentosates are also carried down with the barium glucosates, which have a different composition, and it is impossible to isolate the sugar in this way from a urine containing 0.75 per cent. of xylose. The phloroglucinol and orcinol reactions of the pentoses are not distinguishable in presence of large quantities of glucose, but in such cases the pentoses may be estimated by separating as the barium compounds, and fermenting.

In reference to the use of phenylhydrazine in fermentation experiments, it is to be noted that mixtures of pentosazone and glucosazone often show a higher melting point than that of glucosazone alone.

Since rhamnose does not form a barium compound which can be precipitated by alcohol, it may be readily separated from the pentoses, but it cannot be detected by the orcinol or phloroglucinol reactions in the presence of comparatively small quantities of xylose. Xylose and rhamnose may be estimated in a mixture by first determining the reducing power of both sugars, and then precipitating the xylose in another portion, and determining the reducing power of the filtrate after removing the barium and alcohol. The results obtained are, however, 1—2 per cent. too high for the rhamnose. In separating arabinose and rhamnose, the greater solubility of barium diarabinoate in alcohol prevents the complete precipitation of this compound.

E. W. W.

Analysis of Golden Syrup. By NORMAN LEONARD (*Analyst*, 1900, 25, 85—87).—The author replies to the criticism of Bodmer, Leonard, and Smith's process (this vol., ii, 320) by Miller and Potts (*ibid.*), and states that their suggested improvement is not suited so well for the wants of public analysts as the process given by himself and colleagues.

L. DE K.

Treacle or Golden Syrup. By EDWARD W. T. JONES (*Analyst*, 1900, 25, 87—89).—The author suggests the following simple formula for arriving at the percentage of glucose syrup in a sample of golden syrup if this has a *dextro*-rotation *after inversion*.

$$[a], \frac{([a], \text{after inversion} + 12.3) 100}{133.3} = \text{per cent. of glucose syrup.}$$

$$[a]_D \frac{([a]_D \text{ after inversion} + 11) 100}{120} = \text{per cent. of glucose syrup.}$$

A sample of commercial golden syrup declared to contain 18 per cent of glucose syrup had a specific rotation *after inversion* of $[a] + 12.3$ or $[a]_D + 11.07$ therefore by the above formula it shows 18.4 per cent.

The method of working is as follows. A 10 per cent. solution is made at 15.5°, and its sp. gr. taken. This should not be less than 1.032, indicating 20 per cent. of water. The factor, 3.86, is correct for about 10 per cent. solution of pure sucrose, but when dealing with ordinary golden syrups, the amount of water thus found is too low to the extent of about 3 per cent. The solution is now heated to 17.5°, and examined in the 10 cm. tube. Fifty c.c. of the same solution are heated with 5 c.c. of normal acid in a 100 c.c. flask in boiling water for 20 minutes, cooled, mixed with 5 c.c. of normal soda, and then diluted to 100 c.c. at 15.5°. This solution is again polarised at 17.5° and the result multiplied by 2.

For the cupric reducing power, if required, 10 c.c. of the first solution is taken and diluted to 100 c.c.; 20 c.c. of this is added to 50 c.c. of Fehling's solution diluted with 30 c.c. of water which has been standing for some time in boiling water. After 12 minutes, the cuprous oxide is collected, washed, and gradually ignited in a porcelain

crucible to convert it into oxide, from which the amount of sugar corresponding is calculated. Of the inverted solution, 20 c.c. are diluted to 100 c.c., and of this 20 c.c. are treated in the same manner; the difference in copper oxide represents cane sugar. L. DE K.

Analysis of a Sample of Treacle and of so-called Golden Syrup. By CHARLES G. MATTHEWS and A. HYDE PARKER (*Analyst*, 1900, 25, 89—94).—The process adopted by the authors consists in taking the sp. gr. of a 10 per cent. solution of the sample, and making a due allowance for the ash. The usual factor, 3.86, is then used for calculating the organic solid matter. Cane sugar is estimated by polarising the solution as usual after a partial fermentation with yeast at 52° for 5 hours, and boiling to destroy birotation. The cupric reducing power is taken by the gravimetric method on 0.1 gram of the sample. The rotation and cupric reducing power are also taken after fermenting for 72 hours at 18°. When analysing commercial golden syrup, a determination is also made of combined dextrin (amyloindextrin), by treating of the fermented solution with cold water malt extract, and noticing the increase in cupric reducing power, but as a further fermentation on adding yeast does not take place to any appreciable extent, the authors do not think themselves justified in using the figures so obtained for dextrin.

Using a Soleil-Ventzke-Scheibler apparatus, the value of a 1 per cent. solution of the substance observed in a 20 cm. tube has been taken to be: for maltose, 8.02 divisions; for dextrin, 11.56; for dextrose, 3.05; for gallisin, 4.85; and for cane sugar, 3.84. These figures may be converted into Laurent degrees by multiplying by 0.344.

The cupric reducing power for maltose has been taken as 1.37; for dextrose, as 2.46; and for gallisin, as 1.01. L. DE K.

The Unrestricted Use of Starch Syrup in Articles of Food. By JOSEF KÖNIG (*Zeit. Unters. Nahr.-Genussm.*, 1900, 3, 217—221).—In Germany, the employment of starch-sugar, or syrup in articles of food without declaration is prohibited, but in view of the harmlessness of these products and the advantageous results which they afford in certain confections, the question has been raised whether this restriction is called for. The presence of dextrin in these articles, and especially in the syrup, confers on them a viscosity which enables them to take the place of stronger solutions of cane sugar, and in consequence of the hindrance which the presence of 5—10 parts of starch syrup in 100 parts of cane sugar opposes to the crystallisation of the latter, enables them in part to replace fruit juice itself. The author has made comparative estimations of the viscosity of solutions of cane sugar, starch sugar, and starch syrup, both with Engler's viscosimeter and with Weiss' "consistence measurer," and gives the preference to the latter, both from its convenience in use, and from the fact that when the retardation of the revolutions is calculated for a unit weight of substance, the results are almost independent of the concentration of the solution, which is by no means the case with the viscosimeter.

M. J. S.

Estimation of Cellulose. By CARL BECK (*Zeit. Unters. Nahr.-Genussm.*, 1900, 3, 158—164).—Upwards of 45 methods of estimating

cellulose in vegetable structures have been proposed. That of Henneberg and Strohmänn, which for 30 years has been generally accepted, consists in boiling the substance with dilute sulphuric acid (1.25 per cent.) and then with potassium hydroxide of corresponding strength. Lebbin (*Arch. Hyg.*, 1897, 212) suggested the use of a mixture of hydrogen peroxide and ammonia, and König (*Abstr.*, 1899, ii, 68) has proposed heating under certain defined conditions with a mixture of glycerol and sulphuric acid, the special object being the removal of pentosans. The author has made comparative estimations in cotton-wool, filter-paper, straw, wood-wool, wheat-bran, pearl barley, and wheat flour, by the three methods, as well as by a modification of Lebbin's method (which is not described because the author himself does not recommend it), and concludes that Lebbin's process has neither a scientific nor a practical value; that in König's method (with a reflux apparatus) it is difficult to maintain the exact temperature prescribed, and that the results obtained with a small gas flame are higher than those with a large flame. Finally, that Henneberg's process gives the most concordant results, and is, on the whole, the most trustworthy. König's reagent attacks cellulose itself strongly; nevertheless, his process gives higher numbers than Henneberg's with bran and flour.

M. J. S.

[Estimation of Cellulose.] By JOSEF KÖNIG (*Zeit. Unters. Nahr. Genussm.*, 1900, 3, 164—166).—The discordant results obtained by Beck with the author's process are due to the irregularity of the temperature of boiling. If the instructions are carefully complied with and a small flame is used, the temperature will only vary between 131° and 133°, and should never be allowed to exceed the latter.

M. J. S.

Isolation and Separation of the Chief Organic Acids. By N. SCHOORL (*Zeit. angew. Chem.*, 1900, 367—370).—The process is based on the fact that formic and acetic acids may be distilled in a current of steam after acidifying the liquid to be tested with sulphuric acid, congo test-paper serving as indicator.

The residue, after being concentrated on the water-bath, is extracted in a suitable apparatus with ether, which rapidly dissolves salicylic, benzoic, succinic, and lactic acids, and gradually removes oxalic, malic, citric, and even tartaric acids.

The ether is then evaporated and the residue treated with boiling water, which, on cooling, deposits most of the salicylic and benzoic acids. The further separations present, on the whole, no novel features. The microscope renders good service in the recognition of calcium citrate or zinc lactate.

L. DE K.

Estimation of Formic Acid in Presence of Acetic Acid. By FIN SPARRE (*Zeit. anal. Chem.*, 1900, 39, 105—106).—The author recalls and strongly advocates the method of Portes and Ruyssen (*Abstr.*, 1876, ii, 663), but points out that the instruction to employ a 10 per cent. solution of the substance must be a misprint for 1 per cent., since the quantity of mercuric chloride prescribed is not sufficient for the stronger solution, and with solutions containing more than 1 per cent. of formic acid the results are too high.

M. J. S.

Cider Vinegar: Its Solids and Ash. By R. E. DOOLITTLE and WILLIAM H. HESS (*J. Amer. Chem. Soc.*, 1900, 22, 218—220).—Pure cider vinegar may be distinguished from spurious vinegar (generally made from dilute acetic acid) by the fact that the solids consist of glycerol, albuminous matters, gums, malic and other organic acids and mineral matters, give no rotation in the polariscope and have little or no cupric reducing power after the usual clarification with lead acetate. On the other hand, the spurious vinegars leave generally a residue of molasses-like appearance and properties.

The ash of cider vinegar, which should amount to not less than 0.25 per cent., contains principally potassium, with small amounts of aluminium, calcium, magnesium, and sulphuric and phosphoric acids, with variable amounts of carbon dioxide, but its chief characteristic is the complete absence of sodium. Spurious substitutes often contain a large proportion of either calcium or sodium.

Analyses are given of the solids and the ashes of cider, cider vinegar, and spurious samples. L. DE K.

Estimation of Uric Acid in Urine. By ADOLF JOLLES (*Zeit. physiol. Chem.*, 1900, 29, 222—248).—By boiling with an excess of permanganate in a solution acidified with sulphuric acid, uric acid is quantitatively converted into urea, which can then be estimated by the hypobromite process. The urine (50—200 c.c. according to concentration), which, if necessary, must be warmed to dissolve urates and be filtered if turbid, is treated with solid ammonium acetate (1 gram per 10 c.c.) and made feebly alkaline with ammonia. After $2\frac{1}{2}$ —3 hours, the ammonium urate is collected on a filter, and washed free from chlorides with a saturated solution of ammonium carbonate. It is then rinsed into a beaker and boiled with 0.1—0.2 gram of pure magnesia for $\frac{1}{2}$ — $\frac{3}{4}$ hour, or until perfectly free from ammonia. The liquid, measuring 300—400 c.c., is then acidified with 10 c.c. of sulphuric acid (sp. gr. 1.4) and permanganate solution (8 grams per litre) is gradually added, until the last c.c. remains unreduced after 15 minutes boiling. The excess of permanganate is removed by oxalic acid, the liquid cooled, rendered alkaline with soda, and transferred to the reaction vessel (330 c.c. capacity) of a special azotometer, where it is treated with hypobromite. Test estimations, with pure uric acid, gave excellent results. When applied to urine, the results were compared with those of the Ludwig-Salkowski process (*Wien. med. Jahrbuch*, 1884, 97), which the author affirms to be trustworthy and exact, but which is admitted by Ludwig to give numbers which are 2 per cent. too low. With a number of normal and pathological urines, the differences ranged from -1.9 to +5.0 per cent., the average difference being 2 per cent. above the Ludwig-Salkowski numbers. The present method may, therefore, be regarded as one of the most exact. The Hopkins-Folin method (*Abstr.*, 1898, ii, 196), which gives accurate results with pure uric acid, is liable to give excessively high numbers with certain pathological, and especially with highly concentrated, urines. M. J. S.

Estimation of Fat in Dairy Produce. By LÉON LINDER (*J. Pharm.*, 1900, [vi], 11, 368—373. Compare this vol., i, 67).—This

method is based on the fact that a hot solution of resorcinol dissolves the casein from milk, cheese, &c., and leaves the fat as a supernatant layer, which is easily distinguished from the lower layer if the milk has been previously coloured with a little magenta. If the milk is rendered faintly alkaline with sodium hydroxide, the casein is readily dissolved by simply heating the mixture in boiling water. Five grams of resorcinol, 5 c.c. of the milk, 2 drops of a solution (36°) of sodium hydroxide, and 1 drop of the colouring solution are heated in a special form of graduated tube, and the volume of the separated fat is read off. One gram of butter fat at 15° occupies 1.154 c.c. In the case of cheese, 1 gram of the substance and 15 c.c. of a hot, aqueous 100 per cent. solution of resorcinol are the quantities employed. The method is rapid, and gives accurate results. H. R. LE S.

Sour Milk. By H. DROOP RICHMOND and J. BRISTOWE P. HARRISON (*Analyst*, 1900, 25, 116—124).—The first part of the paper is devoted to an investigation of the fact noticed by de Koningh (Abstr., 1899, ii, 707) that milk, on being mixed with 5 per cent. of a solution of sodium hydroxide of the same sp. gr., suffers a diminution in sp. gr. The authors confirm this fact, but state that it depends on the state of acidity of the milk, because when lactic (or, in fact, any other) acid is neutralised with solution of soda, the resulting sp. gr. is less than the calculated sp. gr. If, however, ammonia is used for neutralisation, the resulting sp. gr. is practically the same as the calculated one. Tables are given showing the loss in sp. gr. when various acids are neutralised with soda, and of the slight increase noticed when ammonia is used.

Owing to this fact, the authors think that ammonia is the best alkali for the purpose of liquefying sour milk so as to be able to take its sp. gr. with a hydrometer. This idea is not novel, having already been proposed in 1893 by Weibull, but the authors have much simplified the process by mixing pure milk with 5 per cent. by volume of a strong ammonia, and noticing once for all the decrease in sp. gr. which takes place. Sour milk is then treated in the same manner, and the loss caused by the ammonia is allowed for. If the operator prefers using de Koningh's process (*ibid.*), the loss in sp. gr. will be 0.02 for every degree of lactic acid. It must be borne in mind that the acidity of milk is not entirely due to lactic acid; in fact, fresh milk, which is fairly neutral to litmus paper, still shows an acidity of about 20° manifested towards phenolphthalein.

The second part of the paper is devoted to the point at which milk may be considered to be sour, and the rate of souring in the presence or absence of preservatives. The figures as to the degree of acidity necessary to cause the coagulation of milk on boiling confirm the previous experiments of Stokes, who stated that milk is sour when the acidity reaches 44° .

Tables are given showing the retardating action of formaldehyde and boric preservative on the formation of the additional acidity.

L. DE K.

Foreign Colouring Matter in Milk. By ALBERT E. LEACH (*J. Amer. Chem. Soc.*, 1900, 22, 207—210).—150 c.c. of the sample

are heated in a casserole and curdled by means of acetic acid. The curd is, if possible, gathered in one mass, and the whey poured off; or, if the curd is finely divided, the mass is strained. The pressed curd is macerated in a corked flask with ether, which is then poured off and evaporated. The residual fat is treated with aqueous sodium hydroxide, which is then passed through a wetted filter; the fat is washed off the filter and the latter is dried, when, should it have an orange colour, the presence of annato is indicated, which may be further confirmed by the pink colour produced in contact with stannous chloride.

If the extracted curd is colourless, it has no other foreign colour, but if orange or brownish, it may contain aniline-orange, or caramel. It is then shaken in a test tube with strong hydrochloric acid; should it immediately turn pink, aniline-orange is present, but if it turns gradually blue, it indicates caramel, which may be confirmed by the usual tests applied to the whey. L. DE K.

Butters from Various Countries Compared. By CHARLES ESTCOURT (*Analyst*, 1900, 25, 113—116).—This is a tabulated record of the analysis of some 250 samples of butter imported from Finland, Denmark, Iceland, Sweden, Canada, and Germany. The testing was restricted to the percentage of water, the Reichert figure, and search for preservatives.

The results given by the Reichert process varied from 11.9 to 16 c.c. of decinormal alkali. The preservative found in a few foreign samples consisted of boric acid to the extent of about 8—9 grains per pound, but of the 39 samples of Irish butter 35 contained boric acid to the extent of 5—46 grains per pound. The highest percentage of water met with was 20 per cent.; the lowest 8 per cent. L. DE K.

Detection of "Process" or "Renovated" Butter. By WILLIAM H. HESS and R. E. DOOLITTLE (*J. Amer. Chem. Soc.*, 1900, 22, 150—152).—"Process" or "renovated" butter is an article prepared by melting rancid butter and mixing the clarified fat with milk. The method given for the identification of such butter is based on the fact that the curd from cream such as exists in genuine samples of butter is physically and chemically different from curd derived from milk.

When the curd of a sample of "process" butter is separated by washing with ether, and then spread out in a thin layer on a clean glass plate, its physical appearance when viewed with a magnifier of 3—6 diameters is quite distinct from that obtained from genuine butter. The latter has an amorphous, non-granular appearance, whilst the curd of the former has a very coarse, curdy appearance. The curd from cream is a gelatinous, ropy mass, which settles rapidly, but the other is a granular, easily divided substance. Casein dissolves readily in acid or alkali; the curd of genuine butter only dissolves on prolonged treatment with these reagents. The curd of pure butter yields scarcely any albumin to water, but when the curd from milk, after thorough washing with ether, is treated with water, the filtrate coagulates on adding acetic acid and boiling. By means of the Kjeldahl process, the relation between casein and albumin may be

readily estimated, and in samples containing only the curd of milk this amounts to 9 : 1.

L. DE K.

Comparison of some Tests for Formaldehyde. By BENJAMIN M. PILHASY (*J. Amer. Chem. Soc.*, 1900, 22, 132—135).—Schiff's reagent, magenta decolorised by sulphurous acid, is not a trustworthy test, as the violet coloration is also obtained by the action of the air or by warming the suspected liquid. The scarlet ring noticed when liquids containing formaldehyde are poured on to sulphuric acid containing a little phenol is also produced by most other aldehydes. The same may be said of the violet colour produced by diazobenzene-sulphonic acid in the presence of free alkali and sodium amalgam. Nessler's solution, and also aniline, give a precipitate both with formaldehyde and acetaldehyde.

The author has proved that Trillat's dimethylaniline test does not show the presence of formaldehyde, but is due to the dimethylaniline itself, or of its salts when these are not completely volatilised.

Lebbin's test is supposed to detect 1 part of formaldehyde in 10,000,000 parts of water, but the author states that 1 in 200,000 is the limit. The purple ring formed by bringing the liquid in contact with a solution of morphine hydrochloride in sulphuric acid is no longer distinct if the dilution of the formaldehyde exceeds 1 : 1000.

A solution of 1 gram of phenylhydrazine hydrochloride and 1.5 grams of sodium acetate in 10 c.c. of water seems to be the best reagent. To 1 c.c. of the liquid 2 drops of the reagent and 2 drops of sulphuric acid are added, producing a green coloration. When the dilution is 1 : 10,000 or 1 : 100,000, 3 c.c. of the liquid, 4 drops of the reagent, and 4 drops of sulphuric acid are used, and the mixture is heated for half a minute. In case of a dilution 1 : 250,000, 3 c.c. of the liquid are heated for about a minute with 5 drops of the reagent and 5 drops of sulphuric acid, when a very light tinge of green will be noticed after 3 minutes, and a decided tint after 10 minutes.

Another delicate test has been proposed by Rimini: 1 c.c. of the liquid is mixed with 2 drops of solution of phenylhydrazine hydrochloride, 2 drops of solution of sodium nitroprusside, and 1 c.c. of aqueous sodium hydroxide. A blue colour is developed, which changes quickly to green, yellow, light brown, and red; a peculiarity is the rise of the red colour to the top, leaving a yellow layer below. The limit for this test seems to be reached when the dilution is as 1 : 1,000,000.

L. DE K.

Two Deceptive Reactions. By CARL AMTHOR (*Zeit. Unters. Nahr.-Genussm.*, 1900, 3, 233—235).—The violet colour observed by Leonard and Smith (*Abstr.*, 1899, ii, 454) when milk containing formaldehyde is heated with fuming hydrochloric acid, and by Fisher with milk to which boric acid has been added, is obtainable with normal milk, and is a reaction of albuminous substances in presence of sugar. With sour milk from which most of the sugar has disappeared, or with muscular tissue or egg-albumin, the reaction is feeble, but in all these cases it is given strongly after adding lactose. The

colour may also be obtained with butter if new and used in the unfiltered state, in consequence of the presence of both casein and lactose. With old butter, the reaction is only observed after adding some lactose. It is producible in the cold, but more strongly on heating, and appears to be due to the formation of furfuraldehyde by the action of the acid on the sugar present. It is, in fact, immediately obtained with unfiltered butter to which some furfuraldehyde is added. The furfuraldehyde test for sesamé oil is therefore quite untrustworthy if applied to butter which has not, by filtration or by dissolving in ether, been completely freed from proteids (compare this vol., ii, 325). M. J. S.

Colour Reaction of Acetaldehyde. II. By ENRICO RIMINI (*Gazzetta*, 1900, 30, i, 279—281).—The colour reactions obtained by Lewin (this vol., ii, 179) by the addition of a secondary amine and sodium nitroprusside to either acetaldehyde or propionaldehyde were described in earlier papers by the author (this vol., ii, 56, and *Rendiconti Amministr. Civile. Ministero del Interno*, 1898). As stated by Simon (*Abstr.*, 1898, ii, 315), no reaction is obtained with carefully purified paraldehyde. T. H. P.

Physico-chemical Properties of Chloral Hydrate and their Applications to Pharmacology. By RICHARD MAUCH (*Zeit. anal. Chem.*, 1900, 39, 116—131; from *Diss. Strassburg*, 1898).—The author greatly extends Schaefer's observations (this vol., ii, 57) on the solvent powers of strong (60—80 per cent.) solutions of chloral hydrate and chloral alcoholate. With few exceptions, the reactions of the alkaloids can be well observed with their chloral hydrate solutions. Most resins and gum resins, camphors, tannins, organic dyes, sugars, dextrans, gelatin, and keratin are also freely soluble. The dammar resins from dipterocarpous trees are almost insoluble, whilst those from *Coniferae* dissolve completely. Many reactions of solutions of gum-resins and balsams are described in the paper. M. J. S.

Vanillin in Wine Vinegar. By A. STOCKT (*Zeit. Unters. Nahr.-Genussm.*, 1900, 3, 235).—In two samples of commercial vinegar, a substance was detected having the odour of vanillin. The acid was evaporated with calcium carbonate, the residue extracted with ether, and the residue from the evaporation of the ethereal extract crystallised from alcohol. It reduced ammoniacal silver solution, and gave Etti's phloroglucinolvanillin (Abstr., 1883, 62). M. J. S.

[**Estimation of Carvone in Essential Oils.**] By HENRI LABBÉ (*Bull. Soc. Chim.*, 1900, [iii], 23, 280—286).—See this vol., i, 398.

A Quantitative Reaction of Ureides and Purine Derivatives. By ADOLF JOLLES (*Ber.*, 1900, 33, 1246—1248).—A number of ureides and purine derivatives are not oxidised directly to ammonia by potassium permanganate and sulphuric acid, but give a quantitative yield of carbamide, provided that the weight of acid does not exceed 40 grams per litre. After removing the excess of permanganate with oxalic acid, neutralising with alcoholic potash, and evaporating nearly to dryness, the carbamide can be extracted from the inorganic salts with

absolute alcohol, precipitated with ethereal oxalic acid, and the oxalate analysed in the usual way.

The nitrogen is completely converted into carbamide in the case of alloxan, alloxantin, allantoin, uric acid, and xanthine. In hypoxanthine, adenine, and guanine, 1 atom of nitrogen appears in the form of guanine, and the remaining 4 atoms as urea. T. M. L.

[Estimation of Nicotine in Cigars.] By HERMANN THOMS (*Chem. Centr.*, 1900, i, 826—827; from *Ber. Deut. pharm. Ges.*, 10, 19—31).—See this vol., ii, 428.

Strychnine Salts and Chloroform. By J. RUTHERFORD HILL (*Pharm. J.*, 1900, [iv], 10, 185).—Normal salts of strychnine are not quite insoluble in chloroform. One part of the hydrochloride dissolves in 169 parts of chloroform, the arsenate requires 1178 parts, and the sulphate 1055 parts; but in the case of the arsenate and sulphate the portion dissolved is no longer the pure normal salt, but contains free alkaloid.

When aqueous solutions of these salts are shaken with chloroform, the latter abstracts a small amount of the hydrochloride as such, particularly in the presence of hydrochloric acid, but with the two other salts a notable amount of alkaloid is abstracted, leaving the liquid correspondingly acid. The only way to prevent even traces of strychnine from passing into the chloroform is to add a fair excess of sulphuric acid. L. DE K.

Action of Chloroform and Similar Solvents on Alkaloid Salts. By EDWARD SCHAEER (*Pharm. J.*, 1900, [iv], 10, 308).—The author is continuing Hill's researches (preceding abstract).

Experiments already made with atropine and veratrine have shown that their acid salts are also soluble in ether or chloroform. 0.102 gram of atropine dissolved in water acidified with tartaric acid yielded 0.0623 gram to 30 c.c. of chloroform and 0.0913 to the same quantity of ether. Veratrine dissolved in solution of tartaric acid yielded to chloroform an amount of veratrine tartrate varying with the quantity of free acid present. L. DE K.

Examination of Tea. By ADOLF BEYTHIEN, PAUL BOHRISCH, and JOSEPH DEITER (*Zeit. Unters. Nahr.-Genussm.*, 1900, 3, 145—153).—An attempt to estimate the extractive matter in tea by Trillich's method, which consists in taking the specific gravity of an extract obtained by boiling 10 grams of tea with 250 grams of water for 15 minutes, gave results about 10 per cent. below those yielded by complete exhaustion. In consequence of the bulkiness of boiled tea-leaves and the slowness with which they yield up their extractive matter, 5 grams of tea requires four boilings with 750 c.c. of water each time to extract it completely. The extract should not be evaporated, but the exhausted leaves be dried and weighed, allowance being made for the moisture in the original substance. Identical results are obtained by a percolation method, in which the tea, supported in a tube on cotton-wool, is exposed for 8—10 hours to the percolation of condensed steam from the receiving flask, but when numerous samples have to be examined the following method gives good results with very little

trouble : 3 grams of the tea are placed on a circular piece of linen, which is then drawn together, so as to form a small bag ; 8 to 10 of these bags, each weighted with a numbered piece of lead, are suspended in an enamelled saucepan full of water, which is kept boiling, and is changed for fresh water either intermittently or continuously. When the decoction is no longer coloured, the bags are spread open, dried, and the exhausted tea-leaves transferred to watch-glasses. The extraction by this method requires 3 or 4 days.

The examination of 130 samples of tea, purchased in Dresden, showed, in 100 parts :

	Extractive matters.	Ash.	Ash soluble in water.	Percentage of ash soluble in water.
Mean	35.03	5.78	3.13	54
Minimum ...	29.53	5.32	2.08	33
Maximum ...	44.75	6.40	3.99	68

All the samples appeared to be perfectly genuine.

M. J. S.

Testing Antipyrin for Antifebrin, Phenacetin, and Exalgin. By P. N. RAIKOW and P. SCHTARBANOW (*Chem. Centr.*, 1900, i, 999 ; from *Oesterr. Chem. Zeit.*, 3, 125—127).—By-boiling with phosphoric acid of sp. gr. 1.7, in which these substances are soluble, the anilides antifebrin and phenacetin are hydrolysed and yield acetic acid free from bye-products, so that very small quantities may be recognised. Antipyrin colours the phosphoric acid golden-yellow, which gradually becomes darker and brownish-yellow. Antifebrin gives a pale yellow colour, turning brown on prolonged boiling. Phenacetin causes first a rose, then a brownish-red coloration, passing from reddish-violet, through violet and bluish-green into dirty green. The appearance of the violet colour is particularly characteristic for phenacetin.

Antifebrin and phenacetin are distinguished by their behaviour towards potassium hydroxide. A few grams of the substances are heated with 2—4 c.c. of strong aqueous potash in a test-tube closed by a perforated india-rubber cork, through which passes a bent tube dipping into another test-tube containing 1 to 3 c.c. of a clear solution of bleaching powder. In the presence of antifebrin, the first drops which distil over cause the well known violet colour due to aniline. In the absence of antifebrin and the presence of phenacetin, the first drops cause no colour, but those following give a vermilion-red turbidity, due to phenetidine ; finally, an amorphous, red substance separates on the surface of the liquid, which becomes clear yellow after some time. If the test-tube is changed, both the reactions, the violet colour and the separation of phenetidin may be noticed in succession. When boiling a mixture of phenacetin and antipyrin with potassium hydroxide, the distillate does not give with bleaching powder the characteristic red coloration for phenacetin, but the solution turns first yellowish-green and then yellowish-grey, whilst with antipyrin alone it remains colourless.

Exalgin readily evolves acetic acid when boiled with phosphoric acid, and the liquid turns golden-yellow. The separated methylaniline distils in oily drops, which collect on the surface of the bleaching

powder solution, and soon become green, then greyish-green, and finally dirty brown. Contrary to Fischer's statement, exalgin is easily hydrolysable by caustic alkalis.

When boiled with aqueous potash, quinine gives no volatile products which act on bleaching powder solution. When boiled with phosphoric acid, the liquid turns first yellow, and shows an intense yellow, bluish-green fluorescence; it then soon becomes dirty brown and opaque. The presence of anilides in quinine may be safely detected by this method.

Traces of *p*-aminophenol may be detected in phenacetin, antifebrin, &c., by the intense red colour developed when dissolving these substances in cold phosphoric acid. When pure, they dissolve to a colourless liquid.

L. DE K.

Analysis of Tanning Materials. By PAESSLER (*Zeit. angew. Chem.*, 1900, 318—323).—Attention is called to the fact that, in order to get trustworthy commercial results, directions issued by the "International Committee of Leather Trades Chemists" must be scrupulously followed. The merest deviation from those instructions may cause a difference of several per cent. in the amount of tannic acid found.

L. DE K.

Distinction of Indigo from other Blue Dyes on Fabrics. By FREDERIK H. VAN LENT (*Zeit. anal. Chem.*, 1900, 39, 92—95).—Indigo is readily soluble in hot phenol, and woollen fabrics dyed with indigo alone can be deprived of the dye completely by heating with that solvent in the water-bath. At higher temperatures, the fabrics are attacked. Other blue dyes except indophenol are wholly or partially unattacked, the wool remaining coloured. From cotton, indoin is dissolved as well as indigo.

M. J. S.

Rosin's Method for the Determination of the Reducing Power of Urine, &c. By SPIEGEL and PERITZ (*Chem. Centr.*, 1900, i, 675; from *Münch. Med. Wochschr.*, 47, 225—226).—The authors have arrived at the conclusion that Rosin's method with leucomethylene-blue (this vol., ii, 319) is quite untrustworthy as it is influenced by the temperature, and by other constituents of urine such as uric acid, whilst, moreover, the reducing power of the various reducing substances is not a quantitative one.

L. DE K.

[Cystine in Impure Well Waters in the Neighbourhood of Lyons.] By HENRI CAUSSE (*Compt. rend.*, 1900, 130, 579—581).—Impure well waters which had caused typhoid were found to contain cystine, probably in the form of ferric cystinate. The waters gave a yellow coloration with sodium *p*-diazobenzenesulphonate mercurichloride, weakened, but not discharged, by addition of sulphurous acid; when boiled for some time, they gave off hydrogen sulphide, free sulphur being precipitated at the same time. The cystine was isolated by precipitation with a solution of barium hydroxide containing some barium chloride, and its identity was established by recognition of its crystalline form, by determinations of the ratios C:N and Fe:S, and by its reactions with lead, silver, and mercuric salts.

The typhoid bacillus could not be isolated from the waters in

question, but they contained an abnormally large number of bacteria that liquefy gelatin, and especially of *Bacterium termo*. C. H. B.

Detection and Estimation of Cystine, and its Variation in Amount in Contaminated Water. By HENRI CAUSSE (*Compt. rend.*, 1900, 130, 785—788. Compare preceding abstract).—The reagent employed in testing for cystine in natural water is prepared by adding mercuric chloride to a solution of sodium sulphanilate, and dissolving the mercurichloride thus produced in a solution of sodium chloride. The water under examination is shaken with a few c.c. of this reagent, a few drops of dilute hydrochloric acid and potassium nitrite solution are added, and the mixture left for 6 hours in a dark place. The yellow coloration which develops in water free from cystine is entirely destroyed by sulphurous acid. The orange colour of the meniscus persists when traces of cystine are present, and in the presence of larger quantities of this substance the whole of the liquid retains its colour, and the meniscus is red.

The colorimetric estimation of cystine in water is effected by comparing the tint which persists after the addition of sulphurous acid with that obtained in a similar manner with standard solutions of cystine.

Analyses of the potable water of Lyons show that there is an intimate connection between the accumulation of cystine in the water and the outbreak of typhoid fever.

The amount of cystine in well water varies with the seasons; it is at its minimum in February and March, and reaches its maximum at the close of the summer; this is also true of the water from the Rhone; under ordinary circumstances, water from the latter source contains far less cystine than well water, but when the river is in flood, the amount of this substance greatly increases. G. T. M.

Presence of Tyrosine in Contaminated Well Waters. By HENRI CAUSSE (*Compt. rend.*, 1900, 130, 1196—1198. Compare preceding abstracts).—Tyrosine is present in contaminated well waters, which give a yellow coloration on the addition of the reagent composed of mercuric chloride and sodium *p*-diazobenzenesulphonate. The tyrosine is not originally present in the water, but results from the subsequent oxidation of the inorganic and organic constituents in the water. It was isolated either by precipitation with Millon's reagent (slightly modified) or with barium hydroxide solution.

H. R. LE S.

The Ferricyanide Method of Determining the Oxygen Capacity of Blood. By JOHN S. HALDANE (*J. Physiol.*, 1900, 25, 295—302).—When the fallacies due to incomplete laking of the blood and to the presence of bacteria are eliminated, the ferricyanide method of determining the oxygen capacity of the hæmoglobin in blood gives exact results. The present paper deals with the precautions to be taken to attain these objects; the most important modification introduced is the substitution of ammonia for sodium carbonate to prevent the evolution of carbon dioxide, the advantage being that laking is more readily produced.

W. D. H.

Simultaneous Estimation of Two Colouring Matters in Blood by the Spectrophotometer. By GUSTAV HÜFNER (*Chem. Centr.*, 1900, i, 512—513; from *Arch. anat. Phys.*, 1900, 39).—The ratios of the luminosity of different regions of the absorption spectrum of alkaline solutions of the blood-colouring matters are constant, even in the blood of different animals. Thus, with oxyhæmoglobin, the ratio of ϵ_0 , the extinction coefficient of the darkest part of the broader absorption band, 531·5 to 542·5 $\mu\mu$, to ϵ_1 ; that of the bright portion, 554—565 $\mu\mu$, between the two bands, is 1·578. Similarly, with reduced hæmoglobin, the value ϵ'_r/ϵ_r , in which ϵ'_r and ϵ_r are the extinction coefficients respectively of the same regions = 0·762. In mixtures of both oxyhæmoglobin and hæmoglobin, the equation $157·8 - (100 \cdot \epsilon'_r / \epsilon_r) / (0·529 \cdot \epsilon'_r / \epsilon_r) + 0·414 = x$, the percentage of hæmoglobin; $100 - x$ is the percentage of oxyhæmoglobin. To ascertain the absolute amount of the two colouring matters, the mixture is shaken with air, and the amount of oxyhæmoglobin estimated. For a mixture of methæmoglobin and oxyhæmoglobin, the fraction becomes $x = 157·8 - (100 \cdot \epsilon'_r / \epsilon_r) / 0·393$, in which x is the percentage of methæmoglobin, and for one of carboxy-hæmoglobin (x) and oxyhæmoglobin, $\epsilon'_r / \epsilon_r = 157·8 + 0·061 \cdot x / 100 + 0·497 \cdot x$. The original paper contains tables for these values. M. J. S.

Estimation of Absorbable Proteids in Foods. By KARL BÜLOW (*Chem. Centr.*, 1900, i, 831—832; from *J. Landw.*, 48, 1—38).—The greatest amount of proteids which can possibly be attacked are dissolved by treating foods or fæces by pepsin according to Kühn's method; some of the undissolved nitrogen is still soluble in alkaline trypsin solution. Excessive drying renders a portion of the proteids insoluble, and the temperature employed should not exceed 55—60°.

The Stutzer-Pfeiffer method for estimating digestible proteids does not yield results in accordance with those of experiments with animals. Treatment of foods with pepsin-trypsin gives numbers which are too high, whilst the action of as little as 250 c.c. of pepsin solution on fæces does not dissolve all the nitrogen soluble in acid pancreatic juice.

Kühn's method is suitable for estimating proteids dissolved by the intestines, and is useful for rapidly ascertaining the amount of digestible proteids in foods; it does not, however, render direct experiments unnecessary. The correctness of the method is established as regards ruminants; further experiments are necessary to show whether it is available in the case of other animals.

N. H. J. M.

Sulphosalicylic Acid as a Test for Albumin [in Urine]. By MANKIEWICZ (*Chem. Centr.*, 1900, i, 630; from *Berl. Klin. Woch.*, 36, Litteraturauszüge, 93).—The urine, if turbid, is clarified by means of a little magnesium sulphate or sodium hydrogen carbonate; 10 c.c. of the clear filtrate are mixed in a test-tube with 0·1—0·15 gram of sulphosalicylic acid, and well shaken. In the presence of 0·001 per cent. of albumin, a faint bluish diffused coloration is noticed on placing the tube against a dark surface; if 0·005—0·01 per cent. is present, the turbidity is plainly opalescent, and when 0·02 per cent. is present, the liquid becomes quite opaque. L. DE K.

Examination and Valuation of Commercial Pastry. By ADOLF JUCKENACK (*Zeit. Nahr. Genussmitt.*, 1900, 3, 1—17).—Artificial yellow dyes are added to commercial pastry to simulate the appearance of the use of eggs; they are, however, all soluble in 70 per cent. alcohol, but insoluble in ether, whilst lutein is soluble in both menstrua. Since yolk of egg is a residual product of certain industries, it is often used instead of entire eggs. The large proportion of cholesterol in yolk of egg renders its detection in pastry an almost certain proof of the presence of egg-substance. About 15 grams of the substance should be extracted with cold ether, the ether evaporated, the residue saponified with potash, the soap dissolved in 5 c.c. of water, and the solution shaken with ether. The crude cholesterol so obtained is extracted with chloroform; half of the chloroform solution is evaporated, and the residue crystallised from alcohol for microscopic examination; other portions are tested by Salkowski's and Liebermann's reactions.

For quantitative purposes, the phosphorus present in the form of lecithin and its compounds is estimated, since the proportion in egg so largely exceeds that in wheat flour. About 35 grams of the thoroughly dry substance is extracted with absolute alcohol in a Soxhlet apparatus at 55—60° for 10—12 hours. The matter soluble in alcohol is saponified with potash, and evaporated and incinerated in a platinum capsule. The phosphoric acid in the ash is estimated in the usual way by molybdate. By means of the equation $0.0225 \times 5 \times 86.95 + 13.16a = x(5 \times 86.95 + 12.375a)$, in which x is the amount of phosphoric acid found, there can then be calculated the number of eggs (a) which have been added to 1 lb. (500 grams) of flour, whilst if the yolks alone have been used, the equation becomes $0.0225 \times 5 \times 86.95 + 13.16a_1 = x(5 \times 86.95 + 7.835a_1)$.

To decide whether entire eggs or the yolks only have been used, a more complete analysis, including at least moisture, ash, total phosphoric acid, and nitrogen, must be made. Except in cases where yolk of eggs preserved by adding common salt has been employed, the ash will generally be in larger proportion to the total dry substance where whole eggs have been used than where only the yolks are present; whilst in the latter case phosphoric acid will form a far larger proportion of the total ash than in the former. It is to be observed that, unless an alkali is added, a loss of phosphoric acid will occur when incinerating yolk of egg; with whole eggs, this loss does not take place. For equal percentages of lecithin-phosphoric acid, the nitrogen will be higher when whole eggs are added than when the yolks only have been employed.

M. J. S.

Examination of Commercial Pastry. By SIGISMUND BEIN (*Zeit. Unters. Nahr.-Genussm.*, 1900, 3, 167—168); and by ADOLF JUCKENACK, *ibid.*, 168).—A question of priority.

M. J. S.

General and Physical Chemistry.

Refraction of Normal Salt Solutions. By CARL BENDER (*Ann. Physik.*, 1900, 2, 186—196. Compare Abstr., 1899, ii, 621).—The previous investigations are extended to solutions of potassium chloride at concentrations $N/2$, N , and $2N$, and at temperatures ranging from 10° to 70° , interpolation formulæ being given for each solution for the ranges 10° to 40° and 40° to 70° . With a fair degree of accuracy, that is, ± 2 in the fourth place of decimals, one formula only serves for the three solutions and for pure water for the range 10° to 40° , and one for 40° to 70° , the first term alone differing for the different compounds and for different wave-lengths of light, that is, the dispersion is approximately independent of temperature or concentration, and another formula is given also of the form $A + B\mu + C\mu^2$, where μ is the concentration. The molecular refraction is also calculated by both Gladstone's and Lorenz's formulæ, and the atomic refraction of the potassium is hence obtained, the values 8.5—9.6 (Gladstone) and 5.55—5.78 (Lorenz) being found. L. M. J.

Refractive Power of Methyl Acetate near the Critical Point. By PRINCE BORIS B. GALITZIN and J. WILIP (*Chem. Centr.*, 1900, i, 901; from *Bull. Acad. St. Pétersb.*, [v], 11, 117—196).—In order to determine whether the refractive power of a substance at a temperature near the critical point is the same in the gaseous as in the liquid state, direct measurements of the refractive index were made by the lens and by the prism method. In the first method, the tube containing the liquid served as a cylindrical lens, and in the second a very acute angled prism was inserted in the tube so that one face was parallel to the wall. By the former method, which proved the better, the critical temperature of ethyl acetate was found to be 193.7 — 193.8° . For accurate determinations, a good thermostat is required, and it is necessary to stir the contents of the tube in order to insure thorough mixing of the layers, for even at a temperature above the critical, the density may vary in different parts of the tube, although the temperature and pressure are the same throughout. In one case, it was found that the variations of density amounted to 35 per cent. at the critical point, and to 14 per cent. at 5° above this point. These variations probably indicate that, owing to retardation of ebullition, the substance may exist as a liquid, even above the critical point. When the liquid is thoroughly agitated, the refractive index for the same phase is the same at all parts, and is independent of the total volume occupied by the substance, if the substance is in presence of saturated vapour. If the tube is filled with a homogeneous substance, the refractive index depends only on the total volume, and is independent of the temperature. The relation between the refractive index and the volume for large variations of temperature, and for both the liquid and gaseous states, is well expressed by Lorentz's formula, $C = (x_2 - 1)/(x_2 - 2) \cdot v = 0.3025$.

If the substance is not stirred, it may be assumed that at a tempe-

perature a few degrees below the critical, the refractive index in each layer is the same at the same phase, but as the temperature approaches the critical, the refractive indices of the lower layers tend to become greater. Above the critical temperature, the mean value of the refractive indices of the various layers is that corresponding with the total volume of substance.

E. W. W.

Conditions Determining the Stability of Rotatory Power. By JOSEPH A. LE BEL (*Compt. rend.*, 1900, 130, 1552—1555).—The existence of optical rotation in a chemical compound depends, not only on the asymmetric disposition of at least four dissimilar radicles around a central atom, but also on the stability of the geometric system; the mobility of the substituent radicles produces a loss of optical activity by racemisation.

The stability of an asymmetric system increases with (1) the chemical activity of the central element, (2) the specific volume of the substituent radicles.

The chemical activity of carbon is greater than that of nitrogen, and hence the compounds containing the former element in an asymmetric condition are sufficiently stable to exhibit optical activity at the ordinary temperature; this, however, is not always the case with asymmetric nitrogen. Even with asymmetric carbon compounds containing small radicles, the activity readily disappears; the optical rotation of amyl alcohol is diminished by converting it into its sodium derivative at the ordinary temperature; its rotation greatly decreases on heating it at 100° or 150°, and at 200° it is completely racemised.

The failure to obtain active forms of the salt $\text{NHMeEtPr}\cdot\text{Cl}$ is very probably due to the mobility of its light radicles; the compound $\text{C}_{10}\text{H}_{24}\text{NCl}$, obtained by adding methyl to each of these radicles, exhibits optical isomerism, the rotation diminishing as the temperature rises. The salts of the C_{10} bases are, however, less stable than those employed by Pope and Peachey, which contain 17 carbon atoms (*Trans.*, 1899, 75, 1127).

The stability of active substances also depends on the chemical influence exerted by the substituent radicles on one another; it is therefore considerably modified by the replacement of one radicle by another of a different chemical nature: for example, the bromosuccinic acid, obtained by replacing hydroxyl by bromine in malic acid, racemises at the ordinary temperature.

These results indicate that at 100° the presence of four dissimilar radicles attached to a carbon atom is not in itself sufficient to determine the existence of optical rotation, for at this temperature sodium amyloxide and bromosuccinic acid resemble the compounds of active nitrogen, and readily undergo racemisation.

G. T. M.

Solidification and Transition Phenomena of Optical Antipodes. By J. H. ADRIANI (*Zeit. physikal. Chem.*, 1900, 33, 453—476).—The distinction between racemic and pseudoracemic compounds is not as simple as many observers consider; contrary to the opinion of Kipping and Pope (*Trans.*, 1897, 71, 989), the crystallographic form of a racemic compound may be very similar to that of the active components, whilst further, a pseudoracemic compound may be different

in crystallographic form, density, &c. The author considers that there is no satisfactory proof of the existence of a racemic compound in the liquid state as change of volume and production of heat which have been taken as indication of the formation of a racemate also occur when no chemical action takes place; similar doubts also apply regarding the gaseous state. The most satisfactory test for a racemic compound is the complete examination of the melting point curve for mixtures of the two antipodes, and these curves are given for dimethyl tartrate, dimethyl diacetyltartrate, mandelic acid, benzoyltetrahydroquinoline, camphoroxime, and carvoxime. The first four curves, each consisting of three portions with a central maximum, are typical of the formation of racemic compounds as described by Roozeboom; the fifth is a straight line, and the sixth a continuous curve with a maximum. The last two curves hence indicate a series of mixed crystals, but in the last case no statement can be made regarding the existence of a racemic compound. The transition temperatures were also determined for the whole series of the camphoroxime mixtures, and it was found that the continuous series of the β -modification changes into a continuous series of the α -modification, the transition curve being continuous with a central minimum. Although only mixed crystals may exist at the melting point, yet it is possible that racemic compounds may exist at the ordinary temperature, and it is shown that this is probably the case with carvoxime (compare Roozeboom, this vol., ii, 64, 70, 132).

L. M. J.

Asymmetry and Vitalism. By C. ULPANI and S. CONDELLI (*Gazzetta*, 1900, 30, i, 344—382).—A discussion of Japp's Sectional Address at the British Association in 1898 and of the controversy to which it gave rise. The views of Pasteur, Peré, Hahn, and Fischer are also discussed. The authors find that whilst *Penicillium glaucum* destroys *l*-lactic acid, *d*-alanine, and *d*-tartaric acid, the cholera bacillus attacks *d*-lactic acid, *l*-alanine, and *d*-tartaric acid; these results throw doubt on Japp's biological theory of the propagation of life in an asymmetric sense.

T. H. P.

The Lead Accumulator. By MARTIN MUGDAN (*Zeit. Elektrochem.*, 1899, 3, 309).—The author shows that, when an accumulator is discharged, lead sulphate separates on both the positive and negative plates in almost theoretical quantity, and that no lead oxide is formed. If sodium sulphate is used as the electrolyte in place of sulphuric acid, however, some lead oxide is formed on the positive plate. A partially oxidised negative plate takes up sulphuric acid very slowly, whereas a positive plate containing oxide absorbs the acid very rapidly. The potential difference between a negative (spongy lead) plate and sulphuric acid of given concentration is independent of the quantity of lead sulphate on the plate. The alterations in the E.M.F. of an accumulator during charge and discharge are due to local changes of the concentration of the acid at the electrodes. When at rest, the condition of affairs may be represented thus: $\text{Pb, PbSO}_4 \mid \text{acid} \mid \text{PbSO}_4, \text{PbO}_2$. During charge, the acids at the electrodes are more, but during discharge, are less concentrated than the main bulk of the acid. The total E.M.F. is therefore obtained by

superimposing the E.M.F.'s of two concentration cells on the main E.M.F. The two concentration cells may be represented thus: $\text{Pb}, \text{PbSO}_4 \mid \text{dil. or conc. acid} \mid \text{acid} \mid \text{PbSO}_4, \text{Pb}$ and $\text{PbO}_2, \text{PbSO}_4 \mid \text{dil. or conc. acid} \mid \text{normal acid} \mid \text{PbSO}_4, \text{Pb}$. The E.M.F.'s of these concentration cells are calculated from Nernst's theory (see Dolezalek, this vol., ii, 2), and compared with actual measurements made by the author. For acids containing less than 0.75 gram-mol. per litre, the agreement is excellent. A change of concentration at the lead dioxide plate makes about 1.4 times as much difference in the E.M.F. as an equal change at the lead plate. Further, the concentration of the acid at the lead dioxide plate increases or decreases during charge and discharge $1 + \frac{2v}{u}$ times as quickly as that at the lead plate (u and v are the relative mobilities of the H and SO_4 ions). The effect of the changes of concentration at both electrodes is to diminish the E.M.F. of the cell during discharge and increase it during charge.

T. E.

Chemical Equilibrium and Electromotive Force. By H. DANNEEL (*Zeit. Elektrochem.*, 1899, 6, 293).—From theoretical considerations, the author draws the conclusion that, when a metal is precipitated from a solution of one of its salts by another metal, the ratio of the concentrations of the ions of the two metals in the solution when equilibrium is attained is the same as the ratio of the solution tensions of the two metals. This conclusion is tested experimentally in the case of the precipitation of silver from a solution of silver iodide in hydriodic acid by hydrogen. The concentration of the hydrogen ions when equilibrium is attained is calculated to be 0.057 gram-mol. per litre at 18° , whilst the concentration 0.042 at 13° is found experimentally. The further conclusion is drawn that, in reactions of this kind, the final equilibrium is independent of the nature of the anion.

T. E.

Additivity of Atomic Heats. By STEFAN MEYER (*Ann. Physik.*, 1900, 2, 135—140).—By the comparison of the molecular heats and molecular volumes of a large number of compounds with the sum of the atomic heats or atomic volumes of the components, it is seen that the molecular heat is only equal, or approximately equal, to the sum of the atomic heats in those cases where the molecular volume is also equal or approximately equal to the sum of the atomic volumes, and the differences in the two cases are, moreover, in the same sense.

L. M. J.

Boiling Point Curves. By CLARENCE L. SPEYERS (*Amer. Jour. Sci.*, 1900, 9, 341—344).—The expression $n_1/(n_2 + n_1) = (p - p')/p$, previously used by the author for the determination of molecular weights in liquid mixtures (Abstr., 1899, ii, 145), may also be used to calculate the boiling point curves of the latter if the states of molecular aggregation of the components are known. The curves so calculated agree well with the experimental determinations in the case of mixtures of carbon tetrachloride with benzene or chloroform; for benzene and chloroform, however, the agreement is not so good, but fair accord was obtained for mixtures of benzene and ethyl

alcohol, where complex molecules are known to occur. If the molecular weights of the components are normal, the curves will be straight lines if $dp_1/dt_1 = dp_2/dt_2$, while if $dp_2/dt_2 > dp_1/dt_1$, the curve will be convex or concave to the axis of abscissæ according as $p_2 >$ or $< p_1$. A mixture cannot have a minimum boiling point unless one or both components have abnormal molecular weights. In the first case, a minimum would probably occur when the constituent with the lower vapour pressure is associated; in the latter case, absence of a minimum would be exceptional, although possible. L. M. J.

Phenomenon Noticed in the Cooling of Superfused Substances. By R. MORESCHINI (*Gazzetta*, 1900, 30, i, 339—344).—Mixtures of fatty acids obtained from soap exhibit the phenomenon of superfusion, the temperature at which resolidification occurs varying with the method of determination employed. When such a mixture is heated in a tube to, say, 15° above its melting point, and then allowed to cool in a constant temperature air-bath, conveniently 15° below the melting point, the rate of cooling diminishes regularly until the melting point is reached, when a sudden diminution takes place; cooling afterwards proceeds regularly, although more slowly than before. In the case of pure substances, however, this sudden change in the rate of cooling occurs just at the melting point, whilst with mixtures of fatty acids, especially if much oleic acid is present, it appears at a temperature about 0.15° above the melting point.

T. H. P.

Determination of the Transition Temperature of Monotropic Dimorphous Substances. By RUDOLF SCHENCK (*Zeit. physikal. Chem.*, 1900, 33, 445—452).—In the case of a monotropic dimorphous substance, the transition temperature lies above the melting point, and hence cannot be directly determined. If the melting points of the two modifications be lowered by the addition of a foreign substance, the depression will be less for the stable form, in consequence of the smaller value of the latent heat of fusion—if curves be drawn for melting point against concentration of foreign substance, the curves, by extrapolation, will meet at a certain negative concentration and higher temperature. For this concentration, there is no physical interpretation, but the author considers the temperature to be the transition temperature of the compounds. By this means, the transition point of *m*-nitro-*p*-acetyl-toluidine was found to be 105.9° , the melting points of the two modifications being 93.32° and 91.58° . For monochloroacetic acid, the melting points of the two varieties of which were found to be 56.3° and 61.5° , no result could be obtained, owing to the very slight difference between the depression constants.

L. M. J.

Apparatus for Determining the Calorific Value of Fuels. By GAETANO MAGNANINI and V. ZUNINO (*Gazzetta*, 1900, 30, i, 395—401).—A modified form of Lewis Thompson's calorific bomb is described, the use of an oxidising mixture to burn the fuel being obviated, and the combustion carried on in a regular stream of oxygen. A series of 15 different samples of coal were examined in the new

apparatus and good results obtained, the calorific values found being in every case but two higher than the numbers yielded by the Lewis Thompson method.

T. H. P.

Thermochemistry of Hyperacids. By L. PISSARJEWSKY (*J. Russ. Phys. Chem. Soc.*, 1900, 32, 155—169).—The following heats of neutralisation by sodium hydroxide of acids of the elements of the sixth series in Mendeleeff's table have been determined: Pyrouroanic acid, $\text{H}_2\text{U}_4\text{O}_7$, +17·559 Cal.; tungstic acid, H_2WO_4 , +13·698 Cal.; permolybdic acid, H_2MoO_5 , +13·248 Cal.; molybdic acid, H_2MoO_4 , +21·278 Cal. Comparing the heats of neutralisation of molybdic and tungstic acids with the value, +24·720 Cal., for chromic acid, it is seen that as the atomic weight of the element of this series increases, the acid function of the corresponding acid decreases. The following heats of reaction were also determined:

T. H. P.

Absorption. VI. Absorption of Matters from Solution. By JACOBUS M. VAN BEMMELN (*Zeit. anorg. Chem.*, 1900, 23, 321—372).—In the partition of a crystalloid between a colloid or porous substance and the liquid solution, the ratio of the concentrations may be greater than, equal to, or less than, unity; the last case, termed by the author negative absorption, has been observed when kaolin is added to a solution of salt, the concentration of the latter in the solution being thereby increased. The absorption of the crystalloid is influenced by various factors. (1) By the structure and state of the colloid; thus, red colloidal manganese peroxide absorbs more acid or salt from an aqueous solution than does the black, and the absorptive power of stannic or metastannic acid is dependent on its condition. (2) By the nature of the solvent, picric acid is absorbed by silk in greater quantity from an aqueous solution than from an alcoholic solution, and not at all from a benzene solution; this is not merely due to the solubility in the different solvents, as picric acid is more soluble in alcohol than in either of the other two. (3) By the nature of the solute; the metastannic acid hydrogel, for example, absorbs potassium chloride but slightly, but hydrogen chloride very strongly. (4) By the molecular state of the solute in the solutions, and (5), by the temperature. The case of the absorption of two compounds from a solution by a colloid is greatly complicated by the influence of each on the absorption of the other, and of the compounds produced by their interaction. In the colloid, hydrolysis frequently occurs even in the case of salts of strong acids or bases, as, for instance, potassium sulphate or chloride, from solutions of which various hydrogels absorb an excess of base (compare this vol., ii, 338; *Abstr.*, 1899, ii, 12, 84, 487).

L. M. J.

Theory of Capillarity. By G. BAKKER (*Zeit. physikal. Chem.*, 1900, 33, 477—499).—The author considers the usual treatment and

derivation of the laws of capillarity to be unsatisfactory, and gives a different method for their derivation, but without deducing any important new results.

L. M. J.

Solution Tension of Zinc in Ethyl Alcohol. By HARRY C. JONES and ARTHUR W. SMITH (*Amer. Chem. J.*, 1900, 23, 397—403).—Jones's experiments (Abstr., 1894, ii, 374) have shown that the solution tension of silver is considerably less in alcoholic than in an aqueous solution of its salts. As the solution tension of silver is very small, the authors have extended the investigations to zinc, the solution tension of which is very great. The dissociation of a $N/10$ solution of zinc chloride in ethyl alcohol was found by the boiling point method to be 6.5 (this vol., ii, 187); Kahlenberg had found the E.M.F. of the chain zinc | aqueous $N/10$ zinc chloride | alcoholic $N/10$ zinc chloride | zinc to be 0.19 volt, from which the value 1.9×10^{10} atmos. is obtained for the solution tension of the zinc in alcohol. By the determination of the E.M.F. of the alcoholic electrode alone (0.327 volt), the value 2.7×10^{-10} atmos. is obtained for the solution tension, agreeing fairly with the previous value, and about 10^{-8} times the solution tension in water, so that metals cannot be regarded as possessing a definite solution tension independent of the solvent.

L. M. J.

Changes of Solubility by Addition of Salts. By VICTOR ROTHMUND (*Zeit. physikal. Chem.*, 1900, 33, 401—414).—Although it is frequently assumed that the addition of a salt should have no effect on the solubility of a non-electrolyte in water, yet Gordon (Abstr., 1896, ii, 154) and Roth (Abstr., 1898, ii, 18) have shown that the solubility of gases in water is diminished by the addition of salts, and Euler has shown that the solubility of ethyl acetate is similarly decreased (this vol., ii, 196), and to about the same extent, the relative order of the salts examined being also similar in the various cases. The author has determined the influence of the addition of salts on the solubility of phenylthiocarbamide, and curves are given for salt concentration against solubility, these curves being approximately straight lines. The sulphates and carbonates produce the greatest depression, the equivalent solubility depression being about 0.4; nitrates were found to have the least effect, ammonium nitrate causing an increase of solubility, whilst the order of the salts is also the same as that found for carbon dioxide, hydrogen, nitrous oxide, and ethyl acetate. The equivalent solubility depression $1/n \cdot (s_0 - s)/s_0$ was found to be independent of temperature, hence s/s_0 is constant, so that $d \log s / dT = d \log s_0 / dT = q / 2T^2 = q_0 / 2T^2$, where q is the heat of solution, which is hence the same in salt solutions as in pure water.

L. M. J.

Chemical Kinetics and Free Energy of the Reaction
 $2\text{HI} + 2\text{Ag} \rightleftharpoons 2\text{AgI} + \text{H}_2$. By H. DANNEEL (*Zeit. physikal. Chem.*, 1900, 33, 415—444).—The E.M.F. of a cell consisting of silver and hydrogen electrodes in normal solutions of the corresponding ions is 0.78 volt, and hence it follows that the E.M.F. of any similar cell is $0.78 + 0.058 \log C_{\text{Ag}}/C_{\text{H}}$ volts where C_{Ag} and C_{H} are the concentrations of the silver and hydrogen ions. The solubility of silver iodide is

not known with certainty, but accepting the value 10^{-8} , it follows that at the concentration $C_H = 0.053$ the E.M.F. of the cell is zero, and equilibrium obtains. The equilibrium concentration obtained by direct experiment was 0.043, a value which gives $0.567 + 10^{-8}$ as the solubility of silver iodide, a value lower than those previously obtained by other methods. The reaction-velocities in each direction were determined; the values indicate that the reaction proceeds as $Ag + HI \rightleftharpoons AgI + H$, so that the hydrogen takes part in the reaction as H , not as H_2 . The equilibrium constant calculated from the reaction velocities is in complete accord with the direct determination. The value of the E.M.F. of any similar cell is $0.1154 \log C/C_0$, where C is the actual and C_0 the equilibrium concentration of the hydrogen, but the values experimentally obtained are not in accord with those so calculated, an almost constant difference of 0.02 volt being found. No explanation could be given, although it is pointed out that a higher pressure of hydrogen in the electrode would cause such a difference.

L. M. J.

Reactions in Water and Acetone. By PAUL ROHLAND (*Chem. Zeit.*, 1900, 24, 312—314).—Owing to differences in the extent of the dissociation and in solubility, many reactions proceed differently in aqueous and acetone solutions. The colour of dilute solutions of copper salts is alike in both solvents, but with moderately strong solutions the colour differs, owing to the smaller value of the dissociation in acetone. The velocity of an ionic reaction may also be very small; thus silver nitrate and sodium dichromate gave no precipitate until the lapse of 30 seconds or more, whilst the precipitates frequently differ from those obtained in aqueous solutions, being probably allotropic forms. Anomalous reactions as those previously recorded (*Abstr.*, 1899, ii, 144) may occur, and fresh examples are given. Many reactions dependent on particular ions, as, for example, the action of hydroxyl compounds on the halogens, and on various indicators, may not occur in acetone solutions, owing to the absence of the particular ion involved.

L. M. J.

Behaviour of Perfumes with Liquid Air. By HUGO ERDMANN (*J. pr. Chem.*, 1900, [ii], 61, 225—228).—Preliminary experiments show that some perfumes lose their odour more or less completely when dissolved in liquid air, but on shaking the flask the odour is strongly apparent. The perfumes dissolved in liquid air therefore evaporate with it; hence it is possible that the volatility of any perfume does not depend alone on its vapour tension, but also on its specific solubility in air.

R. H. P.

Apparatus for Sublimation. By C. N. RIIBER (*Ber.*, 1900, 33, 1655—1657).—The author describes an apparatus for subliming substances under reduced pressure. For heating the apparatus, a Lothar Meyer air-bath, or simply two iron dishes fitting into one another, but separated by a layer of air and covered with an asbestos lid, may be employed. The apparatus itself consists of a horizontal glass cylinder ground into a glass cup, in which the substance to be sublimed is placed, the upper end of the cylinder is drawn out into

a narrow tube, which can be attached to the pump. The process of sublimation is quickened if the cup and cylinder do not fit quite airtight, as a gentle current of warm air is thus kept passing over the substance. The apparatus may also be employed for separating two substances of different volatility, for the estimation of water of crystallisation, &c.

J. J. S.

Lecture Experiments Illustrating Equilibrium and Dissociation. By JULIUS STIEGLITZ (*Amer. Chem. J.*, 1900, 23, 404—408).—The effect of excess of one of the products on the dissociation of a compound is easily seen by heating two tubes containing bromine with (1) an equivalent quantity, and (2) an excess of phosphorus tribromide. It is still more marked if phosphorus bromodichloride be used, and the difference between this and the previous case forms an illustration of the different magnitudes of dissociation constants. The decrease of electrolytic dissociation, on addition of one of the ions, is well seen on adding an ammonium salt to a solution of phenolphthalein coloured red by a few drops of a dilute ammonia solution, the red colour almost disappearing in consequence of the decrease of concentration of the hydroxyl ions. A somewhat similar result is obtained by the addition of an acetate to a solution of methyl-orange reddened by a drop of acetic acid.

L. M. J.

Inorganic Chemistry.

Limits of Combustibility of Hydrogen and Gaseous Hydrocarbons when Diluted with Large Volumes of Air and Passed over Red Hot Cupric Oxide. By ARMAND GAUTIER (*Compt. rend.*, 1900, 130, 1353—1360).—Definite mixtures of hydrogen or methane or both with air previously freed from hydrogen and carbon compounds, were passed slowly through two consecutive tubes containing cupric oxide heated just to redness. With two tubes each 35 cm. long, hydrogen is completely oxidised even when diluted with 5000 times its volume of air, but it is noteworthy that only 70 per cent. of the oxidation takes place in the first tube.

Methane, however, under similar conditions, is incompletely burnt. With two tubes each 30 cm. long and a dilution of 1 in 4000, 71·6 per cent. of hydrogen and 58·9 per cent. of the carbon are burnt; with a dilution of 7 in 100,000, 45·2 per cent. of hydrogen and 36 per cent. of carbon. With methane, 16 parts, and hydrogen, 8 parts, in air, 100,000 parts, all the free hydrogen, 58·3 per cent. of the hydrogen in the methane, and 47·4 per cent. of the carbon in the methane are burnt. It would seem, therefore, that the presence of free hydrogen promotes the oxidation of the hydrogen of the methane. The use of a third tube of cupric oxide, even 80 cm. long, has no appreciable influence on the results obtained with mixtures of hydrogen and hydrocarbons.

C. H. B.

Higher Hydrogen Peroxides. By A. BACH (*Ber.*, 1900, 33, 1506—1517).—Whilst hydrogen dioxide, H_2O_2 , when reduced with potassium permanganate, gives $5O_2$ for each $2KMnO_4$, hydrogen tetroxide, H_2O_4 , should give $10O_2$ for each $2KMnO_4$. The method adopted in order to detect the presence of higher hydrogen peroxides consisted in measuring the volume of gas liberated in the titration with potassium permanganate and comparing it with that calculated from the ratio $2KMnO_4:5H_2O_2$. The proportion of gas found in titrating hydrogen peroxide from different sources was as follows :

From barium peroxide.....	1
„ oxidation of palladium hydride.....	1·07
„ sodium dioxide	1·17
„ potassium tetroxide	1·28
„ a mixture of hydrogen peroxide with two volumes of concentrated sulphuric acid...	1·65

From these results, the existence of a higher hydrogen peroxide is assumed, and the formula H_2O_4 is assigned to it from analogy to K_2O_4 , and also because H_2O_2 is regarded as a substance which would probably have no oxidising power.

T. M. L.

[The large volume of oxygen produced from a mixture of hydrogen peroxide and sulphuric acid is readily explained by the presence of a 'persulphuric acid' in the mixture; this was demonstrated by Berthelot as long ago as 1878, and it was found that, whilst it does not reduce potassium permanganate, it is readily hydrolysed to sulphuric acid and oxygen.—T. M. L.]

Evolution of Chlorine by the Aid of Manganese Dioxide. By LEONHARD WACKER (*Chem. Zeit.*, 1900, 24, 285).—Manganese dioxide or one of its hydrates is obtained when chlorine gas is passed into a solution of crystallised manganese chloride in concentrated hydrochloric acid for some hours, and the dark coloured liquid thus obtained poured into warm water. The author thinks that this confirms the conclusion that manganese tetrachloride is the first product formed by the action of hydrochloric acid on manganese dioxide (compare Meyer and Best, this vol., ii, 77).

J. J. S.

Electrolytic Preparation of Hypochlorites. By ADOLF SIEVERTS (*Zeit. Elektrochem.*, 1900, 6, 364, 374).—The experiments were made in order to decide whether the yield of hypochlorite in the electrolysis of solutions of the chlorides of the alkali or alkaline earth metals is increased by an increased current density. Oettel had observed an increased yield with the electrolyte at rest, and Schoop a decreased yield with a flowing electrolyte. In the author's experiments, the solution flows at constant speed through the cell, the quantity of hypochlorite formed after the passage of a definite quantity of electricity at varying current density being determined. An increased yield was observed at higher current densities both with sodium and potassium chlorides. The yield of hypochlorite is very good at the beginning of an experiment, when its concentration in the solution is small, but it decreases rapidly (owing to cathodic reduction) as the concentration rises.

Further experiments were made in order to decide whether the superior bleaching properties of electrolytic hypochlorite solutions are due to the presence of free hypochlorous acid. The free hypochlorous acid present is determined by a method due to Jorre, depending on the reactions $\text{MOCl} + \text{H}_2\text{O}_2 = \text{MCl} + \text{H}_2\text{O} + \text{O}_2$ and $\text{HOCl} + \text{H}_2\text{O}_2 = \text{HCl} + \text{H}_2\text{O} + \text{O}_2$. The hydrogen chloride liberated is finally titrated. The following table contains the principal results. The solutions were all treated in the same way and the time which they required to bleach a piece of turkey red cloth noted.

Grams salt per 100 c.c.		Hypochlorite current efficiency.	Per cent. of HOCl free.	Time of bleaching.	Per cent. of hypochlorite undecomposed after 24 hours.
10	grams NaCl.....	51.7	0	5½ hours	98
12.7	„ KCl	44.4	0	4 „	98
9.5	„ CaCl_2 ...	73.4	49.3	15 min.	45
3.48	„ MgCl_2 }	62.1	94.9	10 „	90
+ 8	„ NaCl }				

The effect of the presence of free hypochlorous acid is quite clear. A solution of pure magnesium chloride gave a liquid which readily decomposed, contained free chlorine, and was not further investigated.

T. E.

Electrolytic Formation of Chlorates. By HEINRICH WOHLWILL (*Zeit. Elektrochem.*, 1900, 6, 410).—A continuation of the discussion with Förster (see Abstr., 1899, 278; this vol., ii, 72, 400). T. E.

Chlorine Heptoxide. By ARTHUR MICHAEL and WALLACE T. CONN (*Amer. Chem. J.*, 1900, 23, 444—446).—The method described by Roscoe (*Trans.*, 1863, 16, 82) for the preparation of perchloric acid is improved by heating the perchlorate and sulphuric acid under 10—20 mm. pressure. Perchloric acid boils at 19° under 11 mm. pressure. When it is mixed with alcohol or ether, no explosion occurs; it dissolves in benzene, forming a green solution which gradually becomes charred. Iodine dissolves in the acid with the production of a dark solution which, on exposure to bright light, becomes converted into a white solid; when this white substance is heated, it is decomposed into iodine and iodic acid (compare Vorländer and Schilling, this vol., ii, 340).

Chlorine heptoxide is obtained by slowly adding perchloric acid to phosphoric oxide cooled below -10° ; the mixture is left for a day and then gradually warmed until the new oxide distils over. It is a colourless, very volatile oil, which boils constantly at 82° under ordinary pressure; on standing for 2—3 days, it becomes greenish-yellow and evolves a greenish gas. It explodes violently on percussion or when brought into a flame, but is without action on wood or paper. By the action of water on the oxide, it is gradually converted into perchloric acid. It dissolves in dry, well-cooled benzene and slowly attacks it. It reacts with iodine with liberation of chlorine and formation of a white substance which is probably iodine heptoxide; this decomposes at 380° with the production of iodine and oxygen. Chlorine heptoxide is not, however, similarly attacked by bromine.

E. G.

Preparation, Properties, and Analysis of Thionyl Fluoride. By HENRI MOISSAN and PAUL LEBEAU (*Compt. rend.*, 1900, 130, 1436—1442. Compare this vol., ii, 341).—Thionyl fluoride, which was first obtained by Meslans (*Bull. Soc. Chim.*, 1896, [iii], 15, 391), is most conveniently prepared by mixing together arsenic trifluoride (2 mols.) and thionyl chloride (3 mols.) and heating the mixture at 100°; it is separated from arsenic trichloride and traces of its generators by fractional distillation at low temperatures. It is also produced by the action of fluorine on thionyl chloride; this reaction, however, is somewhat complicated, and the thionyl fluoride is contaminated with chlorine and a more volatile sulphur oxyfluoride which is not absorbed by water.

Thionyl fluoride is a colourless gas which boils at -32°, fumes slightly in moist air, and has a suffocating odour; it has no action on mercury at the ordinary temperature. Its composition was determined both by synthesis from weighed quantities of its generators and also by volumetric and gravimetric analyses. The volumetric determination was made by heating the gas in a dry glass vessel at 400°; under these conditions, 4 vols. of the gas yield 6 vols. of gaseous products in accordance with the following equation, $2\text{SOF}_2 + \text{SiO}_2 = \text{SiF}_4 + 2\text{SO}_2$. Its decomposition by water ($\text{SOF}_2 + \text{H}_2\text{O} = \text{SO}_2 + \text{H}_2\text{F}_2$) furnishes a method for the gravimetric analysis, the sulphurous acid being estimated iodometrically and the fluorine by precipitation as calcium fluoride. The gas is soluble in arsenic trichloride, ether, turpentine, or benzene, and is absorbed by fused sodium or tin; when treated with hydrogen chloride over mercury, a gaseous mixture is produced which gradually attacks this metal.

The action of the electric discharge from an induction coil on thionyl fluoride contained in glass vessels is similar to that of heat; when this decomposition takes place in the presence of hydrogen, the sulphur dioxide produced undergoes reduction, and hydrogen sulphide, sulphur, and water are produced; the last named reacts with the silicon fluoride, giving rise to a small quantity of hydrofluosilicic acid.

The presence of oxygen does not affect the decomposition of the thionyl compound as produced by the action of heat, but when a mixture of the two gases is submitted to the action of the induction spark a certain amount of the more volatile sulphur oxyfluoride is produced. Sulphur and phosphorus do not act on the gas at 500°; water, hydrogen fluoride, and sulphur are produced by the action of hydrogen sulphide at high temperatures; there is, however, no interaction in the cold.

Ammonia is absorbed by thionyl fluoride, yielding first an orange compound having the composition $2\text{SOF}_2 \cdot 5\text{NH}_3$, and finally a white substance corresponding with the fixation of 7NH_3 by 2SOF_2 ; when treated with hydrogen chloride, the latter product is decomposed, giving rise to sulphur dioxide and sulphur. G. T. M.

Estimation of Sulphuric Acid in the Presence of Iron: Solid Solution and the Hydrolysis of Chromium and Iron Salts. By THEODORE W. RICHARDS (*Zeit. anorg. Chem.*, 1900, 23, 383—390).—The paper contains a theoretical criticism of Küster

and Thiel's work on the estimation of sulphuric acid in the presence of iron (Abstr., 1899, ii, 247, 611; this vol., ii, 242). Since a precipitate of calcium carbonate obtained in a solution saturated with salt contains only 0.1 per cent. of sodium chloride, it is evident that the precipitation of impurities together with barium sulphate which amount to several per cent. is a different phenomenon. This the author calls *occlusion* to distinguish it from mechanical inclusion, and compares it with the occlusion of hydrogen by palladium. Aluminium sulphate and green chromium sulphate are also occluded by barium sulphate. The occlusion is probably brought about by the formation of an electrically neutral substance or complex. The nature of the groups which cause the occlusion in the case of iron, chromium, and aluminium salts is not determined, but they are probably of a basic character and similar to the basic complex described by Racoura (Abstr., 1896, ii, 27) and Whitney (Abstr., 1896, ii, 525). The green chromium sulphate solution probably contains not only a basic complex, but also a chromosulphuric acid which is not precipitated by barium solutions and is only slightly occluded by barium sulphate as it is strongly dissociated.

E. C. R.

Spontaneous Decomposition of Thiosulphuric Acid. By ARNOLD F. HOLLEMAN (*Zeit. physikal. Chem.*, 1900, 33, 500—501. Compare van Oettingen, this vol., ii, 400).—The author had previously shown that opalescence must not be regarded as the first indication of the decomposition of thiosulphuric acid, for if the solution is neutralised before opalescence is produced, it still occurs later. The decomposition is also not necessarily entirely due to hydrogen and S_2O_3 ions, as there is no evidence against the view that the undissociated molecules are also reactive.

L. M. J.

Tellurium. By F. D. CRANE (*Amer. Chem. J.*, 1900, 23, 408—425).—Tellurium may be obtained from the dross produced in the final purification of the precious metals from the electrical refining of copper (compare Whitehead, Abstr., 1896, ii, 164) by extracting it with hydrochloric acid and precipitating by means of sodium hydrogen sulphite. In order to remove selenium, the precipitate is allowed to act as the positive pole of an electrolytic cell containing hydrochloric acid; the nascent chlorine effects the solution of the tellurium, the selenium remaining undissolved. Further purification is carried out by boiling the precipitated tellurium with a reserve portion of the solution from which it has been obtained, in order that any metallic elements with which it may be contaminated may be dissolved and an equivalent quantity of tellurium precipitated.

Keller (Abstr., 1898, ii, 638) has stated that selenium and tellurium may be separated by means of ferrous sulphate, the selenium being precipitated, whilst the whole of the tellurium remains in solution. The author finds that this is only true if the tellurium is present entirely as tetrachloride, for if the solution contains any dichloride, some tellurium is always precipitated. When tellurium is added in excess to a mixture of selenium dichloride and tellurium tetrachloride

dissolved in hydrochloric acid, the selenium becomes completely replaced by tellurium, and is thus removed from the solution.

Tellurium tetrachloride dissolves in water, forming a yellow solution; when this solution is diluted, it yields a precipitate of tellurous acid, which gradually changes into the crystalline dioxide. If a metal, such as iron, arsenic, or antimony, is present, the precipitate appears to consist of a double oxychloride. E. G.

Some Properties of Liquid Ammonia. By C. FRENZEL (*Zeit. Elektrochem.*, 1900, 6, 477, 487, and 493).—The author has determined certain properties of very carefully purified liquid ammonia. The specific conductivity of the purest ammonia obtained was 1.33×10^{-7} ohms per cm. at -79° . The conductivity increases 1.9 per cent. of its value at 60° per degree rise of temperature. The conductivity increases and the temperature coefficient decreases with increasing impurity of the ammonia; in these particulars, it resembles water. By observations of the current which passes between a small cathode and a large anode through solutions of salts in ammonia when the applied E.M.F. is gradually increased, it is shown that there are three points at which anions, formed from the ammonia itself, are discharged. The author concludes that electrolytic dissociation of NH_3 into H^+ , NH_2^- , NH^- , and N^{3-} takes place. The addition of traces of water to liquid ammonia produces a comparatively very small increase in its conductivity. This is probably due to the fact that the greater part of the water remains uncombined, a very small portion forming NH_4OH . T. E.

Azoimide. By THEODOR CURTIUS and AUGUST DARAPSKY (*J. pr. Chem.*, 1900, [ii], 61, 408—422. Compare Curtius and Rissom, *Abstr.*, 1899, ii, 90).—The precipitation of aluminium hydroxide from a solution of ammonia-alum by sodium azoimide proceeds quantitatively if the azoimide set free is expelled by boiling. Chrome alum gives a green solution of chromium azoimide which is completely hydrolysed on boiling, the whole of the chromium being precipitated as hydroxide; a second *basic chromium azoimide* containing $1\text{Cr}:1\text{N}_3$ has been precipitated as a green salt from the solution by adding alcohol and ether. Ferric alum gives a blood-red solution of the azoimide which soon deposits a brown basic azoimide.

Zirconium and thorium give no azoimide, but are completely precipitated as hydroxides. Yttrium resembles chromium in that it gives a soluble azoimide, from which the hydroxide is precipitated on boiling. Lanthanum, cerium, and didymium give soluble azoimides, from which basic azoimides are precipitated on boiling containing 1La , Ce , or Di to 2N_3 . Uranium gives a much more stable azoimide, which is hydrolysed very slowly to uranyl hydroxide on boiling the solution.

On precipitating with alcohol and ether, manganese azoimide only gives the basic azoimide already obtained by evaporation, but *nickel azoimide*, $\text{NiN}_3 + \text{H}_2\text{O}$, is thrown down as a green, explosive powder, which dissolves again in water to a clear solution.

Arsenic dissolves in azoimide, but the azoimide is completely hydrolysed on evaporating the solution; antimony behaves similarly, but is only dissolved very slowly.

Azoimide is partially reduced to ammonia by zinc, and also by arsenic or antimony, but not by sodium amalgam; no hydrazine, hydroxylamine, or 'triimide' could be detected amongst the products of reduction.
T. M. L.

Preparation of Free Hydroxylamine. By RUDOLF UHLENHUTH (*Annalen*, 1900, 311, 117—120).—Although hydroxylamine oxalate yields the free base on distillation, the method is not suitable for the preparation of the purified substance, because water and carbon dioxide are produced at the same time. When hydroxylamine phosphate is distilled under reduced pressure, a very pure specimen of the base can be obtained; under 13 mm. pressure, distillation occurs at 135—137°, and the distillate solidifies almost immediately when the receiver is plunged into melting ice.
M. O. F.

Formation of Nitric Acid during Combustion: Carbon. By MARCELLIN P. E. BERTHELOT (*Compt. rend.*, 1900, 130, 1345—1353).—In the course of his researches on heats of combustion, the author has determined the quantities of nitric acid formed by the action of water and air on the nitrogen oxides produced during combustion in oxygen containing a small proportion of nitrogen, either at atmospheric pressure or in the calorimetric bomb. When amorphous carbon is burnt in the bomb under a pressure of 25 atmos. in oxygen containing 8 per cent. by volume of nitrogen, about 0.051 gram of nitric acid is formed per gram of carbon, although the actual amount varies with the rate of combustion, &c. The ratio of carbon dioxide to nitrogen is approximately $106\text{CO}_2 : \text{HNO}_3$. With graphite, under similar conditions, the quantity of nitric acid formed is only about one-fifth, and with diamond only about one-third of that formed in the case of amorphous carbon.

At the ordinary pressure in the same mixture of nitrogen and oxygen, even less than 1 milligram of nitric acid is formed per gram of amorphous carbon, whilst with air in place of oxygen, the proportion barely reaches 0.1 milligram per gram. Small though this amount is, the total quantity of nitric acid formed during the combustion of such substances as coal, petroleum, &c., must in the aggregate be very large. In the Department of the Seine it will amount to at least 8 kilograms of nitric acid per hectare per annum.
C. H. B.

Formation of Nitric Acid during Combustion: Sulphur, Metals. By MARCELLIN P. E. BERTHELOT (*Compt. rend.*, 1900, 130, 1430—1436. Compare preceding abstract).—When sulphur is burnt in atmospheric air or in oxygen containing 5—8 per cent. of nitrogen, a small amount of the latter element always undergoes oxidation; the results are therefore similar to those obtained in the combustion of carbon, although the amount of nitric acid produced when the action takes place in oxygen is much smaller. When the sulphur is burnt in compressed oxygen containing a small quantity of nitrogen, traces of ammonia can also be detected. The combustion of iron and zinc

under these conditions is not attended by the oxidation of nitrogen. The difference in the electrical properties of the combustibles and their oxides is suggested as the cause of this disparity. These phenomena were investigated quantitatively, and the paper contains a full discussion of the numerical data.

G. T. M.

Supposed Transformation of Phosphorus into Arsenic. By CLEMENS WINKLER (*Ber.*, 1900, 33, 1693—1697).—A destructive criticism of a paper by F. Fittica (*Leopoldina, Halle*, 1900, 36, 3, 40), in which it is stated that phosphorus can be partly transformed into arsenic by treatment with ammonium nitrate at 200°. Fittica's experiments have been repeated, and it is shown that the arsenic he obtained was really derived from impurities in the materials used.

R. H. P.

Dihydroxides. By ROBERT DE FORCEAND (*Compt. rend.*, 1900, 130, 1555—1558).—The addition of 1 mol. of hydrogen peroxide to aqueous solutions containing 2 mols. of sodium, potassium, or lithium hydroxides is attended by a heat disturbance of +5.821, +6.123, and +6.533 Cal. respectively; on adding a second mol. of the peroxide, more heat is developed, the additional amounts being respectively +4.845, +4.510, and +4.826 Cal. When ammonia and methylamine are substituted for these alkalis, the heat change, due to the first mol. of peroxide, is +0.589 and +2.584 Cal. respectively; the second molecule producing a further development of +0.464 and +1.464 Cal.

Appreciable thermal effects attend the addition of a third mol. of the peroxide to solutions of sodium and potassium hydroxides, the increments being +0.809 and +0.491 Cal. respectively; with lithium hydroxide, however, the change is only +0.005 Cal. These results point to the existence of compounds of the types $\text{NaO}\cdot\text{OH}$ and $\text{NaO}\cdot\text{ONa}$ and the heat of neutralisation of the acidic functions of hydrogen peroxide by various basic hydroxides can be calculated from the above data. The values of these constants are intermediate between those of the glycols and dihydric phenols. In the *m*- and *p*-dihydroxybenzenes, the heats of neutralisation of the first and second hydroxyl groups are approximately equal; the numerical values of these constants differ widely in the case of catechol and hydrogen peroxide which contain these radicles in close proximity to each other; the latter compound also resembles the phenols in its behaviour towards ammonia.

G. T. M.

Electrolysis of Sodium Chloride. By RICHARD LORENZ and H. WEHLIN (*Zeit. Elektrochem.*, 1900, 6, 389, 408, 419, 437, 445, and 461).—The authors have made a very elaborate investigation of the electrolysis of saturated solutions of common salt under conditions similar to those which occur in technical practice. The potential differences between platinum electrodes saturated with hydrogen, oxygen, and chlorine, and solutions containing sodium chloride, hypochlorite, hydroxide, and chlorate are also measured. In addition to determining the chemical effects of the current, the authors have made complete measurements of the electrical quantities necessary for an

exact understanding of the process, such as the polarisations at the electrodes, the reverse E.M.F.'s at the electrodes during the passage of the current, &c. The main results arrived at are as follows. The potential difference between an electrode of platinised platinum saturated with hydrogen and a solution of sodium chloride (saturated) + *N* sodium hydroxide is +0.52 volt. (The + sign indicates that the solution is at a higher potential than the electrode). In neutral solutions of salt, the potential difference is +0.12 volt, and the addition of sodium hypochlorite reduces it still further, owing to removal of hydrogen from the electrode, until in a concentrated solution of sodium hypochlorite the potential difference $\text{Pt}/\text{NaOCl} = -1.4$ volts is reached. In the electrolysis of neutral solutions of sodium chloride, the cathodic polarisations found immediately after breaking the circuit vary from -0.6 to -0.98 volt and thus correspond with the potential difference of the hydrogen electrode in solutions containing some hypochlorite. When alkaline solutions of sodium chloride are electrolysed, however, the cathodic polarisation changes sign and has values varying from +0.44 to +0.53 volt, thus again corresponding with the potential of the hydrogen electrode in alkaline solutions.

The E.M.F. required to produce decomposition at the cathode, or the reverse E.M.F. at the cathode during electrolysis, varies from +0.78 to +1.12 volts with polished platinum electrodes, whereas with platinised electrodes it varies from +0.25 to 0.62 volt. The authors conclude, therefore, that the evolution of hydrogen is a reversible process at the platinised cathode, but that a process analogous to supersaturation gives rise to the higher potential difference at the smooth cathodes. The great influence of the presence of sodium hypochlorite on the potential difference of the hydrogen electrode shows clearly the chemical reaction which takes place between hydrogen and hypochlorite at the cathode.

The changes at the anode are more complicated. The potential difference between a platinised platinum electrode saturated with chlorine, and a saturated solution of sodium chloride is about -1.58 volts. The addition of sodium hydroxide to the solution diminishes this value, so that in 2*N* sodium hydroxide the potential difference is -0.935 volt. An oxygen electrode in a saturated solution of sodium chloride gives the potential difference -0.9 volt, whilst in solutions containing sodium hypochlorite the potential difference varies irregularly and independently of the concentration of the hypochlorite from -1.4 to -1.5 volts; this is the potential difference between platinum and sodium hypochlorite solution. This shows that sodium hypochlorite is not oxidised by anodic oxygen, a result which is confirmed by chemical experiments. In the electrolysis of saturated neutral solutions of sodium chloride, the anodic polarisation observed after breaking the circuit varies from -1.66 to -1.53 volts, the lowest values being observed in the solutions containing the most hypochlorite; in alkaline solutions, the values vary from -1.35 to -1.31 volts. These numbers agree well with the potentials of the chlorine electrode in neutral and alkaline solutions, which proves that the anode is always saturated with chlorine even in alkaline solutions. It follows, therefore, that the formation of hypochlorite is due to the action of chlorine on dissolved alkali.

The reverse E.M.F. at the anode during electrolysis is very constant under the most varying experimental conditions. The platinised and smooth anodes give, however, different values, and there is also a very remarkable difference in their chemical behaviour. With a well platinised anode, the reverse E.M.F. is -1.75 volts, which is very nearly the potential of the chlorine electrode in saturated salt solution. The evolution of chlorine is, therefore, almost reversible, and it is found that practically no decomposition of water and no formation of chlorate takes place. With the smooth anodes, the reverse E.M.F. is -2.28 to -2.41 volts in neutral, and -2.26 to -2.3 volts in alkaline solutions. With these anodes, there is a considerable decomposition of water and simultaneous formation of chlorate. At the higher potential reached with the smooth anodes, it is probable that OH ions are discharged along with the chlorine ions, and that the formation of chlorate is due to their combination. The quantity of chlorate formed rises and falls with the potential difference at the anode. T. E.

Combination of Lithium Bromide with Gaseous Ammonia. By J. BONNEFOI (*Compt. rend.*, 1900, 130, 1394—1397. Compare Abstr., 1899, ii, 96).—Dry lithium bromide combines with gaseous ammonia to form four solid highly deliquescent compounds, the properties of which are summarised in the following table:

Composition.	Temperature of formation.	Heat of dissolution.	Heat of formation.	Dissociation pressure.	Variation of entropy $\frac{Q}{T}$.
LiBr, NH ₃	Above 95°	+6.857 Cal. at 15°	+13.298 Cal.	730 mm. at 95.5° 806 mm. at 97.5°	0.086
LiBr, 2NH ₃	Between 87° and 95°	+3.018 Cal. at 8°	+25.987 Cal.	665 mm. at 85° 847 mm. at 90°	0.084
LiBr, 3NH ₃	Between 71.5° and 87°	+0.287 Cal. at 10°	+37.463 Cal.	636 mm. at 67° 807 mm. at 71.8°	0.28
LiBr, 4NH ₃	About -18°	-1.548 Cal. at 8°	+45.098 Cal.	681 mm. at 56° 760 mm. at 58.3°	0.32

The heat developed by combination with the four successive molecules of ammonia is +13.293, +12.644, +11.526, and +10.635 Cal., and the relation between these values and the dissociation pressures agrees closely with Clapeyron's formula. The heats of formation given in the above table are the heats of formation from the solid salt and gaseous ammonia. C. H. B.

Lithium Peroxide. By ROBERT DE FORCRAND (*Compt. rend.*, 1900, 130, 1465—1468. Compare this vol., ii, 277, 344, 401, 479).—A *hydrated lithium peroxide*, Li₂O₂·H₂O₂·3H₂O, is precipitated in the form of hard, brilliant, colourless crystals on adding hydrogen peroxide and alcohol to a solution of lithium hydroxide. The heat of solution of this substance is -4.50 Cal., and its decomposition by hydrochloric acid is accompanied by a thermal change of 19.50 Cal.

The *anhydrous peroxide*, Li₂O₂, is obtained by drying the above hydrate for 8 days over phosphoric oxide; its heat of solution is 7.19 Cal., whilst its heat of formation from the monoxide is 3.64 Cal.

In the series lithium, calcium, strontium, and barium, the heat of

peroxidation of the monoxide increases, and the heat of formation of the monoxide decreases, as the atomic weight increases; these quantities vary to the same extent, but in opposite sense, and consequently the heat of formation of the peroxide is almost constant, its approximate value being 151. These properties tend to emphasise the relationship existing between lithium and the alkaline earth metals.

G. T. M.

Physical Properties of Cæsium. By MORITZ ECKARDT and EDMUND GRAEFE (*Zeit. anorg. Chem.*, 1900, 23, 378—382).—The following constants were determined: liquid cæsium has a sp. gr. 1·827 at 40° and 1·836 at 27°; solid cæsium has a sp. gr. 1·886 at 26°. The solidifying point is 26·37°; electrical conductivity, 3·63 at 27° ($\text{Ag} = 100$); specific heat, 0·04817; atomic heat, 6·406; heat of fusion = 3·73 cal. per 1 gram; contraction on solidification, 0·02627 per 1 c.c. or 2·627 per cent. by volume; coefficient of expansion, 0·0003948.

E. C. R.

Anhydrous Calcium Peroxide and the Constitution of its Hydrates. By ROBERT DE FORCAND (*Compt. rend.*, 1900, 130, 1388—1391. Compare this vol., ii, 277, 344, 401, 478).—Anhydrous calcium peroxide dissolves in dilute hydrochloric acid with development of +18·93 Cal., and hence $\text{CaO sol.} + \text{O} = \text{CaO}_2 \text{ sol.}$ develops +5·43 Cal.

The corresponding values for strontium and barium are +10·875 and +12·10 Cal. respectively, and here the stability of the peroxide and the possibility of preparing it by direct oxidation of the monoxide increase with the atomic weight of the metal, adopting Moissan's value for the heat of formation of calcium monoxide,

$\text{Ca sol.} + \text{O}_2 \text{ gas} = \text{CaO}_2 \text{ sol.}$ develops +150·43 Cal.,

which is higher than the corresponding value for strontium (+142·075 Cal.). The heats of formation of the hydrates are

$\text{CaO}_2 \text{ sol.} + 8\text{H}_2\text{O liq.} = \text{CaO}_2 \cdot 8\text{H}_2\text{O sol.}$ develops +15·636 Cal.

$\text{CaO}_2 \text{ sol.} + 8\text{H}_2\text{O sol.} = \text{CaO}_2 \cdot 8\text{H}_2\text{O sol.}$ „ +4·196 Cal.

The conversion of $\text{CaO}_2 \cdot 2\text{H}_2\text{O}$ into $\text{CaO}_2 \cdot 8\text{H}_2\text{O}$, however, develops +17·851 Cal., hence the formation of the first compound absorbs -2·215 Cal. This result can only be explained by assuming that $\text{CaO}_2 \cdot 2\text{H}_2\text{O}$ is not a hydrate of calcium peroxide, but a combination of the hydroxide with hydrogen peroxide, $\text{CaH}_2\text{O}_2 \cdot \text{H}_2\text{O}_2$. The heat of formation of this compound from its proximate constituents is -9·815 Cal., and its conversion into the true octohydrate of the peroxide involves changes of opposite signs, the true heat of hydration being +15·636, which corresponds with that of an unstable hydrate.

C. H. B.

Dehydration of Selenite and Hydration of Anhydrite. By V. ZUNINO (*Gazzetta*, 1900, 30, i, 333—339).—Pure precipitated calcium sulphate loses 18 per cent. of its water at 100°, and becomes completely anhydrous at 188°. When heated at 230° in a brisk current of steam, the anhydrous salt absorbs the whole of its water of crystallisation, whilst at 280° the water taken up—only 0·2 per

cent. of the total—is probably mechanically held by the salt. On heating a mixture of sodium chloride and anhydrous calcium sulphate to a white heat for 2 hours, and then cooling the fused mass slowly, small triclinic crystals of anhydrite are obtained. When calcium chloride is used in place of the sodium salt, the residue left after washing the mass with water showed in places signs of setting, which must be due to the conversion of anhydrite into gypsum by hydration. By prolonged boiling in saturated aqueous sodium chloride, the hydrated sulphate is partially converted into anhydrite crystals which by the continued action of water are transformed into gypsum. T. H. P.

Ammonium Earthy Phosphates. By LEONCE BARTHE (*Bull. Soc. Chim.*, 1900, [iii], 23, 422—425).—According to Kippenberger (*Grundlagen Nachweis Giftstoffen*, 1897, 222), the interaction of barium chloride, disodium hydrogen phosphate, and ammonia results in the formation of ammonium barium phosphate, NH_4BaPO_4 . The author is unable to confirm this statement, the precipitate obtained being found to have the composition BaHPO_4 . Attempts to prepare ammonium strontium phosphate were also unsuccessful, only the phosphates $\text{SrH}(\text{PO}_4)$ or $\text{Sr}_3(\text{PO}_4)_2$ being obtained, according to the experimental conditions; these are also formed by the action of methylamine, ethylamine, aniline, or *p*-toluidine on strontium chloride and disodium hydrogen phosphate. Ammonium magnesium phosphate appears to be the only compound of this class capable of existence.

N. L.

Radioactive Barium and Polonium. By FRITZ GIESEL (*Ber.*, 1900, 33, 1665—1668. Compare von Lengyel, this vol., ii, 402; Curie, this vol., ii, 82).—When concentrated uranium nitrate solution is mixed with a little sulphuric acid, then with a solution of a barium salt, care being taken that sufficient barium salt is not added to cause a precipitate, and finally diluted with water, a strongly radio-active precipitate of barium sulphate is obtained. When this sulphate is converted into a soluble barium salt, and this is then treated with ammonium hydroxide, a small amount of precipitate is obtained which is even more strongly radio-active than the original sulphate; but when the barium is subsequently precipitated as carbonate, it has completely lost its activity. The radio-activity is probably due to small quantities of radium, or more probably of actinium.

Polonium preparations obtained from lead chloride from uranium residues have proved to consist of bismuth hydroxide, which, either in this form or as oxychloride, exhibits strong activity. J. J. S.

Bronzes from Ephesus. By KONRAD NATTERER (*Monatsh.*, 1900, 21, 256—262).—A bronze plate (I) and a bronze statue (II) from Ephesus had the following composition:

I. Tin, 8.67; lead, 12.86; zinc, 0.025; copper, 78.77.

II. Tin, 6.09; lead, 4.87; copper, 89.04.

R. L. J.

Lead and Copper Polysulphides. By F. BODROUX (*Compt. rend.*, 1900, 130, 1397—1398).—When a solution of calcium polysulphide is added to an excess of a dilute solution of lead nitrate cooled at 0° and the precipitate is washed with water, alcohol, and, finally, carbon

disulphide, a purple-red polysulphide, PbS_x , is obtained which decomposes rapidly above 10° into the monosulphide and sulphur.

Cupric acetate under similar conditions yields a brown-red sulphide, Cu_2S_x , which is fairly stable at the ordinary temperature, but gradually decomposes into the monosulphide and sulphur. Both polysulphides are insoluble in alkali sulphides.

O. H. B.

Mercury Chlorosulphide. By F. BODROUX (*Compt. rend.*, 1900, 130, 1398—1399).—When a solution of calcium polysulphide is added to an excess of a cold, saturated solution of mercuric chloride, a chlorosulphide, $\text{Hg}_2\text{S}_x\text{HgCl}_2$, is obtained as a yellow solid, very stable at the ordinary temperature, but altering superficially when exposed to light. It is insoluble in alkali sulphides, but is blackened and decomposed by alkali hydroxides. When heated, it yields sublimates of sulphur and mercuric chloride; it is completely decomposed by concentrated sodium hypobromite solution, but is not affected by fuming nitric acid at the ordinary temperature.

C. H. B.

Action of Water on Mercurous Sulphate. By A. GOUV (*Compt. rend.*, 1900, 130, 1399—1402).—Mercurous sulphate is decomposed by water with formation of a yellow basic sulphate, $\text{Hg}_2\text{O}, \text{Hg}_2\text{SO}_4 + \text{H}_2\text{O}$, which resembles basic mercuric sulphate, but has a marked greenish tinge. Equilibrium is established when the water contains 0.410 gram of mercury and 0.164 gram of sulphuric acid per litre. Water which contains 0.08 gram of sulphuric acid per litre does not convert the normal into the basic salt, and a higher proportion of acid converts the basic salt into the normal. When treated with dilute sulphuric acid, the yellow basic salt becomes white and is thus readily distinguished from basic mercuric sulphate.

Saturated solutions of zinc or cadmium sulphate decompose mercurous sulphate much less readily than water does, but they dissolve more of the unchanged salt.

C. H. B.

Unknown Earths contained in Crude Samarium Oxide. By EUGÈNE DEMARÇAY (*Compt. rend.*, 1469—1472. Compare Abstr., 1896, ii, 475).—The author has previously designated by the symbol Σ an unknown element contained in crude samarium oxide and having an atomic weight intermediate between that of samarium and gadolinium. On fractionating the crude samarium oxide by the aid of the double magnesium nitrate method (this vol., ii, 347), a product is obtained containing the unknown element in a highly concentrated form. Certain lines in the spectrum of the element become greatly enhanced as a result of this fractionation, and amongst these are three blue rays considered by Lecoq de Boisbaudran to be characteristic of the hypothetical element Z_e (Abstr., 1893, ii, 323). It therefore seems highly probable that the two elements Σ and Z_e are identical, and the symbol $\Sigma-Z_e$ is proposed for this constituent of crude samarium oxide. The oxide and salts containing the highest percentage of the new element have a pale rose colour and exhibit characteristic absorption, spark, and reversal spectra; the atomic weight obtained by the synthesis of the sulphate is approximately 151.

The paper contains a detailed description of the spectra which is not suitable for abstraction. G. T. M.

Some Properties of Aluminium : Preparation of Hydrogen Phosphide. By CAMILLE MATIGNON (*Compt. rend.*, 1900, 130, 1391—1394).—Aluminium powder freed from grease burns completely in air if strongly heated at one point, the oxide formed being mixed with a small quantity of nitride. If the powdered metal which has begun to burn in air is lowered into a vessel filled with steam, it continues to burn brilliantly, and the liberated hydrogen burns at the mouth of the vessel. Similarly, aluminium powder will burn in carbon monoxide, carbon dioxide, nitric and nitrous oxides, and nitric peroxide, sulphur dioxide, carbon disulphide, the halogens and halogen hydracids, and the vapours of arsenic, antimony, phosphorus, and sulphur chlorides, and also in the vapour of formic acid in the same manner as in steam. With phosphorus, arsenic, antimony, sulphur, and selenium, results were obtained identical with those described by Fonzen-Diacon (this vol., ii, 405).

The phosphide obtained by the action of red phosphorus on the aluminium powder can be used for the preparation of pure hydrogen phosphide, by placing it together with water in a hydrogen apparatus and adding a very small quantity of dilute sulphuric acid. If hydrochloric acid is used, some hydrogen may be liberated. C. H. B.

Composition of Bottle Glasses. By CHR. DRALLE (*Chem. Zeit.*, 1900, 24, 323—328. Compare Zulkowski, *Chem. Ind.*, 1899, 22, 280; 1900, 23, 108).—A number of analyses of modern glasses have been made in order to see whether Zulkowski's conclusions hold good, as these were based on old analyses. The author does not agree with Zulkowski that the whole of the iron and manganese oxides necessarily act as acids; in some cases, as the result of reduction processes, they act as bases. According to Zulkowski, the "saturation coefficient" (that is, equivalents of base/equivalents of acid) of a good non-soluble glass should be 0.333. According to the author, the coefficient may lie between 0.333 and 0.5.

Again, according to Zulkowski, only one alkaline earth may be present in a good glass, but the author finds that the presence of magnesium in addition to calcium does not lower the quality of the glass. J. J. S.

[Preparation of] Permanganic Acid by Electrolysis. By HARMON N. MORSE and J. C. OLSEN (*Amer. Chem. J.*, 1900, 23, 431—443).—A method of preparation of a solution of pure permanganic acid by the electrolysis of its potassium salt is described in detail. Determinations of the conductivity of permanganic acid produced by the electrolysis of the silver salt gave results agreeing closely with those obtained by Lovén (*Abstr.*, 1895, ii, 451), but differing from those of Franke (*Abstr.*, 1895, ii, 252). E. G.

Crystalline Form of the Nickel Sulphate Compound of Hydroxylamine. By RUDOLF UHLENHUTH (*Annalen*, 1900, 311, 127—128).—The compound $\text{NiSO}_4 \cdot 6\text{NH}_2 \cdot \text{OH}$, first described by the

author (Abstr., 1899, ii, 661), belongs to the triclinic system; measurements and a figure are given in the paper. M. O. F.

Silicovanadiomolybdates. I. By CARL FRIEDHEIM and C. CASTENDYCK (*Ber.*, 1900, 33, 1611—1629).—On mixing ammonium vanadate and ammonium silicomolybdate into a paste with water, interaction occurs, and a clear red solution is obtained, the intensity of the colour being greatest when the molecular ratio $(\text{NH}_4)_2\text{O}$, V_2O_5 : $2(\text{NH}_4)_2\text{O}$, SiO_2 , 12MoO_3 , $8\text{H}_2\text{O}$ is 2:1; from a solution prepared in this way, an *ammonium silicovanadiomolybdate*, $3(\text{NH}_4)_2\text{O}$, SiO_2 , V_2O_5 , 11MoO_3 , $27\text{H}_2\text{O}$, separates in lustrous, red, well-formed crystals, often 2 cm. in length. These crystals are easily soluble in water, and during their formation become contaminated by sparingly soluble ammonium vanadiomolybdates of varying composition, the latter being separated mechanically. The composition of these ammonium vanadiomolybdates, according to the order of their separation, is as follows: (1) $2(\text{NH}_4)_2\text{O}$, $2\text{V}_2\text{O}_5$, 5MoO_3 , $8\text{H}_2\text{O}$, yellow; (2) $(\text{NH}_4)_2\text{O}$, V_2O_5 , 2MoO_3 , $4\text{H}_2\text{O}$, yellowish-green; (3) $2(\text{NH}_4)_2\text{O}$, $3\text{V}_2\text{O}_5$, 4MoO_3 , $11\text{H}_2\text{O}$, bright brown; (4) $(\text{NH}_4)_2\text{O}$, $2\text{V}_2\text{O}_5$, 2MoO_3 , $8\text{H}_2\text{O}$, reddish-brown; (5) $4(\text{NH}_4)_2\text{O}$, $12\text{V}_2\text{O}_5$, 5MoO_3 , $24\text{H}_2\text{O}$, brownish-red. The first three of these are microcrystalline, whilst the two last form felted needles.

On recrystallising the foregoing ammonium silicovanadiomolybdate from water, either hot or cold, decomposition occurs, and a series of new compounds, (1) $3(\text{NH}_4)_2\text{O}$, SiO_2 , V_2O_5 , 9MoO_3 , $20\text{H}_2\text{O}$; (2) $3(\text{NH}_4)_2\text{O}$, SiO_2 , V_2O_5 , 10MoO_3 , $21\text{H}_2\text{O}$; (3) $3(\text{NH}_4)_2\text{O}$, SiO_2 , V_2O_5 , 15MoO_3 , $24\text{H}_2\text{O}$, is obtained; these differ little from the parent substance and from one another in colour and crystalline form, but are differentiated by the behaviour of their saturated solutions with silver, lead, and mercurous nitrates. The following table gives their principal physical properties:

Ammonium silicovanadiomolybdate, $(\text{NH}_4)_2\text{O}:\text{SiO}_2:\text{V}_2\text{O}_5:\text{MoO}_3$	Sp. gr. of solid at 18°.	Sp. gr. of saturated sol. at 18°.	Solubility in grams per c.c.
3:1:1: 9+20H ₂ O	2·8020	1·21322	0·32016
3:1:1: 10+21H ₂ O	2·8044	1·25275	0·35026
3:1:1: 11+27H ₂ O	2·8074	1·29266	0·38086
3:1:1: 15+24H ₂ O	2·8162	1·43761	0·48997

It is noteworthy that the addition of each mol. of molybdenum trioxide causes a regular increase of approximately 0·00237 unit in the sp. gr. of the solid salt; 0·037 unit for the sp. gr. of the saturated solution, and 0·030 unit for the solubility. The salts containing 9MoO_3 and 15MoO_3 can be recrystallised unchanged from water, but that containing 10MoO_3 yields a mixture of the other three salts.

On adding potassium chloride to cold saturated solutions of these ammonium salts, crystalline compounds are precipitated which owe their origin to the replacement of $2\text{K}_2\text{O}$ for $2(\text{NH}_4)_2\text{O}$ in the parent substances; the following table gives their physical properties:

Composition.	Sp. gr. of solid.	Sp. gr. of sat. sol. at 18°.	Solubility in grams per c.c.
$(\text{NH}_4)_2\text{O}, 2\text{K}_2\text{O}, \text{SiO}_2, \text{V}_2\text{O}_5, \left. \begin{array}{l} 9\text{MoO}_3, 20\text{H}_2\text{O} \end{array} \right\}$	2.8648	1.17031	0.24021
$(\text{NH}_4)_2\text{O}, 2\text{K}_2\text{O}, \text{SiO}_2, \text{V}_2\text{O}_5, \left. \begin{array}{l} 10\text{MoO}_3, 21\text{H}_2\text{O} \end{array} \right\}$	2.8682	1.19184	0.25914
$(\text{NH}_4)_2\text{O}, 2\text{K}_2\text{O}, \text{SiO}_2, \text{V}_2\text{O}_5, \left. \begin{array}{l} 11\text{MoO}_3, 12\text{H}_2\text{O} \end{array} \right\}$	2.8704	1.21378	0.27914
$(\text{NH}_4)_2\text{O}, 2\text{K}_2\text{O}, \text{SiO}_2, \text{V}_2\text{O}_5, \left. \begin{array}{l} 15\text{MoO}_3, 14\text{H}_2\text{O} \end{array} \right\}$	2.8803	—	—

Similar laws to those obtaining in the case of the original ammonium compounds regulate the change of sp. gr. and solubility of these salts; moreover, the replacement of 4K for 4NH₄ in the original salts increases the sp. gr. in each case by a constant amount equal to 0.0634 unit. On the other hand, the difference between the sp. gr. of saturated solutions of the corresponding ammonium and potassium salts increases by approximately 0.02 unit for each addition of 1MoO₃, whilst a similar increase of 0.01 unit is observed in the solubility. W. A. D.

Preparation of some Uranium Oxides. By JULES ALOY (*Bull. Soc. Chim.*, 1900, [iii], 23, 368—370).—Uranium oxide, UO₂, is obtained in the form of microscopic, black crystals by heating crystallised uranic hydroxide in a current of hydrogen. When thus prepared, it is not pyrophoric, and is only slowly converted into the green oxide by heating to redness. The violet hydrate of uranosouranic oxide, U₃O₈, which Ebelmen prepared by exposing to sunlight a solution of uranium oxalate, is more readily obtained, in a similar manner, from an alcoholic solution of the acetate, or from a mixture of the aqueous solution of the acetate with ether; it could not be obtained crystalline. The violet hydrate is readily oxidised to uranic hydroxide by exposure to air, and when boiled with water it yields orthorhombic crystals of the composition UO₃·H₂O, which are stable in dry air at 100°. A crystallographic study of these crystals has been made by Bertrand. N. L.

Compounds of Uranic Acid with Sulphurous Acid. By VOLKMAR KOHLSCHÜTTER (*Annalen*, 1900, 311, 1—25).—The simplest compound of uranium trioxide with sulphur dioxide was first obtained by Girard (*Compt. rend.*, 1852, 34, 22) from the action of aqueous sulphurous acid on uranic acid, and is also produced when sulphur dioxide is passed into solutions of uranyl acetate and uranyl nitrate. It is a pale green, crystalline substance, forming minute, slender needles which exhibit double refraction. The composition is expressed by the formula UO₃·SO₂·4H₂O, and when exposed to a temperature of 105° during an hour, the substance loses 3½H₂O.

The compounds, 2UO₃·3SO₂·R₂O, prepared by dissolving the foregoing substance in much sulphurous acid, and adding an alkali hydrogen sulphite to the solution heated on the water-bath, are identical with compounds obtained by Scheller (*Annalen*, 1867, 144, 238), who ascribed to them the erroneous formula UO₂·OR·SO₂H; the potassium, ammonium, and sodium derivatives of this substance are described.

When uranyl sulphite, $\text{UO}_3 \cdot \text{SO}_3 \cdot 4\text{H}_2\text{O}$, is heated on the water-bath with aqueous sulphurous acid in amount insufficient to dissolve it, large, golden-yellow prisms separate; this compound has the empirical formula, $\text{UO}_3 \cdot \text{SO}_3 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, and loses $2\frac{1}{2}\text{H}_2\text{O}$ when heated at 105° .

The compounds, $4\text{UO}_3 \cdot 5\text{SO}_3 \cdot \text{R}_2\text{O} + x\text{H}_2\text{O}$, is prepared by adding an alkali hydrogen sulphite to uranyl nitrate, filtering the amorphous precipitate, and heating it on the water-bath with aqueous sulphurous acid in quantity insufficient for dissolution; the *potassium*, *ammonium*, and *sodium* derivatives of this substance are described.

The compounds, $3\text{UO}_3 \cdot 2\text{SO}_3 \cdot \text{R}_2\text{O}$, produced by the action of water on the foregoing substances, are orange-yellow, crystalline salts; the *potassium*, *ammonium*, and *sodium* derivatives have been prepared.

The compounds, $\text{UO}_3 \cdot 2\text{SO}_3 \cdot \text{R}_2\text{O}$, obtained by passing sulphur dioxide through uranyl nitrate to which excess of alkali hydroxide has been added, separate from the clear, dark yellow liquid in crystalline crusts; the *ammonium* and *potassium* derivatives have been prepared.

Constitutional formulæ for these compounds are suggested by the author.

M. O. F.

Mode of Decomposition of Certain Metallic Perchlorides.

By WILLIAM OESCHNER DE CONINCK (*Compt. rend.*, 1900, 130, 1551—1552).—Auric, platinic, and ferric chlorides are decomposed when their aqueous solutions are filtered through animal charcoal, the metals being completely retained by the filter whilst the acid radicle remains in the filtrate. Similar results were obtained with saw-dust, brick-dust, and coarse or fine grained coke-dust; fine sand, on the other hand, has no action on the perchlorides. This mode of decomposition does not obtain with ferrous chloride, and its nickel, cobalt, manganese, zinc, copper, and magnesium analogues; stannous chloride in dilute hydrochloric acid undergoes oxidation and the oxychloride produced is completely absorbed by the animal charcoal. G. T. M.

Platinum Compounds of Hydroxylamine. By RUDOLF UHLENHUTH (*Annalen*, 1900, 311, 120—126).—The *platinum base*, $\text{Pt}(\text{NH}_2 \cdot \text{OH})_4(\text{OH})_2$, prepared by treating hydroxylamine (12 mols.) with hydroplatinichloric acid (1 mol.) in dilute aqueous solution, boiling the liquid till colourless, and allowing it to cool slowly, separates in slender, snow-white needles, insoluble in water, alcohol, or ether, but readily soluble in dilute mineral acids, acetic acid, or formic acid. Cold dilute nitric acid dissolves it, and when heated, decomposes it completely. When heated at 173° , the dry base explodes and becomes ignited. The *sulphate*, $\text{Pt}(\text{NH}_2 \cdot \text{OH})_4\text{SO}_4$, forms large, triclinic crystals containing $1\text{H}_2\text{O}$. The *hydrochloride*, $\text{Pt}(\text{NH}_2 \cdot \text{OH})_4\text{Cl}_2$, crystallises in flat needles; the action of dilute hydrochloric acid on the base also gives rise to the yellow *salt*, $\text{Pt}(\text{NH}_2 \cdot \text{OH})_2\text{Cl}$, which forms long, golden-yellow needles, and the blue *salt*, $\text{Pt}(\text{NH}_2 \cdot \text{OH})_2\text{Cl}_2$, which crystallises in blue needles. The *nitrate* forms lustrous, colourless needles.

Mineralogical Chemistry.

Roumanian Petroleums. By LAZAR EDELEANU and G. A. FILITI (*Bull. Soc. Chim.*, 1900, [iii], 23, 382—403).—The first part of this preliminary paper deals with the chemical composition of Roumanian petroleums. These consist principally of carbon and hydrogen, but small quantities of oxygen are often found, especially in the denser varieties from Matita and Sarata, owing to the presence of compounds of an acid character which are extracted from the oil by alkalis. In some specimens, traces of nitrogen and sulphur are found, the latter possibly in the form of compounds analogous to thiophen. A sample of petroleum from Berka (Buzen), having a sp. gr. 0.824 at 15°, was specially examined with the object of ascertaining the nature and amount of benzene hydrocarbons contained therein. From the results obtained by fractionally distilling the oil, treating the separate fractions with nitric acid, and isolating the nitro-derivatives thus produced, the presence of considerable quantities of benzene, toluene, *m*-xylene, mesitylene, and probably higher homologues, was proved. Nearly all the Roumanian petroleums examined were found to contain hydrocarbons of the benzene series, some only in very minute quantities, as with the oils from Casin and Recea, and others in much larger proportions, as was the case with oils from Campeni-Parjol, Colibasi, &c.

In the second part of the paper the physical and technical properties are dealt with, and the results obtained from 36 specimens of petroleum from the provinces of Dambovita, Buzeu, Prahova, and Bacau, are recorded in five tables. The colour of the oils varied from clear yellow to opaque brown or black, and all exhibited a greenish fluorescence. The sp. gr. at 15° ranged from 0.7833 to 0.9050, the boiling point from 25° to 62°, and the viscosity at 20° (water at 20° = 1) from 1.04 to 4.88, but usually lay between 2.00 and 2.80. The odour was in most cases feebly ethereal and agreeable, but some specimens had a strong alliaceous odour and others an odour of hydrogen sulphide. The flash point, as determined with the Abel-Pensky apparatus, was almost always below 0°. The behaviour of the oils on distillation was carefully studied and the characters of the various products examined. The best light oils are yielded by petroleums from Campeni-Parjol, Casin, Poiana, Plopeni, and Predeal Berka, whilst the Gura-Ocniti, Tintea, and Sarata petroleums are richest in heavy, high boiling oils.

N. L.

Minerals from the Bogoslowsk District, Urals. By EUGRAPH S. VON FEDOROFF and W. W. NIKITIN (*Ann. Geol. Min. Russie*, 1899, 3, 79—91, 91—103).—A description is given of several mineral species from the Bogoslowsk mining district, where ores of copper and iron are won. Analyses are given of the following.

Quartzine in the form of microscopic spherulites, with a little bright green chloritic mineral in the interspaces, occurs as blocks embedded in diabase on the river Kakwa. Analysis gave:

SiO ₂	Al ₂ O ₃ , FeO ₃	CaO.	MgO.	H ₂ O.
90.83	5.25	0.33	0.29	2.1

Garnet from augite-garnet rocks gave I for the resin-brown, and II for the pale greenish crystals.

	SiO ₂	Fe ₂ O ₃	Al ₂ O ₃	Mn ₂ O ₃	FeO.	CaO.
I.	34.98	23.77	3.32	1.22	3.33	34.06
II.	38.22	25.62	2.11	0.58	1.96	31.80

Datolite occurring as a crust on the walls of a diabase dyke gave, on analysis by Januskewitsch :

SiO ₂	Al ₂ O ₃ , Fe ₂ O ₃	CaO.	MgO.	H ₂ O, CO ₂	B ₂ O ₃
36.77	0.31	33.78	1.5	8.4	[19.24]

Muschetowite is the name given to a pseudomorph of magnetite after hæmatite; it has the platy structure of hæmatite, but a black streak, and is strongly magnetic with polarity. The analysis (Fe₂O₃, 75.35; FeO, 19.88; H₂O, 0.31; insol., 4.4) shows that the change from hæmatite to magnetite has not been quite complete.

Marsjatskite is the name given to a manganglauconite which forms the bulk of a Tertiary sandstone in the Marsjat forest; the microscopic grains are amorphous, and have a very pale green tint. A partial analysis of the rock, which also contains grains of quartz and other minerals, gave: SiO₂, 20.94; Fe₂O₃, 8.78; Mn, 25.66 per cent. On exposure to air, the material is easily altered, giving rise to workable deposits of manganese ores containing 35—40 (max. 50) per cent. of manganese.

L. J. S.

Jadeite from Piedmont. By GIUSEPPE PIOLTI (*Jahrb. Min.*, 1900, i, Ref. 341; from *Atti Accad. Sci. Torino*, 1899, 34, 600—608. Compare Abstr., 1898, ii, 525).—A green pebble found in a moraine at the entrance of the Susa Valley, near Rivoli, has the characters of jadeite. Sp. gr. 3.407. The results of the analysis differ considerably from those required by the jadeite formula, NaAl(SiO₃)₂, but agree with those of an analysis by Damour of Asiatic jadeite :

SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	Cr ₂ O ₃	CaO.	MgO.	Na ₂ O.	Loss on ignition.	Total.
55.11	9.66	7.55	trace	12.04	7.33	7.84	0.33	99.86

Only one pebble was found, and the original locality of the material is not known. This occurrence is discussed in connection with the neolithic jade implements of Central Europe.

L. J. S.

Minerals from the Radauthal, Harz. By JOHANNES FROMME (*Jahresber. Ver. Naturwiss. Braunschweig*, 1900, 12, 31—42).—Descriptions are given of several minerals from the gabbro and the pegmatite of the Radauthal near Harzburg in the Harz.

Cavities between the gabbro and pegmatite are filled with calcite and a chloritic mineral; the latter, which is referred to chalcodite, occurs as scaly to granular masses of a greyish-green colour; sp. gr. 2.44. It is easily decomposed by hydrochloric or sulphuric acid, with separation of flocculent silica. The following is the mean of two analyses made on material separated from calcite by the action of acetic acid. Direct determinations of the iron on unprepared material gave Fe₂O₃, 4.82; and FeO, 28.20 per cent.

SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	FeO	MnO	CaO	MgO	H ₂ O	K ₂ O, Na ₂ O	Total
47.15	4.49	9.00	24.60	1.49	0.50	3.71	8.70	traces	99.64

L. J. S.

Weathering of Diabase in Virginia. By THOMAS L. WATSON (*Amer. Geologist*, 1899, 24, 355—369. Compare Abstr., 1898, ii, 612).—Analyses are given of the fresh and altered rock from a dyke adjacent to the one previously described, and similar results are obtained.

L. J. S.

Meteorite from Ergheo, Somaliland. By ETTORE ARTINI and GILBERTO MELZI (*Jahrb. Min.*, 1900, i, Ref. 357—360; *Soc. d'Esplorazione Commerciale in Africa*, Milan, 1898, 12 pp., and *Rend. R. Ist. Lombardo*, 1898, [ii], 31, 983—994).—This stone fell in July, 1889, at Ergheo, near Brava, in the Somali peninsula; it weighs 20,375 grams, but was originally somewhat larger. Sp. gr. 3.31. Chondrules of olivine or of enstatite or of both are set in a crystalline ground mass of olivine and enstatite; troilite, metallic nickel-iron, magnetite, glass, maskelynite, and possibly feldspar are also present. Analysis by G. Boeris gave the following results:

Metallic Fe.	Ni + Co.	FeS.	Sol. in HCl.	Insol. in HCl.	Total.
0.57	0.17	9.48	56.50	32.73	99.45

	SiO ₂	FeO.	Al ₂ O ₃	CaO.	MgO.	Na ₂ O, K ₂ O.	Total.
Sol. in HCl	23.69	12.95	0.56	0.71	18.59	—	56.50
Insol. in HCl	57.62	12.79	5.11	1.13	23.06	0.41	100.12

L. J. S.

Meteoric Iron from Morradal, Norway. By EMIL W. COHEN (*Jahrb. Min.*, 1900, i, Ref. 354; *Videnskabs-Selskabets Skrifter, Christiania*, 1898, Class I, No. 7, 12 pp.).—This iron was found at Morradal near Grjotli, between Skiaker and Stryn; it weighs 2750 grams. It belongs, with the irons from Smithland and Babb's Mill, to the group of ataxites rich in nickel. Analysis by O. Sjöström gave:

Fe.	Ni.	Co.	Cu.	Cr.	P.	S.	Sp. gr.
79.67	18.77	1.18	0.06	0.06	0.18	0.27	7.8543

This corresponds with the following mineralogical composition: nickel-iron, 98.12; schreibersite, 1.17; troilite, 0.55; daubréelite, 0.16.

L. J. S.

Mineral Water from the Cold or "Park" Spring at Evaulles-Bains (Creuse). By EDMOND BONJEAN (*Bull. Soc. Chim.*, 1900, [iii], 23, 405—407).—This is a saline, alkaline water containing 1.492 grams of solid matter per litre and having a temperature of 8°; minute quantities of lithium, manganese, arsenic, and fluorine were detected.

N. L.

Mineral Water from the Brault No. 3 Spring at Sail-sous-Couzan (Loire). By EDMOND BONJEAN (*Bull. Soc. Chim.*, 1900, [iii], 23, 408—409).—The water contains 2.1305 grams per litre of solid

matter, consisting chiefly of sodium, potassium, calcium, and magnesium carbonates; it is remarkable for the large quantity of free carbon dioxide it contains, namely, 1438 c.c. per litre. N. L.

Waters of Salsomaggiore. By RAFFAELE NASINI and FRANCESCO ANDELLINI (*Gazzetta*, 1900, 30, i, 305—333).—The mineral constituents of these waters consist mainly of sodium and calcium chlorides, small quantities of a large number of other salts being also present. They are very rich in bromine and iodine, and contain a larger proportion of strontium and lithium than any other known natural water; the quantities of these constituents in grams per litre of the water from the spring "delle Saline" are: Br, 0.26411; I, 0.06050; Sr, 0.42780; Li, 0.12152. The dissolved gases, present to the extent of 20.64 c.c. per litre, consist principally of methane, ethane, and carbon dioxide, with smaller quantities of heavy hydrocarbons, nitrogen and oxygen (compare this vol., ii, 415). T. H. P.

Physiological Chemistry.

Action of Morphine on Respiration. By HUGO WINTERNITZ (*Pflüger's Archiv*, 1900, 80, 344—350. Compare this vol., ii, 221).—Polemical. The work of, and conclusions drawn by, Impens (this vol., ii, 28) are criticised. W. D. H.

Rôle of Purine Substances in Human Metabolism. By RICHARD BURIAN and HEINRICH SCHUR (*Pflüger's Archiv*, 1900, 80, 241—343).—Every healthy adult excretes a certain characteristic amount of alloxuric or purine substances, which is independent of his diet. This is the result of tissue metabolism, and may be termed 'endogenous urinary purine.' Its amount may be directly estimated by examining the urine after a diet of substances which are practically free from purine compounds (milk, white bread, potatoes, rice, green vegetables, eggs, and cheese). Examination of the urine during hunger does not give trustworthy results; but on ordinary diet, the amount of urinary purine is increased by a part of the 'nutrition purine,' and this may be termed 'exogenous urinary purine.' The nutrition purine does not pass wholly into the urine; a certain fraction remains in the organism, the purine double ring being broken down. The amount of the remainder (exogenous urinary purine) differs for different forms of food, and is but little affected by the individuality of the subject of the experiment. The following table gives some of the figures quoted:

Diet.	Total percentage of purine substances in diet.	Percentage of exogenous urinary purine.
Beef and veal	0.06	0.03
Coffee	0.2	0.075
Calf's liver	0.12	0.06
Calf's spleen.....	0.16	0.08
Calf's thymus	0.4	0.1

By subtracting the exogenous from the total urinary purine, the endogenous urinary purine is obtained, and the results agree closely with the numbers obtained by direct estimation; it varies in the majority of people from 0.1 to 0.2 gram daily; but higher and lower values were obtained.

W. D. H.

Use of Horse-flesh as Food. By EDUARD PFLÜGER (*Pflüger's Archiv*, 1900, 80, 111—138).—Horse-flesh by itself causes digestive disturbances, especially diarrhoea. This is partly, but not wholly, explained by the poorness of the tissue in fat. There is, however, besides, some toxic material in the flesh, which is removed by extraction with hot water or alcohol; it is not soluble in ether. It was not further identified. Horse-flesh, before it is eaten, should, therefore, be extracted with hot water, and mixed with either mutton or beef fat; these solid fats are better than that of the pig. The modern view of fat absorption, namely, that hydrolytic decomposition of the fat is necessary, is supported.

W. D. H.

NOTE BY ABTRACTOR.—Pflüger's experiments were made on dogs, but recent experiences during the siege of Kimberley have led to the same result. The necessity of mixing the horse-flesh with beef suet was well known to the medical men in South Africa.—W. D. H.

Sugar as Food. By FRIEDRICH STROHMER (*Bied. Centr.*, 1900, 29, 172—174; from *Oest.-Ung. Zeit. Zuckerind. Landw.*, 1899, Heft 3).—The importance of sugar as food is indicated by the fact that in human milk lactose is the most prominent constituent, and the results of Soxhlet and Biedert's experiments showed that sucrose is at any rate not inferior to lactose.

According to Schumburg, even small amounts of sugar (30 grams) will renew the power of muscles, tired by work, in half or three-quarters of an hour. Sugar is accordingly specially suited for the production of muscular force, this property being increased by the action of sugar on the nervous system in overcoming the feelings of fatigue.

Excessive consumption of sugar is to be avoided, as digestion would be interfered with; no injury to the teeth will result, as is frequently supposed. When properly employed, sugar is of great value as food, especially after bodily exertion.

N. H. J. M.

Mineral Statics of the Human Foetus during the last Five Months of Intrauterine Life. By LOUIS HUGOUNEQ (*Compt. rend.*, 1900, 130, 1422—1424).—Sodium chloride is assimilated by the human foetus chiefly at the beginning and during the middle period of gestation, but the assimilation of this compound falls off markedly towards the end of the period. During the second half of gestation, the assimilation of phosphoric acid is very regular, but increases somewhat towards the end, whilst the assimilation of calcium increases very markedly towards the end and becomes relatively greater than that of phosphoric acid, the excess being found in the ash in the form of calcium carbonate. With these exceptions, the assimilation of inorganic constituents is almost constant during the last five months, although there is a marked increase in the total weight towards the

end. The cellule of the embryo at four months has practically the same requirements, as regards inorganic food, as the cellule at the end of gestation. The maximum rates of assimilation of sodium chloride on the one hand, and of phosphoric acid and calcium on the other, correspond respectively with the genesis of the red corpuscles and of the osseous system.

C. H. B.

Rôle of Iron in Blood Formation. By A. HOFMANN (*Virchow's Archiv*, 1900, 160, 235—306).—Iron in various forms of organic and inorganic combination is absorbed in the duodenum, and is carried in union with proteid in the 'transport' cells of the blood to the spleen, liver, and especially to the bone marrow. The principal use of the metal is to act as a stimulus to the red marrow. It causes an increase in the growth and activity of this tissue, and so leads to an increased formation of the blood discs. In chlorosis, the bone marrow becomes comparatively inactive.

W. D. H.

Action of Oxygen on the Excised Mammalian Heart. By GÜNTHER STRECKER (*Pflüger's Archiv*, 1900, 80, 161—175).—A new apparatus is described and figured for artificially feeding an excised mammalian heart. The most important result of the experiments recorded is the importance of oxygen in the nutritive fluid. Blood containing carboxyhæmoglobin soon brings the heart to a standstill, not because carbon monoxide is a poison to the organ, for it still remains excitable, but because it contains no free or readily dissociable oxygen. Fresh arterial blood will set such a heart beating again. This need of oxygen for cardiac activity has been previously insisted on by Yeo (*J. Physiol.*, 1885, 6, 535), and more recently in connection with the mammalian heart by Porter (*Amer. J. Physiol.*, 1898, 1, 511).

W. D. H.

Value of Calcium and Potassium Ions in Cardiac Activity. By JACQUES LOEB (*Pflüger's Archiv*, 1900, 80, 229—232).—The conclusion is drawn that calcium and potassium ions are unnecessary for the maintenance of cardiac and other rhythmical actions, but their usefulness is indirect in neutralising the poisonous action of the sodium chloride which is present in the blood and in sea water.

W. D. H.

Elementary Composition and Heat of Combustion of Human Fat. By FRANCIS GANO BENEDICT and EMIL OSTERBERG (*Amer. J. Physiol.*, 1900, 4, 69—76).—The composition of human fat appears to be remarkably constant; the average of twenty-four determinations gives hydrogen, 11.78, and carbon, 76.08 per cent. The heat of combustion averages 9.523 cal. per gram.

W. D. H.

Preparation of Pure Glycogen. By ERNST BENDIX and JULIUS WOHLGEMUTH (*Pflüger's Archiv*, 1900, 80, 238—240).—Glycogen prepared by Pflüger's modification of Külz's method gives the phloroglucinol and orcinol reactions for pentoses. This is due to an admixture with a pentose or pentosan, for after repeated solution in hot water and precipitation by alcohol, the reaction is lost. After treatment of the impure glycogen with hydrochloric acid, and removal

of the greater part of the sugar so formed by fermentation with yeast, the product yields two osazones, one of which is hexosazone, from the remains of the sugar not decomposed by the yeast; the other, which melts at 153–155°, has all the characters of pentosazone. The source of the pentose is believed to be the nucleo-proteid of the liver; indeed, the glycogen is usually contaminated with nuclein.

W. D. H.

Physiology of the Suprarenal Capsules. By BENJAMIN MOORE and C. O. PURINTON (*Amer. J. Physiol.*, 1900, 4, 51–56, 57–59).—The cause of the death which often supervenes within 24 hours after extirpation of the suprarenals is obscure. In cats, cardiac thrombosis is, however, frequently found. A predisposing condition for the ready occurrence of intravascular clotting is to be found in the enfeeblement of the circulation.

The large relative size of these organs in foetal animals is not found in all animals, as, for example, in the cat. In the human embryo and new-born child, the glands are comparatively large, but their medulla contains neither chromogen nor active physiological principle. In the embryonic ox and goat, both appear to be present.

W. D. H.

Alimentary Oxaluria. By GALILEO PIERALLINI (*Virchow's Archiv*, 1900, 160, 173–185).—The soluble and insoluble salts of oxalic acid, the latter in smaller degree, are absorbed, and pass as calcium oxalate into the urine. Foods containing excess of oxalates cause the excretion to increase. The absorption of such insoluble oxalates as that of calcium can hardly be explained as the result of the action of the dilute acid of the gastric juice, but is attributed to decomposition, brought about by the presence of alkali carbonates in the intestine.

W. D. H.

Action of certain Renal Poisons. By W. LINDEMANN (*Ann. Inst. Pasteur*, 1900, 14, 49–59).—This records the commencement of a research on poisons which affect the kidneys, and aims at the elucidation of the manner in which the toxins in serum, and in such diseases as scarlet fever, bring about renal disorder. The special poison here investigated is vinylamine, and the experiments were performed on mice, rabbits, and dogs, some of which were rapidly killed with fatal doses, and others subjected to chronic poisoning. In immediately fatal cases, the main effects in the kidney are explicable by anæmia. In the more chronic cases, the urine is dilute, highly albuminous, and contains casts and epithelial *débris*; the kidneys show signs of acute nephritis. The interstitial connective tissue is not affected. Certain toxic serums produce somewhat similar results.

W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

Fermentation of Cellulose. By V. OMELIANSKY (*Chem. Centr.*, 1900, i, 918—919; from *Arch. Sci. biolog. St. Pétersb.*, 7, 411—434. Compare Abstr., 1898, i, 291).—The morphological properties of *Bacillus fermentationis cellulose* are described in the original paper. Cellulose is attacked by this organism in solutions which contain only mineral salts, the fermentation being effected through a series of changes, by which the specific ferment is gradually purified, and eventually left as a pure culture. The cellulose yields 70 per cent. of fatty acids, acetic acid, and butyric acid, and 30 of gases (carbon dioxide and hydrogen); methane is only formed in the last phases, and is possibly due to the action of another microbe. Hoppe-Seyler's fermentation of cellulose in which carbon dioxide and marsh gas are formed, but no solid or liquid products, is probably effected by a bacillus which has not yet been isolated; this bacillus is probably not the amylobacterium.

E. W. W.

Identity of the Aërogenic Bacillus of Milk with the Pneumobacillus of Friedländer. By LEON GRIMBERT and G. LEGROS (*Compt. rend.*, 1900, 130, 1424—1425).—The aërogenic bacillus of milk and the pneumo-bacillus of Friedländer agree in the following characteristics, and seem to be completely identical; they are immobile, do not liquefy gelatin, and do not produce indole in culture fluids containing peptone, but ferment various carbohydrates, yielding products which vary with the nature of the sugar; and they produce capsules in the blood of animals inoculated with them.

C. H. B.

Action of the Bacillus Anthracis on Carbohydrates. By MDLLE. NAPIAS (*Ann. Inst. Pasteur*, 1900, 14, 232—248).—The anthrax bacillus attacks starchy and saccharine materials, yielding lactic and acetic acids. The latter acid is believed to be formed from the former. In virulent species, proteolytic properties are dominant, and in attenuated specimens amylolytic action is predominant.

W. D. H.

Proteolysis produced by Aspergillus Niger. By G. MALFITANO (*Ann. Inst. Pasteur*, 1900, 14, 60—81).—The secretion of a proteolytic enzyme is constant during the life of *Aspergillus niger*, and is chiefly associated with the death of the cells. It is believed that such agents will not only produce effects on the surrounding medium, for instance, the liquefaction of gelatin, but also in the protoplasm of the cells carry out the work of disassimilation.

W. D. H.

Resolution of a Racemic Compound by means of Moulds. By C. ULPANI and S. CONDELLI (*Gazzetta*, 1900, 30, 1, 382—394).—Results are given of a number of experiments made to determine the conditions best suited for the resolution of a racemic compound into its optically active isomerides by means of moulds. The spores of

Aspergillus niger do not develop in absence of oxygen, but they are not killed, unless indeed by a very long exposure in a vacuum. This mould attacks a racemic compound more energetically in presence of a small quantity of oxygen than when a larger quantity is present, but at the same time less of the optically active isomeride is obtained, since Pfeffer's economic coefficient, that is, the ratio of material consumed to that formed, has a greater value when there is a deficiency in the oxygen employed. The life, and hence also the activity, of moulds are almost entirely inhibited by sunlight, and the rapidity with which a racemic compound is resolved increases as the luminosity decreases, and increases also with the temperature. Experiments with racemic, lactic, and mandelic acids and alanine show that *Penicillium glaucum* flourishes best in solutions of greater concentration and less acidity than is the case with *Sterigmatocystis niger*. The proportion of inorganic salts necessary for the complete development of moulds is very small, the small quantity dissolved from the glass vessel containing the solution being sufficient. On growing *Sterigmatocystis niger* in 5 litres of solution containing 120 grams of crystallised racemic acid and small quantities of ammonium, potassium, and magnesium salts, it was found that in the first period, extending to the end of the 32nd day, *d*-tartaric acid was almost exclusively destroyed; after this, the destruction of the dextro-acid continued, and was completed after a further 33 days, 27 per cent. of the total lævo-acid being also destroyed; during the third period, from the 65th to the 123rd day, the fermentative process became weaker, since, besides the last traces of dextro-acid, only 7 per cent. of the initial quantity of lævo-acid was destroyed. After this, no further appreciable action took place, although the mould was found to be capable of vigorous growth in a suitable medium. From the residual liquid, only potassium hydrogen *l*-tartrate could be separated, and in a solution of this salt, as stated by Pfeffer, no development of *Aspergillus niger* is possible.

T. H. P.

Denitrification. By ALBERT STUTZER and HJALMAR JENSEN (*Bied. Centr.*, 1900, 29, 268—273; from *Centr. Bakt.*, 1897, 622 and 698).—The results of experiments with pure cultures of various denitrifying bacteria on the utilisation of carbon compounds, showed that citric acid alone is sufficient to supply the necessary carbon. Dextrose alone is unsuitable, and in presence of citric acid even somewhat retards growth; it is, however, not altogether useless; there is a connection between the nitrate destroyed and the carbon compounds used up in solutions which contain, besides sugar, citric acid. In such solutions, continued addition of nitrate soon stops denitrification, which is, however, renewed on adding more sugar.

Glycerol and starch (compare Déherain, *Abstr.*, 1899, ii, 511) do not produce fermentation, either separately or together; but a mixture of glycerol and a citrate is suitable. Lactic and butyric acids, but not formic acid, are very good sources of carbon when employed in Giltay and Aberson's solution, in the place of citric acid.

When, instead of pure cultures, garden soil is employed, glycerol is decomposed by putrefaction bacteria, and the products are utilised by

denitrifying bacteria. Similar, and still more decided, results were obtained with straw.

The value of stable manure as nitrogenous manure diminishes as the amount of carbonaceous matter available for denitrifying bacteria increases. When fresh manure is ploughed in late, the yield of the succeeding crop is less than when an equal amount of moderately rotted manure is employed, even when the two lots contain the same amount of available nitrogen. This difference is attributed to the much larger amount of energy at the disposal of the denitrifying bacteria in the fresh manure. The number of bacteria is of less importance. Considerable losses through denitrification will not take place in old, rotted manure; but denitrification does not entirely cease even when humification is far advanced.

The general conclusion is drawn that the value of dung as nitrogenous manure depends very essentially on the carbonaceous matter present; the use of plenty of peat litter in stables is recommended.

N. H. J. M.

Morphology and Biology of Denitrifying Bacteria. By HJALMAR JENSEN (*Bied. Centr.*, 1900, 29, 273—275; from *Centr. Bakt.*, 1898, 4, 401 and 448).—The term denitrifying bacteria is restricted to those which liberate free nitrogen; the bacteria which produce organic nitrogenous compounds, or nitrites and ammonia from nitrates, are not included.

The bacteria are aerobic in absence of nitrate, but utilise the oxygen of nitrate when present. Aëration prevents destruction of nitrates.

The bacteria at present known are: (1) *Bacillus denitrificans*, I., Burri and Stutzer = *Bacterium denitrificans*, Lehm. and Neum.; (2) *Bacillus denitrificans*, II., Burri and Stutzer = *Bacterium Stutzeri*, Lehm. and Neum.; (3) *B. Shirokikhi*, Jensen; (4) *B. denitrificans agilis*, Ampola and Garina; (5) *Vibrio denitrificans*, Sewerin; (6) *Bacillus pyocyaneus*, Sewerin; (7) *B. pyocyaneus*, Lehm. and Neum.

In addition to the above, the author has isolated four others: (8) *Bacterium filifaciens* (from an old cultivation of *B. Stutzeri*); (9) *B. centropunctatum* (from cow-dung and guinea-pig fæces); (10) *B. Harilebii* (from soil from Ellenbach), and (11) *B. nitrovorum* (from horse-dung).

As regards the distribution of denitrifying bacteria, analyses of six samples of air gave negative results; it was, however, found that inoculation may take place through the air. Peat and autumn leaves of *Poa annua* and *Senecio vulgaris* gave negative results. Straw always gave positive results, and out of 17 samples of soil, 5 denitrified. In the soil, the bacteria are derived from the dung applied, and disappear if the soil is left unmanured. Fæces from cows, horses, and sheep frequently contained denitrifying bacteria; in the case of guinea-pigs, mice, pigs, and earth worms, the bacteria were sometimes found. Human fæces and the fæces of lions, dogs, canaries, and geese never contained the bacteria. The bacteria are destroyed in their passage through the human digestive system, and the same occurs with dogs and worms.

N. H. J. M.

Effect of Removing the Flowers on the Assimilation of Nitrogen by Leguminous Plants. By MARCO SOAVE (*Expt. Stat. Record*, 1900, 11, 516; from *Staz. sper. agrar. ital.*, 1899, 32, 499—516).—Comparing the results obtained when the flowers were constantly removed, with those obtained with similar plants which were left with the flowers, it was found that, in the case of *Vicia faba*, there was a decided gain in dry matter and nitrogen when the flowers were cut off. In the case of *Phaseolus multiflorus*, *Pisum sativum*, and *Lupinus albus*, there was a loss of either dry matter or nitrogen, or of both.

N. H. J. M.

Effect of Ferments on the Germination of Old Seed. By A. THOMSON (*Expt. Stat. Record*, 1899, 11, 460; from *Gartenflora*, 45, 344).—Cereal seeds, 20—25 years old, were soaked in diastase or pepsin solutions for 24 hours, washed and germinated. Barley which gave a germination of 4.5 per cent. germinated to the extent of 35 per cent. after treatment with 5 per cent. diastase solution, and 48 per cent. when a 10 per cent. diastase solution was employed; in a similar manner, the germination of oats was raised from 16 to 47 and 54 per cent. respectively. Pepsin (5 per cent. solution) increased the germination of oats to 39 per cent. The germination of maize, peas, and clover rose from 3, 5, and 17 per cent. to 49, 22, and 50 per cent. when treated with 5 per cent. diastase solution.

N. H. J. M.

Relation of the Ash to the Height of Plants. By EDMUND J. MILLS, JOHN IMBIE, and ARCHIBALD GRAY (reprinted from *Proc. Phil. Soc. Glasgow*, 1900, 8 pp.).—The stem of a healthy spruce fir, cut down in December, was cut into 14 sections, each 19 $\frac{3}{4}$ inches long. These were burnt in a specially devised apparatus, described with sketch, and the weight of ash in each section determined; silica and lime were determined in the ashes. The actual weights of wood, ash, and constituents, as well as the percentage results, are given in tables, and the relations between the height of the tree and the weights of wood, ash, silica, and lime are shown in smoothed curves.

As regards silica, it was found that the point $h=3.1$ is a critical point, indicating the theoretical position at which the chemical effect of the unexposed trunk, as a mineral carrier, is at its lowest, owing probably to the sudden demand for ash by the large lowest branches. An upper critical point, $h=13.724$, was also found. This depends on the demand due to the exceptional vitality at the summit.

In the case of lime, the lower critical point is somewhat below that for silica; the higher critical point is of an ideal character, being above the top of the tree.

It is supposed that similar points occur in the branches, and even in the twigs.

N. H. J. M.

Distribution of Ash Constituents in the Section of the Copper Beech. By RICHARD HORNBERGER (*Bied. Centr.*, 1900, 29, 187—190; from *Mündener forstl. Hefte* 1898, 14. Compare *Abstr.*, 1897, ii, 280).—The intermediate portions of the sections of the two copper beeches previously examined (*loc. cit.*), corresponding with the 26th to the 87th and 90th years of growth, were divided into three portions, each

representing about 20 years of growth, for more detailed investigation. The middle portion (45th—65th years) was found to contain the least ash in the dry matter, the least phosphoric acid, and also the least, or, in the case of (B), almost the least, potassium; but it contained the greatest amount of calcium, and the most, or almost the most (in B), manganese.

In the same zone, but on different sides of the tree, there may be differences in the composition of the ash; even then, however, the results still show that potassium and phosphoric acid on the one hand, and calcium and manganese on the other, go together. N. H. J. M.

Composition of Cocoa-nut Ash. By A. BAIN and F. BACHOFEN (*Queensland Agric. Jour.*, 1900, 6, 297).—The different parts of the cocoa-nut weighed as follows: (1) Husk, 2·702; (2) shell, 0·546; (3) kernel, 0·875; and (4) milk, 0·593 lb., and contained (1) 34·44, (2) 84·80, and (3) 47·20 per cent. of dry matter, and 1·63, 0·29, 0·79, and 0·38 per cent. respectively of pure ash. Analyses of the ashes gave the following percentage results:

	K ₂ O.	Na ₂ O.	CaO.	MgO.	Fe ₂ O ₃ , Al ₂ O ₃ .	P ₂ O ₅ .	SO ₃ .	SiO ₂ .	Cl.
Husk ...	30·71	27·58	4·14	2·19	0·54	1·92	3·18	8·22	27·82
Shell ...	45·01	23·65	6·26	1·32	1·39	4·64	5·75	4·64	9·44
Kernel..	54·05	2·65	3·10	1·98	0·59	20·33	8·79	1·31	9·24
Milk....	34·54	13·95	7·43	3·97	trace	5·68	3·94	2·95	35·50

N. H. J. M.

Distribution of Sugar, Acid, and Tannin in Pears. By W. KELHOFFER (*Bied. Centr.*, 1900, 29, 248—251; from *Jahresber. Wädensweil*, 6, 68). The following amounts of sugar (invert), acid (tartaric), and tannin were found in the different parts of the pear:

Skin.			Fruit.			Core.		
Sugar.	Acid.	Tannin.	Sugar.	Acid.	Tannin.	Sugar.	Acid.	Tannin.
7·74	6·20	2·80	8·24	14·83	2·36	7·31	11·71	0·97

Whole Pear.		
Sugar.	Acid.	Tannin.
8·00	12·61	2·05

Similar experiments were obtained with two other varieties of pears, (*Bied. Centr.*, 1899, 28, 68), and it is thought that it may be assumed that all varieties would show the same distribution of the different constituents at the same stage of ripeness. As ripening proceeds, the tannin diminishes more quickly in the inner parts of the pear than in the skin. By the time the pears had become doughy, the inside portions were free from tannin, whilst the skin still contained 1·9 per cent., or 65·8 per cent. of the original amount. The acid diminishes most quickly in the skin.

Analyses of three cross-sections of the pear, representing (1) the calyx, (2) the core, and (3) the stem portions, showed, after the removal of the calyx, &c., that the calyx portion contained the highest percentages of sugar, acid, and tannin. The seed portion contained the least tannin and the stalk portion the least sugar and acid. N. H. J. M.

Composition of the Albumens of the St. Ignatius Bean and Nux Vomica. By ÉMILE BOURQUELOT and J. LAURENT (*Compt. rend.*, 1900, 130, 1411—1413).—The albumen of the St. Ignatius bean when hydrolysed with dilute sulphuric acid yields 27 per cent. of mannose and 31 per cent. of galactose, and the albumen from nux vomica yields 11·3 per cent. of mannose and 41·6 per cent. of galactose. The carbohydrate of both albumens is therefore a mixture of mannan and galactan. Either of them can be used for the preparation of crystallised galactose, and will give a better yield than milk sugar. C. H. B.

Agaricus Campestris. By ALEXANDER ZEGA (*Chem. Zeit.*, 1900, 24, 285—286).—The mean result of various analyses give: Water, 89·22; nitrogen compounds, 5·94; fat, 0·23; nitrogen free material, 2·92; fibre, 0·84; and ash, 0·75 per cent. The ash contained P_2O_5 , 0·188; K_2O , 0·156; sand, 0·056. The finely-divided and air-dried fungus was extracted with alcohol at 45—50°, and in this liquid chlosterol and mannitol have been detected. J. J. S.

Composition of Apios Tuberosa. By CELSO BRIGHETTI (*Chem. Centr.*, 1900, i, 914—915; from *Staz. sperim. agrar. ital.*, 33, 72—75).—Analyses of the various portions of the plant, *Apios tuberosa*, are quoted. E. W. W.

Alinit in the Cultivation of Cereals. By L. MALPEAUX (*Ann. agron.*, 1900, 26, 196—211. Compare Abstr., 1899, ii, 242).—Inoculation with alinit had no effect on wheat grown in sand. When inoculated a second time in conjunction with applications of sugar and extract of straw respectively, the production of wheat was increased. Dung gave a greater increase than was obtained by inoculation, and the yield was further increased by inoculation in conjunction with dung. Alinit had a greater effect in increasing the production of wheat grown in rich soil, and the effect was increased by a second application of alinit, together with sugar. The increase due to inoculation was chiefly in the straw.

Field experiments were made with wheat and barley in soil containing 0·134 per cent. of total nitrogen. In the case of wheat, there was no increased production of grain after inoculation, but the straw was increased by about 300 kilos. In the barley experiment, the alinit plots gave slightly more grain and 410 kilos. more straw per hectare; with an application of sodium nitrate (150 kilos.), the yields of grain and straw were increased by 320 and 610 kilos.

The results showed, therefore, that inoculation with alinit is useless in absence of carbohydrates or a great deal of humus; in rich soil, it was decidedly beneficial, but sodium nitrate gave much the best results. Inoculation can only be of use when conditions favourable to the growth of the microbes exist in the soil; and Dehérain has shown that, under these conditions, fixation of nitrogen can take place in soils without inoculation, which is, as a rule, superfluous. N. H. J. M.

[Composition of] Weak Straw. By J. ALAN MURRAY (*Ann. Rep on Field Expts. Univ. Coll. Wales*, 1899, 79—80).—Analyses were made of two lots of rye straw, (1) manured with phosphates, nitrogen, and potash; (2) with phosphates and nitrogen only. Whilst the more fully manured straw was in every respect normal, that obtained on the

plot which had no potash was too weak to stand, and when dried was so brittle that it could almost be reduced to powder when crushed in the hand. The air-dried straw from the two plots had the following percentage composition :

	Water.	Nitrogenous matter.	Oil.	Soluble carbohydrates.	Crude fibre.	Ash.
1.	10.29	6.11	3.35	46.01	30.64	3.60
2.	12.46	10.06	—	45.14	27.80	4.54

Both samples were cut when somewhat immature, but having been cut on the same day and grown from the same seed sown at the same time, the results are comparable.

When distilled with hydrochloric acid, the two samples yielded (1) 9.26 and (2) 10.95 per cent. of furfuraldehyde.

The results indicate that the weakness of the straw (2) cannot be due to defective lignification, and that it is probably connected with the deficient production of oil which was practically absent in the weak straw.

N. H. J. M.

Influence of Nitric and Ammoniacal Nitrogen on the Development of Maize. By PIERRE MAZÉ (*Ann. Inst. Pasteur.*, 1900, 14, 26—45. Compare *Abstr.*, 1899, ii, 237, and Takabayashi, *ibid.*, 1897, ii, 585).—Maize plants grew equally well in solutions containing sodium nitrate and ammonium sulphate, provided that the strength of the latter solution did not exceed 0.05 per cent. ; stronger solutions are injurious. When both salts are present simultaneously, the plant sometimes prefers the one and sometimes the other. Ammonium salts are, therefore, not inferior to nitrate when employed in suitable quantities.

Reference is made to the Rothamsted experiments on wheat as regards the application of ammonium salts, the assumption being that nitrification is comparatively slow until June as indicated by Dehérain's drainage experiments.* It is estimated that an application of 86 lbs. of nitrogen per acre would give a solution in the soil containing 0.075 per cent. of ammonium sulphate, and results are quoted indicating that this and larger amounts of ammonium salts are less beneficial than nitrate.

N. H. J. M.

Agricultural, Botanical, and Chemical Results of Experiments on the mixed Herbage of Permanent Grass-Land, Conducted for many Years in Succession on the Same Land. III. The Chemical Results. Section I. By SIR JOHN B. LAWES and SIR J. HENRY GILBERT (*Phil. Trans.*, 1900, B. 192, 139—210).—The experiments were commenced in 1856, and include about 20 plots, two unmanured and the rest with a variety of manures. The "agricultural results" and the "botanical results" obtained during the first 20 years of the experiments have already been

* The results of analyses of the drainage from the plots of the permanent wheat field at Rothamsted showed, however, that the nitrification of ammonium salts applied as manure to this soil is very rapid in October and November when the soil is sufficiently wet (compare *Abstr.*, 1883, 891). In October, just after the ammonium salts have been applied, the drainage contains small amounts of ammonia, but if it is collected about a week or ten days later, it contains practically nothing but nitrates.—N. H. J. M.

discussed (*ibid.*, 1880, Pt. 1, and 1882, Pt. 4) and the present paper deals with the chemical results (determinations of total nitrogen, and ash analyses) of the same period.

The consideration of the results of the ash analyses showed the importance of including carbon dioxide in the "pure ash," instead of excluding it, as has almost invariably been done hitherto. The ash constituents are, therefore, calculated as percentages of the ash after saturation with ammonium carbonate and drying at 120—130°. The amounts of carbon dioxide in the ash ignited at a low red heat, and the amounts required to form normal salts, reckoning all the phosphoric acid as tribasic, are given in separate tables.

The ashes of different crops vary very characteristically according to the amount of nitrogen which they take up. For example, red clover, a crop which yields large amounts of nitrogen, partly due to fixation, much of which is taken up in the form of nitrates, yields an ash characterised by containing much carbon dioxide, which presumably represents organic acid originally present in the plant. The conclusion is drawn that, besides any physiological function of the bases, their rôle is prominently that of "carriers of nitric acid," and that, after the assimilation of the nitrogen, the base is left in combination with organic acids. It is suggested "that at any rate a large amount of the nitrogen of the chlorophyllous vegetation on the earth's surface was derived from nitrates; whilst, so far as this was the case, the *raison d'être* of much of the fixed base found in the ashes of plants would seem to be clearly indicated."

"The mineral composition of the mixed herbage is very directly dependent on the supplies available within the soil. Indeed, the composition of the mixed produce was found to be a somewhat close reflection of the supplies available within the range of the roots. It was, in fact, more so than in the case of individual crops grown separately. It is at the same time obvious, that when the more functionally important constituents are available in relative abundance, those which are of less importance in this respect are taken up and retained in less amount than they otherwise would be; the result being determined in great measure by the character of the growth induced.

"Luxuriance, or vegetative activity, is intimately associated with the amount of nitrogen available and taken up. Further, chlorophyll formation to a great extent follows nitrogen-assimilation. But the results relating to the increased amount of the non-nitrogenous substance yielded in the mixed herbage under the influence of various manures, clearly indicate that the nitrogen, being taken up, and the chlorophyll formed, the carbon-assimilation, and the carbohydrate formation, depend essentially on the amounts of potash available."

N. H. J. M.

Flax. By JULIUS OLSCHOWY (*Bied. Centr.*, 1900, 29, 240—242; from *Zeit. Landw. Versuchswesen Oesterr.*, 1899, 34, 135 and 515).—A crop of flax, 5000 kilos. per hectare, withdrew 34.1 kilos. of potash, 17.3 kilos. of nitrogen, and 15.5 kilos. of phosphoric acid from the soil. The assimilation goes on until the green seed capsules are formed, a period which represents about two-thirds of the whole vegetative period of flax grown for the production of fibre. Up to the time of flowering,

the assimilation of the above constituents is gradual; during the flowering period, there is a sudden increase followed by a rapid decrease.

Superphosphate, potassium sulphate, and sodium nitrate had a marked effect when applied before the seed was sown, but had no effect when applied as a top dressing. The effect of nitrogen was to increase the yield of straw and to lower the production of seed. Potash, and, still more, phosphoric acid, increased both straw and seed production.

N. H. J. M.

Effect of Nitragin and Inoculation Soil on Yellow Lupins. By MAX ADLER (*Expt. Stat. Record*, 1900, 11, 515; from *Ber. Landw. Versuchs. Stat. Jena*, 1898, 19—20).—Lupins were grown in sandy soil in zinc pots; five without inoculation, five inoculated with nitragin, and five with inoculation from lupin soil.

Nitragin increased the corn and straw 34·4 and 12·2 per cent., whilst the increase after soil inoculation was, corn, 106·5, and straw, 42·9 per cent.

N. H. J. M.

Experiments with German, English, and French Varieties of Mangels. By FERDINAND WOHLTMANN (*Bied. Centr.*, 1900, 29, 242—247; from *Illust. Landw.-Zeit.*, 1899, Nos. 2 and 5).—The results of one year's experiments with 17 varieties of mangels, including the yields of roots and leaves, the weights of the roots, and the percentages of dry matter and sugar, are given. The results so far indicate that the best German varieties are hardly surpassed by any of the other varieties employed, but that greatest differences occurred in the yields of the German varieties.

N. H. J. M.

Sugar-Beet in 1898. By STONE, CLINTON, KINSELY, and CAVANAUGH (*Bied. Centr.*, 1900, 29, 254—256; from *Cornell Univ. Agric. Expt. Stat. Bul.*, 166, 1899).—Results obtained with eight varieties of sugar-beet are given.

Experiments on the effect of various manures, applied both alone and mixed, were made with Klein Wanzleben roots. Sodium nitrate alone greatly reduced the percentage of sugar and the purity coefficient.

N. H. J. M.

Mites in Beet-root Excrescences. By FR. BUBÁK (*Zeit. Zuckerind. Böhm.*, 1900, 24, 355—367).—The excrescences sometimes observed on sugar-beet are produced by mites (*Histiostoma Feroniarum*, Duf.). The latter do not occur in healthy roots, and cannot exist in the excrescences in presence of microbes. The excrescences consist anatomically of the same substances as the roots, but the fibrovascular bundles are very irregularly placed. As regards composition, it has been shown by Schacht, Strohmer and Stift, and Stoklasa that the excrescences contain much less sugar than the roots, sometimes only half as much; whilst Strohmer and Stift and Bartoš found that the percentage of nitrogen is much higher than in the normal portions of the roots. It has been suggested that the less amount of sugar in the excrescences may be due to greater respiration, but it is more probably owing to consumption of sugar by the mites. Strohmer and Stift found 0·25—0·35 per cent. of invert sugar in the excrescences, but it is thought unlikely that it occurs in the healthy excrescences on roots

when taken up. When the excrescences are kept for a short time, the percentage of sucrose is reduced by 2—3 per cent.; subsequently, the sugar completely disappears.

N. H. J. M.

Rational Feeding of Cows. By OSKAR HAGEMANN (*Expt. Stat. Record*, 1899, 11, 484—485; from *Landw. Jahrb.*, 1899, 28, 485—534. Compare this vol., ii, 39 and 103).—Two cows were fed during successive periods with (1) malt sprouts, (2) pea-nut cake meal with cocoa-shells and molasses, (3) linseed meal, (4) maize-cake meal, (5) malt sprouts and 500 grams of emulsified sesamé oil, and (6) sesamé oil in a weak alkaline emulsion, in addition to a basal ration of hay, straw, dried beet diffusion residues, and salt.

The results gave no indication that the fat of food affects the production of milk fat. The milk of period 4 contained the least fat; the greatest yield of milk fat, as well as the highest percentage in the milk, was in the second period, when the ration contained 218 grams of fat for a cow weighing 560 kilos.

It is thought that the percentage of fat in milk and the absolute amount of milk fat produced do not depend on the fat digested in the food, but on certain substances present in some foods, which in some cases stimulate the lacteal glands, and in others modify the cell activity of the glands so as to produce milk containing more fat. This would account for the fact that cocoa-shells and molasses increased the fat in the milk, and that maize-cake maintained the yield, notwithstanding the natural shrinkage, although the percentage of fat in the milk diminished.

The substance which gives the characteristic sesamé oil reaction was not transmitted to the milk.

N. H. J. M.

Feeding Experiments with Blood Molasses. By LILIENTHAL (*Bied. Centr.*, 1900, 29, 166; from *Landw. Presse*, 1899, No. 27).—Blood is preserved from decomposition by adding molasses, and blood molasses is now manufactured at all the large slaughter-houses in Germany. It may contain proteids, 17—19; fat, 2·3—3·5; and non-nitrogenous extract, 55—69 per cent.

Experiments in which horses received 4 lbs. of blood molasses in the place of 6 lbs. (out of 12 lbs.) of oats, gave satisfactory results. Good results were also obtained with cows which received 2 lbs. of blood molasses a day; the yield of milk was raised 2 litres a day, and the cows remained healthy. Further experiments will be necessary.

N. H. J. M.

Maize-germ Molasses as Food for Cows. By BERNHARD SCHULZE (*Bied. Centr.*, 1900, 29, 167—169; from *Fühling's Landw. Zeit.*, 1899, 524. Compare Abstr., 1899, ii, 448).—The food consists of 52·5 per cent. of molasses and 47·5 per cent. of maize-germs, and has the following percentage composition:

Water.	Nitrogenous matter.	Fat.	Non-nitrogenous extract.	Crude fibre.	Ash.
21·00	14·56	3·79	52·00	2·58	6·07

Feeding experiments with 6 cows were made, in which the cows received during four periods, besides hay (6 lbs.), clover hay (6 lbs.),

and sunflower cake (1 lb.), the following amounts of food: Periods 1 and 4, mangels (70 lbs.) and wheat husks (3 lbs.); period 2, mangels (62.5 lbs.), wheat husks (2 lbs.), and maize-germ molasses (2 lbs.); period 3, the same foods as (2) in amounts of 55, 1, and 4 lbs. respectively. The results showed that maize-germ molasses is exactly equivalent to mangels and wheat bran. N. H. J. M.

Feeding Cows with English Cake. By EBERHARD RAMM and E. MÖLLER (*Bied. Centr.*, 1900, 29, 234—235; from *Milchzeit.*, 1899, No. 18).—The cake consisted chiefly of cotton-seed meal, with a good deal of fibre and husks, and, in addition earth-nut, rice- and barley-husks, and small amounts of palm-kernel meal and molasses.

The results of feeding experiments showed that the cake had about the same value as earth-nut cake. The favourable results are attributed to the cotton-seed meal in conjunction with sugar. Owing, however, to the high percentage of crude fibre, the cake is not recommended. N. H. J. M.

Feeding Cows with Bassia-Nut and Palm-Bassia Cake. By EBERHARD RAMM and E. MÖLLER (*Bied. Centr.*, 1900, 29, 233—234; from *Milchzeit.*, 1899, No. 10, 15).—Bassia nuts are obtained from different varieties. The fat is used as food and for candles and soap, the residues being given to cattle. Bassia-cake contains: water, 8.75; proteids, 8.75; fat, 19.90; carbohydrates, 47.45; crude fibre, 9.75; and ash, 5.40 per cent.

The results of experiments with cows in which bassia-cake was compared with earth-nut cake showed that the two foods are very similar in value; the small amount of proteids is counter-balanced by the fat and carbohydrates, provided that the ration contains the necessary amount of proteids.

Similar results were obtained from cake resulting from the manufacture of oil from a mixture of palm-kernels (2 parts) and bassia-nuts (1 part); but it is thought preferable to utilise the two products separately. N. H. J. M.

Feeding Cows with Tropon. By EBERHARD RAMM and E. MÖLLER (*Bied. Centr.*, 1900, 29, 232—233; from *Milchzeit.*, 1899, No. 16).—The cows were fed with rations containing earth-nut cake and Finkler's tropon containing three times the normal amount of digestible proteid. The effect of the tropon was to increase the yield of milk by 0.216 kilo. and the dry matter free from fat by 0.04 kilo. The live weight was reduced by more than 1 per cent., and the percentages and yields of fat and dry matter in the milk were reduced. Tropon residues gave better results. N. H. J. M.

"Manur." By ALEXANDER ZEGA (*Chem. Zeit.*, 1900, 24, 264).—A cheese exported from Servia, prepared from the milk of cows or sheep. The milk is brought to the boiling point and when cold a mixture of butter milk, whey, and a specially prepared rennet is added. The cheese paste is pressed in cloth, slightly salted, and dried. Its composition is about as follows: water, 22.40—23.13; proteids, 17.35—16.80; fat, 52.86—51.22; carbohydrates, 3.41—4.32;

ash, 4.48—4.53; salt, 3.26—3.40. Calculated on the dry substance: proteids, 22.35—21.80; fat, 68.11—66.63 per cent.

It has no particular odour, tastes sweetish, and when cut leaves a perfectly smooth surface.

L. DE K.

Soil Analyses. By CARL VON FEILITZEN (*Bied. Centr.*, 1900, 29, 217—218; from *Svensk. mosskulturfören. tidskr.*, 1899, 271—282).—Determinations of total nitrogen, and of potash, lime, and phosphoric acid, dissolved by 12 per cent. hydrochloric acid, were made in several hundred samples of soils from the different provinces of Sweden. Forty-five per cent. of the samples contained more than 8000 kilos. of nitrogen per hectare, to a depth of 20 cm., and 33 per cent. less than 6000 kilos.; 13 per cent. contained more than 600 kilos. of phosphoric acid and 74 per cent. less than 400 kilos.; whilst as regards lime, 50 per cent. contained more than 4000 kilos., and 39 per cent. less than 3000 kilos. per hectare. The peat-land of Gothland was particularly rich in lime, 96 per cent. of the samples containing over 4000 kilos. per hectare.

N. H. J. M.

Effect of Carbon Disulphide on the Fertility of Arable Soil. By EWALD WOLLNY (*Bied. Centr.*, 1900, 29, 146—150; from *Vierteljahresschr. Bay. Landw.-rats.*, 1898, 319. Compare Oberlin, *Abstr.*, 1896, ii, 67, and Pagnoul, *ibid.*, 66).—The results of pot and field experiments showed that whilst the application of carbon disulphide to soil will destroy the vegetation more or less completely, the fertility of soil is generally considerably increased when the disulphide is applied some months before sowing the seed. The increased fertility, which cannot at present be explained, lasts over one or several vegetative periods and is followed, if no manure is applied, by a considerable falling off.

Nitrifying and other soil microbes, including the leguminous nodule-bacteria, are not destroyed by even large amounts of carbon disulphide; their activity is only temporarily suspended.

N. H. J. M.

Experiments on the Schultz-Lupitz System. By PAUL BÄSSLER (*Bied. Centr.*, 1900, 29, 154—157; from *Ber. Agr.-Chem. Versuchs u. Samenkontrol-Station Köslin* for 1897, 81).—Field experiments were made on various light and other soils to ascertain whether liming or marling, in conjunction with moderate amounts of mineral manures and green manuring with *Leguminosae*, would give, under the unfavourable climatic conditions of the Eastern provinces, results similar to those obtained by Schultz-Lupitz. The composition of the soils is given in each case; about half of them contained satisfactory amounts of phosphoric acid, but all were poor in lime, and some contained very little potash. Several of the experiments failed owing to unfavourable weather.

The potato crop of 1897, which was injured by drought, was scarcely benefited by minerals on the fields which had green manure. On one field, the crop was better after the ploughing in of serradella, containing 156.5 kilos. of nitrogen per hectare, than after lucerne containing 322 kilos. of nitrogen. The loosening of the subsoil raised,

in nearly every case, the percentage of starch (about 0·3 per cent.) in the tubers, and in the majority of cases also increased the crop.

N. H. J. M.

Composition of the Soil under Paved and other Manure Courts at different Depths. By ADOLF EMMERLING and H. WEHNERT (*Bied. Centr.*, 1900, 29, 157—158; from *Jahresber. Versuchs-Stat. Kiel.*, 1898, 23).—The conclusion is drawn that to ascertain the extent of the losses undergone by a manure heap, it is better to examine the drainage collected in a pit, than to analyse the different layers of soil; no analytical results are therefore given.

N. H. J. M.

Manurial Experiments on Irrigated Meadows. By MARIO ZECCHINI and R. NUOLI (*Bied. Centr.*, 1900, 29, 159—162; from *Staz. sper. agrar. ital.*, 1899, 32, 15).—Farmyard manure gave the greatest yield of hay. Mineral and bone superphosphate proved to be about equal in value, and no difference in value was found between sodium nitrate and ammonium sulphate.

N. H. J. M.

Nitragin. By D. DICKSON and L. MALPEAUX (*Jour. agr. prat.*, 1897, 61, i, 191—197).—Inoculation of soil on which leguminous plants had not been grown previously, increased the yields of vetches and white lupins from 113 and 236 grams to 152 and 282 grams respectively. In sand, inoculation with nitragin increased the yields of incarnate clover and white lupins from 111 and 204 grams to 167 and 250 grams.

The results of field experiments with the same plants showed that inoculation had very little effect. In both sets of experiments, application of nitragin to the soil gave better results than when the seed was inoculated. The percentage of nitragin in the produce was increased by inoculation. The composition of the clover and lupins, both inoculated and grown without inoculation, is given.

N. H. J. M.

Nitragin. By E. SCHRIEBAUX (*Jour. agr. prat.*, 1897, 61, i, 813—819).—Pot experiments were made in which clover and peas respectively were grown in sterilised sand both without and with addition of nitragin. In the case of clover, inoculation with clover-nitragin greatly increased the growth, whilst inoculation with pea-nitragin produced no nodules and had no beneficial effect on the growth. With peas, both pea- and clover-nitragin produced nodules; with pea-nitragin, the produce was increased by about 50 per cent., whilst clover-nitragin reduced the yield.

Experiments with clover grown in soil showed that nitragin had no effect; the soil already contained the microbes.

N. H. J. M.

Importance of Various Plants employed for Green-manuring, in Increasing the Amount of Nitrogen in the Soil. By H. C. LARSEN (*Bied. Centr.*, 1900, 29, 230—232; from *Tidsskr. Landbr. Planteavl.*, 1899, 5, 101—112).—Several kinds of plants were grown in pots containing 7 kilos. of light soil (N=7·03 grams per pot) with mineral manures. The non-leguminous plants, especially buckwheat, and some leguminous plants (vetches) left the

soil poorer in nitrogen, whilst the other *Leguminosæ* either had no effect on the amount of nitrogen in the soil, or else increased it.

As regards total nitrogen, the nitrogen of the soil, roots, and above-ground portions of the plants, there was a gain in every case with the *Leguminosæ*, the greatest gains being obtained with *Vicia sativa narbonneensis*, *Pisum arvense*, and *Melilotus albus*.

The portions of the plants left after taking samples were mixed with the soil, and left during the winter. Experiments with barley showed that manuring with buckwheat and mustard was not only much less effective than manuring with leguminous plants, but that less growth was obtained than without green manure. N. H. J. M.

Effect of Manuring on the Inner Processes of some Plants. By HERMANN MÜLLER (*Bied. Centr.*, 1900, 29, 225—226; from 7th *Jahresber. Wädensweil.*, 36).—Potatoes, celery, radishes, and carrots were manured with minerals with 10 and 30 grams respectively of sodium nitrate per square metre in addition; one bed in each case received minerals only. The effect of nitrate was soon very marked, especially in the case of celery. The yield from each bed is given. Increased yields were obtained in each case, except potatoes and carrots, under the influence of nitrate. The radishes on the nitrate beds were partly decayed; the average weight was, however, considerably increased by the larger amount of nitrate. The carrots were also in part decayed on the nitrate beds. The potatoes, however, did not decay, and the diminished yield is attributed to the formation of crusts on the surface of the soil, due to the nitrate. N. H. J. M.

Availability of Fertiliser-Nitrogen. By SAMUEL W. JOHNSON, EDWARD H. JENKINS, and W. E. BRITTON (*Ann. Rep. Conn. Agric. Expt. Stat.*, No. 21, for 1897. Compare this vol., ii, p. 42).—Oats were grown in pots containing soil from the maize field, to which the various manures were added. The following results show the availability of the different forms of nitrogen for oats: sodium nitrate, 100; dried blood, 73·3; dry ground fish, 63·9; ground bone, 16·7; tankage, 49·4; horn and hoof, 68·3; linseed meal, 68·9; cotton seed meal, 6·48; and castor pomace, 64·6. If the roots were to be excluded, the percentage availability would have to be reduced by about 12; even then, greater amounts, especially in the case of nitrate and dried blood, will be seen to have been assimilated in 1897 than in the previous experiments. In the experiment next described, Hungarian grass was grown in soil to which nitrate, cotton seed meal, and raw knuckle bone, free from tendon and grease, were added. The bone was in three degrees of fineness: (A) passed through holes $\frac{1}{16}$ inch in diameter; (B) through holes $\frac{1}{16}$ to $\frac{1}{8}$ inch; and (C) through holes $\frac{1}{8}$ to $\frac{1}{4}$ inch; the three grades contained 3·58, 3·88, and 4·08 per cent. of nitrogen. The nitrogen availability was as follows: sodium nitrate, 100; cotton seed meal, 57·9; bone (A) 11·5, (B) 8·5, and (C) 5·6. N. H. J. M.

Phosphates. By CONSTANT SCHREIBER (*Bied. Centr.*, 1900, 29, 162—164; from *Rev. gén. agron.* Compare *ibid.*, 1897, 26, 803).—Phosphorite and basic slag had no effect on the growth of lupins and

white beans owing, it is supposed, to the power possessed by these plants, as well as by vetches, of obtaining all the phosphoric acid they require from the soil. Mineral phosphates should not be applied for cereals, tobacco, flax, carrots, sugar-beet, potatoes, and maize, and it is not worth while to apply them to serradella, and incarnate, red and white clover. Mineral phosphates are, however, of use in the case of hemp, the *Cruciferae*, peas, vetches (!), and buckwheat.

As regards the use of mineral phosphates in different soils, it was found that results are only certain in the case of peat-land.

In experiments with peas, it was found that calcium carbonate was in every case injurious when mineral phosphates were employed, and that when the amount of carbonate was large, its effect extended to the next year. Similar results were obtained with mustard and with clover, when phosphoric acid was applied in the form of mineral phosphate; in conjunction with basic slag, however, calcium carbonate had practically no injurious effect.

N. H. J. M.

Basic Slag for Spring Manuring. By PAUL WAGNER (*Bied. Centr.*, 1900, 29, 218—220; from *Deut. landw. Presse*, 1895 [?], No. 21, 183).—Basic slag containing 85—95 per cent. of phosphoric acid, soluble in citric acid, can be applied at all times, and will at once be available. The whole principle of phosphate manuring consists in applying an excess of the manure until a further addition produces no effect; in subsequent years, just sufficient phosphate is applied to meet the requirements of the greatest possible crop. The phosphoric acid does not become unavailable. A meadow which only yielded 30 cwt. of hay per hectare was partly manured, in 1899, with basic slag (16 cwt. per hectare); the whole meadow received kainite (16 cwt. per hectare) at the same time (1889) and in each subsequent year. The effect of the one application of basic slag was to increase the yield of hay, not only in 1890, but in each subsequent year as well, the total increase (1890 to 1896) being 243 cwt. per hectare. The greatest increase was in 1894 (59 kilos.), five years after the manure was applied.

N. H. J. M.

Composition of Kraal Manure. By J. LEWIS (*Agr. Jour. Cape of Good Hope*, 1899, 15, 517—521).—Analyses of (1) eleven samples of sheep-dung deposits, and of (2) three samples of burnt kraal manure are given. The average composition of the air-dried substances are as follows:

	Water.	N.	Ash.	K ₂ O.	CaO.	P ₂ O ₅ .	Cl.
(1)	13.52	1.31	41.28	2.84	7.08	1.26	1.25
(2)	2.23	—	86.46	7.60	16.97	2.59	1.57

N. H. J. M.

Analytical Chemistry.

Acidimetry. By A. ASTRUC (*Compt. rend.*, 1900, 130, 1563—1564. Compare Abstr., 1898, i, 222; and this vol., i, 199; ii, 122).—*iso*-Ethionic acid behaves as a strong monobasic acid in the presence of phenolphthalein, litmus, rosolic acid, and Poirrier's blue. With methyl-orange, 0.95 mol. of the alkali is required to give the end point.

Sulphanilic acid may be titrated with the above indicators, including methyl-orange, in this respect differing from the aminobenzoic acids.

Meconic acid behaves as a dibasic acid towards all the indicators except Poirrier's blue; with this reagent, it exhibits a tribasic character.

Mellitic acid reacts as a tribasic acid towards methyl-orange; its hexabasicity is revealed by the use of the other indicators.

G. T. M.

Asbestos Filters. By OTTO LOHSE and P. THOMASCHIEWSKI (*Zeit. anal. Chem.*, 1900, 39, 158—161).—To furnish proof of the utility of Lohse's pattern of asbestos filters (Abstr., 1899, ii, 801), the authors have made numerous estimations of silver, chlorine, barium, sugar (by copper reduction), and nickel, with results which showed only small differences in the fourth significant figure. When the precipitate is to be heated in a current of gas, it may be collected on a layer of coarse crushed glass (2—4 mm.) above the asbestos plug. M. J. S.

Technical Gas Analysis. By C. SCHMIDT (*Chem. Centr.*, 1900, i, 923; from *J. Gasbel.*, 43, 231—232).—In the technical analysis of gases over water, after absorbing the carbon dioxide, heavy hydrocarbons, oxygen, and carbon monoxide, a residual gas is obtained consisting of hydrogen, methane, and nitrogen.

In order to analyse this with a sufficient degree of accuracy, 20 c.c. of the mixture are measured in a Bunte burette, mixed with 125 c.c. of air, and exploded. After absorption of the carbon dioxide formed in the explosion, the total contraction is read off, and the remaining free oxygen, which should occupy about 2—5 c.c., is estimated by absorption with phosphorus. The remainder consists of nitrogen, from which should be deducted the amount of nitrogen contained in the added air (air \times 0.791).

The following formulæ should be used:

$$H = \frac{4}{3}(K + C) - 2V_0 \quad CH_4 = V_0 - \frac{1}{3}(K + C),$$

in which V_0 is the oxygen consumed, C the contraction, and K the generated carbon dioxide.

L. DE K.

Estimation of Combined Hydrochloric Acid in Gastric Juice. By OTTO COHNHEIM and H. KRIEGER (*Chem. Centr.*, 1900, i, 996; from *Münch. med. Wochschr.*, 47, 381—382).—The authors estimate in the ordinary manner the joint acidity and the free acid, each in 10 c.c., of the filtered gastric juice; 10 c.c. are then precipitated with calcium phosphotungstate. (This solution is made by

preparing a 4 per cent. solution of commercially pure phosphotungstic acid, and neutralising this at the boiling point with calcium carbonate; the solution keeps, and 30 c.c. will always be sufficient.) The bulky precipitate is filtered off, and the acidity estimated in the filtrate, using rosolic acid or phenolphthalein as indicator; the difference between this and the total acidity represents the combined hydrochloric acid. If there should be a deficiency of free hydrochloric acid, the deficit is estimated in the usual way, and a known volume of standard hydrochloric acid, about 30—40 c.c. more than the deficit amounts to, is added; the amount of the deficit is to be deducted from the amount of combined acid found.

L. DE K.

Estimation of Chlorine in Gastric Juice. By G. MEILLÈRE (*Bull. Soc. Chim.*, 1900, [iii], 23, 404—405).—The chlorine existing as free hydrogen chloride is estimated by titration with standard baryta solution, using phenolphthalein as indicator. The total chlorine is determined in the solution obtained by evaporating the juice to dryness with excess of calcium carbonate and calcium nitrate, igniting at a low temperature, and extracting the residue with dilute acetic acid. It is useful also to estimate the chlorine in the residue obtained by evaporating the juice to dryness in a vacuum, and in the ash.

N. L.

Chemical Processes in the Stomach. By M. C. SCHUYTEN (*Chem. Zeit.*, 1900, 24, 234—235).—The author has investigated the behaviour of the following reagents, which are usually recommended in testing for minute quantities of hydrochloric acid, towards the more common organic acids: (1) Danilewsky's reagent (Tropæolin OO); (2) Boas's reagent (a mixture of resorcinol and sugar in aqueous or alcoholic solution); (3) Günzburg's reagent (a mixture of phloroglucinol and vanillin in alcoholic solution); (4) an alcoholic solution of Congo red. The conclusion arrived at is that, to prove the presence of free hydrochloric acid in the juices of the stomach, freshly prepared Boas's reagent must be employed, as this reagent is not affected by small quantities of free organic acids, with the exception of tartaric acid, whereas most of the other reagents mentioned are readily affected.

Further experiments have proved that neither carbon dioxide nor different types of fatty acids are capable of liberating free hydrochloric acid from sodium or potassium chloride by their mass action (compare Maly, *Zeit. physiol. Chem.*, 1877, 1, 74).

J. J. S.

Estimation of Ozone from Ozonisers of Large Dimensions. By EUG. ACKERMANN (*Chem. Zeit.*, 1900, 24, 235—236).—A criticism of the method now in vogue of passing a definite volume of ozonised air through a solution of potassium iodide acidified with sulphuric, hydrochloric, tartaric, or other acid, and titrating the liberated iodine.

The method gives very uncertain results, owing to the great technical difficulty of accurately measuring the volume of gas which passes through the iodide solution.

L. DE K.

An Addition to the Apparatus for Kjeldahl's Nitrogen Estimation. By H. MEHRING (*Zeit. anal. Chem.*, 1900, 39, 162—163).—In place of the bulb-tubes of various forms usually inserted between

the flask and condenser to arrest drops of the alkaline liquid, a wide tube, twice bent at obtuse angles in opposite directions, and with narrow ends for making the respective connections, is employed. In the straight, narrow, vertical tube connected with the flask, a column of condensed liquid, about 10 cm. high, collects, and washes the ascending vapour; the upper, narrow tube is bent to a swan-neck shape. Owing to its simplicity, the apparatus is but little liable to fracture, and excellent results are obtained by its use. M. J. S.

Estimation of Nitrous Acid. By GYSBERT ROMIJN (*Chem. Zeit.*, 1900, 24, 145—146).—A criticism of Erdmann's view regarding the importance of nitrous acid in water, and of his patented new reagent (a liquid, containing sodium sulphanilate, and hydrochloric acid, and a powder, a mixture of sodium 1-amino-8-hydroxynaphthalene-4:6-disulphonate with sodium sulphate; this vol., ii, 243).

The results obtained with this new reagent were less satisfactory than those got with Griess' reagent. L. DE K.

Estimation of the Phosphoric Acid available as Plant Food in Soils and Manures. By J. PLOT (*Chem. Centr.*, 1900, i, 996—997; from *Oesterr. Chem. Zeit.*, 3, 127—131).—In order to ascertain the available phosphoric acid in soils or manures, a solvent should be used which resembles as much as possible the juice contained in the root of the plant. The author has now prepared a solvent which is a close imitation of the juice of beet in respect to salts. 0.4004 gram of ferrous sulphate, 1.4616 grams of potassium sulphate, 3.7098 grams of calcium nitrate, and 2.890 grams of magnesium chloride are dissolved and made up to 1 litre. 7.0566 grams of crystallised sodium carbonate, 6.744 grams of potassium carbonate, and 0.2 gram of silicic acid are fused in a platinum crucible; the fused mass is dissolved in water and mixed with 2.75 grams of oxalic acid, 1.9840 grams of malic acid, 2.2994 grams of citric acid, 1.9396 grams of tartaric acid, and then diluted to 1 litre. Before use, equal parts of these solutions are mixed.

25 grams of air-dried soil, or 5 grams of a manure, are shaken for half an hour in a 500 c.c. flask filled with the liquid; the phosphoric acid is then estimated in 200 c.c. of the clear filtrate. The process is well adapted for soils. When dealing with manures, it must be remembered that their soluble phosphoric acid available as plant food may be reduced in quantity when applied to a particular soil. The true value of a manure is, therefore, best ascertained by first analysing the soil itself, and then another portion mixed with a definite amount of the manure. L. DE K.

Sodium Amylzanthate in Qualitative Analysis. By R. GRASSINI (*Chem. Centr.*, 1900, i, 922—923; from *L'Orosi*, 22, 369—372).—The author has used Papasogli's reagent (*ibid.*, 21, 265) (which consists of a yellow solution prepared by mixing equal volumes of 50 per cent. solution of sodium hydroxide, pure amyl alcohol, and carbon disulphide) for other metals beside nickel and cobalt, and has observed the following colour reactions: Silver in ammoniacal solution turns dark blood-red with 2—3 drops of the reagent; lead, in neutral

solution, gives an orange precipitate soluble in sodium hydroxide; mercurous salts give a brownish-black, mercuric salts a dirty yellow, antimony in hydrochloric acid solution (acid solutions require some more of the reagent) an orange, arsenic in acid solution a canary-yellow, tin in acid solution a brown, bismuth in acid solution a reddish-brown, cadmium in ammoniacal solution a bright yellow precipitate; copper in very dilute ammoniacal solution is coloured red, aluminium dissolved in a not too dilute solution of sodium carbonate (1 hydroxide) gives a white, gelatinous precipitate; iron, in a neutral or faintly acid solution, turns a deep yellowish-red; manganese behaves like iron, but the red colour is not so permanent. Chromium, zinc, calcium, barium, strontium, magnesium, potassium, and sodium gave no reaction.

The reagent is, therefore, useful for the identification of individual metals from the groups previously separated from each other by the usual methods.

L. DE K.

Direct Estimation of Calcium in Presence of Iron and Aluminium. By L. BLUM (*Zeit. anal. Chem.*, 1900, 39, 152—155).—In the estimation of calcium in iron ores and blast furnace slags, an important economy of time results from precipitating the calcium by ammonium oxalate from a solution which has not been freed from iron and aluminium, but in which the oxides of those metals are retained in ammoniacal solution by the presence of tartaric acid. For practical purposes, the results of the two methods agree closely, since the amount of the iron, aluminium, and manganese oxides precipitated with the calcium from the ammoniacal tartrate solution is almost exactly balanced by the calcium oxide which escapes precipitation. The method is confined, however, to substances containing less than 0.5 per cent. of manganese.

M. J. S.

Analysis of Calcium Carbide. By HUGO ERDMANN and M. VON UNRUH (*J. pr. Chem.*, 1900, [ii], 61, 233—236).—An apparatus is described in which a known weight of a sample of calcium carbide is allowed to fall into water; the gas evolved escapes after passing over soda lime and from the loss in weight of the apparatus the proportion of calcium carbide in the sample is calculated. The amount of acid required to neutralise the resulting calcium hydroxide is calculated and subtracted from the actual amount required, thus giving the proportion of lime present in the sample. The neutral insoluble residue is also filtered off and estimated.

R. H. P.

Evaluation of Commercial Calcium Carbide. By GAETANO MAGNANINI and F. VANNINI (*Gazzetta*, 1900, 30, i, 401—404).—A description is given of a simple apparatus for determining the volume of acetylene yielded by a given weight of calcium carbide.

T. H. P.

Volumetric Estimation of Mercuric Chloride in Dressings. By MARTIN LEHMANN (*Chem. Centr.*, 1900, i, 998—999; from *Pharm. Zig.*, 45, 238—239).—The author communicates a further process for the volumetric estimation of mercuric chloride (this vol., ii, 443). It is based on the action of phosphorous acid on mercuric chloride which yields mercurous chloride and phosphoric acid. The excess of phos-

phorous acid is then titrated with *N*/100 potassium permanganate or with *N*/100 iodine, using starch as indicator. The action of the phosphorous acid is complete within half an hour at 25–30°. As the solution does not keep, it must always be checked afresh.

If the dressings should be coloured by rosaniline, this may be removed by means of a little animal charcoal. Experiments to estimate the mercuric chloride by means of standard stannous chloride or by *N*/100 potassium ferrocyanide and potassium permanganate have failed to give accurate results.

L. DE K.

Dry Assay of Lead. By J. FLATH (*Chem. Zeit.*, 1900, 24, 263–264).—A series of experiments to show that the dry assay is quite accurate enough for technical purposes; in rich ores, the deficiency does not exceed 1.5 per cent., and it must be remembered that some accompanying metals such as copper and antimony partly pass into the lead regulus.

The most suitable composition of the flux intended either for an acid or a basic material is sodium carbonate, 70 parts; borax, 28 parts; and potassium hydrogen tartrate, 2 parts.

L. DE K.

Estimation of Iron in Tap Cinder. By L. BLUM (*Zeit. anal. Chem.*, 1900, 39, 156–157).—In consequence of the almost universal presence of vanadium in the slag from iron puddling, neither the permanganate nor the stannous chloride volumetric method is available for an exact estimation of the iron. The gravimetric method is the only trustworthy one. The hydrochloric acid solution of the substance (freed from silica) should be twice precipitated by boiling with ammonium acetate to eliminate manganese; the precipitate again dissolved in hydrochloric acid, and, after adding tartaric acid and excess of ammonia, ammonium sulphide added to precipitate the iron.

M. J. S.

Simple Method for Decomposing Chrome-iron Ore. By RUDOLF FIEBER (*Chem. Zeit.*, 1900, 24, 333).—0.5 gram of the finely powdered ore is fused in a platinum crucible with 3 grams of sodium potassium carbonate for 10 minutes; when cold, 3 grams of dry borax are added and the mixture is again fused by first heating for a short time over the flame of a Teclu burner, and then for 45 minutes over the blowpipe. If the decomposition is not yet complete, a further addition of sodium potassium carbonate should be made. It is not really necessary to use the blast; if time is no object, a prolonged heating over the flame of a large Teclu burner will answer the purpose.

L. DE K.

Tin in Preserved Meat; Its Estimation and the State in which it Occurs. By F. WIRTHLE (*Chem. Zeit.*, 1900, 24, 263).—Analyses are communicated of samples of tinned meat from 1 to 5 years old, and the percentage of tin is stated. Where the metal was found to be corroded, which nearly always had occurred at such spots as had been in contact with the fat, the cause of the corrosion was found to be due to the formation of basic stannous chloride. The following process, originated by Orfila, was used for the estimation of the tin.

120 grams of the meat (jelly, fat) are heated in a large porcelain

dish standing on an asbestos plate with 5 c.c. of strong sulphuric acid with constant stirring, adding gradually more sulphuric acid; in all about 15—20 c.c. In this way, after about 4—5 hours a porous, charred mass is obtained which is then powdered and burnt to ash in a porcelain crucible. The ash is now fused with a mixture of sodium nitrate and carbonate, the fused mass treated with water and saturated with carbon dioxide. After remaining overnight, the precipitate is collected, washed, dried, and fused in a covered crucible with potassium cyanide. The fused mass is dissolved in water, the insoluble matter collected, washed, and dissolved in hydrochloric acid. From this solution, the tin is then precipitated in the usual manner with hydrogen sulphide and weighed as oxide. To make sure, this may be fused again with potassium cyanide and once more precipitated with hydrogen sulphide.

L. DE K.

Tinned Fish. By ADELBERT RÖSSING (*Zeit. anal. Chem.*, 1900, 39, 147—152).—The examination of some tins in which sterilised cod-fish and lobsters had been preserved for some years showed that the metal had been strongly attacked and in some cases completely removed from the interior, being converted into a white crust containing stannic oxide, phosphoric acid, and iron. This effect seems to be due to the action of the phosphates and ammonia present. It is in no way connected with imperfect sterilisation, but may always be regarded as evidence of long keeping. Any putrefaction or alteration in the original fresh appearance of the contents of the tins is not to be ascribed to this chemical action on the metal (except in cases where the iron itself is strongly attacked), but is the result of want of cleanliness or of sufficient rapidity in the operation of tinning, or of insufficient sterilisation of the contents of the tin.

M. J. S.

A New Reagent for Phenolic Compounds. By G. CANDUSSIO (*Chem. Zeit.*, 1900, 24, 299—301).—Instead of ferric chloride as a general test for phenols, the author uses a 1 per cent. solution of potassium ferricyanide to which 10—20 per cent. of pure ammonia has been added. This solution has the advantage over ferric chloride that it may be applied to either acid or alkaline solutions. The test may be applied in three ways. (1) By adding the reagent drop by drop to the phenol. (2) By adding the phenol gradually to an excess of the reagent. (3) By adding the reagent drop by drop to a solution of phenol rendered alkaline with sodium hydroxide. The results are communicated in a lengthy table.

From this, it is shown (1) that the sensitiveness of the ferric chloride test and the new test is in some cases the same, but in other cases different, the iron test being generally the less sensitive; (2) that although the phenolic compounds give with ferric chloride a blue, and with potassium ferricyanide mostly a brown colour, there is generally produced a series of different colours or precipitates which are of practical importance; (3) that potassium ferricyanide gives with phenol and commercial guaiacol a brown, with β -naphthol a vermillion, with thymol and morphine a whitish-yellow, with synthetical guaiacol a flesh-coloured, and with eugenol a yellow precipitate; (4) that potassium ferricyanide gives with α -naphthol a

single colour, namely, a blackish-violet, whilst it also gives a single colour with sodium salicylate, vanillin, morphine, and phloroglucinol, namely, a yellow one; (5) that, on the other hand, phenol, guaiacol, creosote, resorcinol, orcinol, catechol, quinol, gallic acid, pyrogallol, and tannic acid give with the same reagent two or more colours in succession. The sensitiveness of the two reagents towards artificial guaiacol, commercial guaiacol, and creosote is remarkable, as it gradually decreases from the first to the third.

It is also worthy of notice that thymol gives with ferric chloride a precipitate soluble in alcohol, and with potassium ferricyanide a precipitate insoluble in that liquid, whilst eugenol behaves in the opposite way. Morphine, like thymol, also gives a precipitate with potassium ferricyanide insoluble in alcohol.

L. DE K.

Detection of Sucrose in Lactose. By JOHN LANDIN (*Chem. Zeit.*, 1900, 24, 211).—The sample is treated with strong sulphuric acid. If the lactose is pure, it turns pale yellow at first and then gradually becomes bright brownish-red, the acid itself showing a reddish colour. If, however, a small quantity of sucrose is present, the mixture assumes at once a dark colour and soon becomes dark brown or brownish-black, and the acid does the same. In the presence of much sucrose, the whole mass turns black at once.

If a quantitative estimation is required, this may be effected by taking the copper reducing power before and after inversion.

L. DE K.

Volumetric Estimation of Free Fatty Acids. By J. SWOBODA (*Chem. Zeit.*, 1900, 24, 285).—A standard solution of sodium hydroxide in alcohol is very unstable, whilst an aqueous solution may cause the precipitation of fatty matter, which must then be redissolved by warming. If the liquid to be titrated contains ether as well as alcohol, two layers are formed which necessitate vigorous shaking after each addition of the alkali.

These inconveniences are avoided by dissolving the fatty matter in a mixture of 1 part of absolute alcohol and 2 parts of amyl alcohol.

L. DE K.

Estimation of Salicylic Acid. By JOSEF MESSINGER (*J. pr. Chem.*, 1900, [ii], 61, 237—248. Compare W. Fresenius and L. Grünhut, *Abstr.*, 1899, ii, 580).—The author shows that the iodometric method of estimating salicylic acid described by him and Vortmann (*Abstr.*, 1890, 1473), but rejected by Fresenius and Grünhut (*loc. cit.*), is quite satisfactory if the iodine and sodium hydroxide are present in sufficient quantity. The process is also satisfactory for other phenols.

R. H. P.

Hübl's Iodine-addition Method. By PAUL WELMANS (*Chem. Centr.*, 1900, i, 926—927; from *Zeit. öffentl. Chem.*, 6, 86—96).—The author's object has been to prepare an iodine solution of great stability, and he now recommends the following liquid for determining the iodine number of fats: 30 grams of iodine, 30 grams of powdered mercuric chloride, and 500 grams of glacial acetic acid are put into a litre flask, and ethyl acetate is then added, leaving space sufficient for

the mixture to be effectively shaken. When solution is complete, the liquid is made up to a litre by adding more ethyl acetate. This solution being an excellent solvent for fats, the use of chloroform becomes superfluous.

A number of analyses are communicated showing the influence of time, temperature, and excess of iodine on the iodine number. With lard, the excess of iodine is of more influence than the time of action; with cotton-seed oil and oil of almonds, no difference is noticed. With castor oil, the results are influenced by the time of action; various kinds of poppy oil behave differently in that respect. With cod-liver oil, the results vary, first with the temperature, then with the time of action, and lastly with the excess of iodine.

The fat extracted from roasted cocoa or chocolate by means of ether, unless dried for several hours at 105°, shows far too high an iodine number. This is caused by the presence of acraldehyde, which may, however, be removed by washing the fat with water at 50°.

L. DE K.

Estimation of Urea in Urine. By ADOLF JOLLES (*Zeit. anal. Chem.*, 1900, 39, 137—145).—The methods of Knop, Hüfner, and Riegler are recognised as giving results in excess of the truth; the author finds that the methods of Pflüger (*Abstr.*, 1887, 90) and Freund and Töpfer (*Wein. Klin. Rundschau*, 1899, 371) give practically identical results, and the latter estimates correctly any artificial addition of urea to urine. In both methods, the use of the azotometer replaces advantageously the estimation of the nitrogen by Kjeldahl's process, and these methods may be further improved as follows:

Freund and Töpfer's Method.—Five c.c. of the urine mixed with 5 c.c. of 95 per cent. alcohol are evaporated to dryness in the water-bath. The residue is repeatedly extracted with absolute alcohol, the alcoholic extract filtered into a flask, and the alcohol distilled off. The residue is then treated with about 70 c.c. of a saturated ethereal solution of oxalic acid, the precipitate of urea oxalate collected on a filter, washed with ether until free from oxalic acid, then dried at 70—80°, dissolved in water, and brought into the reaction vessel of the azotometer, where it is treated with alkaline hypobromite in the usual way.

Pflüger's Method.—Ten c.c. of the filtered urine are mixed with 30 c.c. of water and a sufficient quantity of a hydrochloric acid solution of phosphotungstic acid (100 c.c. of hydrochloric acid of sp. gr. 1.124 + 900 c.c. of phosphotungstic acid, 1:10). The mixture is warmed on the water-bath for 15 minutes, left in the cold for 4 hours (which is found to be long enough), made up to 100 c.c., and filtered through dry paper; 25 c.c. are placed in the azotometer, and made alkaline before introducing the tube containing the hypobromite. With these proportions, each c.c. of nitrogen (at 760 mm. and 15.5°) indicates 1 gram of urea per litre of urine. The author furnishes a table of corrections for other pressures and temperatures.

M. J. S.

Estimation of Tannin. By LEOPOLD SPECHT and FRITZ LORENZ (*Chem. Zeit.*, 1900, 24, 170—171).—The method is based on the principle that safranin is precipitated as a tannin-antimony lake, and

that the excess of saffranine may be readily titrated with solution of ammonium hyposulphite. The difference in c.c. between this estimation and the check experiment is the measure for calculating the amount of tannin.

The authors used as standard tannin a preparation from Schering and Co., "Acid tannic leviss," the moisture which it contained being allowed for. The ammonium hyposulphite was always prepared fresh by mixing 50 grams of zinc dust with 100 grams of water, and gradually adding 600 c.c. of ammonium hydrogen sulphite of sp. gr. 1.16, previously neutralised with ammonia; the temperature should not rise above 36°. After settling, 75 c.c. of the clear liquid are diluted to 2 litres, introduced into a reservoir, and covered with mineral oil. This reservoir is connected in the usual way with a burette, the end of which dips into the liquid to be titrated, which is also covered with mineral oil to exclude air.

L. DE K.

Soil Humus. Some Sources of Error in Analytical Methods. By A. L. EMERY (*J. Amer. Chem. Soc.*, 1900, 22, 285—291).—Hilgard's process for estimating humus in soils, which is frequently employed, briefly consists in extracting the soil, previously freed from calcium salts, with dilute ammonia. The solution is evaporated and the residue dried to constant weight in a platinum dish, the contents are then ignited and the dish weighed. The author has found that this process is not trustworthy, as the soil contains soluble organic matter which gradually combines with the ammonia, thus increasing the weight.

The use of a 4 per cent solution of potassium hydroxide has also been tried for the purpose of extracting the humus after first extracting the calcium salts with dilute hydrochloric acid. It was found, however, that aqueous potassium hydroxide liberates ammonia from the soil and that part of this enters into combination with the organic matter whilst another small portion escapes, so that the estimation of nitrogen contained in the humus gives results below the truth. The last source of error may be prevented by leaching the soil with 4 per cent. solution of aqueous potassium hydroxide in a funnel which is closed at the top with a stopper through which the leaching solution is admitted by a separating funnel. The glass support of a Gooch crucible serves very well for the funnel holding the soil. The solution from the soil is run directly into dilute sulphuric acid, the bottle containing this being sealed with a U-tube containing sulphuric acid. Gentle suction may be applied to hasten the process. It is also stated that humus is not quite insoluble in even very weak hydrochloric acid.

L. DE K.

Detection of Albumin in Urine. By ADOLF JOLLES (*Zeit. anal. Chem.*, 1900, 39, 146—147).—With certain urines poor in chlorides, the author's mercuric succinate test for albumin (*Abstr.*, 1896, 344) has proved to be deficient in sensitiveness unless sodium chloride is also added. It is therefore recommended that the amount of sodium chloride in the reagent should be doubled. In making the comparative test, water is added to the acidified urine instead of the reagent. The presence of mucin or nuclealbumin does not interfere with this test.

M. J. S. Q

General and Physical Chemistry.

Effects of Dilution, Temperature, and other Circumstances on the Absorption Spectra of Solutions of Didymium and Erbium Salts. By GEORGE D. LIVEING (*Trans. Camb. Phil. Soc.*, 1900, 18, 298—315).—Except for a slight difference in the absorption at the more refrangible end, the spectra of the different salts of the same metal in dilute solution are similar. For the chloride and sulphate, the spectrum is the same in different dilutions, so long as the thickness of absorbent is proportional to the dilution: the spectrum of nitrate solutions is modified slightly with increasing concentration. The first of these facts is in accord with Ostwald's view that the spectrum common to all the salts is due to the metallic ions, but the second is against this interpretation: so also is the fact that the intensity of the didymium and erbium bands is not affected by rise of temperature or by addition of the acid with the same negative ion. The author regards the metallic bands as the outcome of chemical actions between the molecules of the salt and of the solvent, whilst the general absorption at the more refrangible end may be due to encounters of molecules without chemical change. A certain interval of freedom is postulated between the rupture of a molecule and the recombination of its parts with each other or with parts of other molecules; during this interval, the parts have a capability of vibrating such as they do not possess in combination. Increased concentration and higher temperature will mean more frequent ruptures, more frequent recombinations, and shortening of the interval of freedom. These effects will compensate each other, and leave the average number of absorbent parts independent of the concentration and the temperature.

When alcohol or glycerol is the solvent, the bands are more diffuse and generally shifted towards the red. When dry hydrogen chloride is passed into the alcoholic solution, the colour changes from pink to bluish-green. The paper is illustrated by reproductions of the photographs obtained.
J. C. P.

Phosphorescence of Phosphoric Oxide. By HERMANN EBERT and BERTHOLD HOFFMANN (*Zeit. physikal. Chem.*, 1900, 34, 80—86).—Phosphoric oxide is capable of phosphorescence in a high degree, and it retains this property even when all impurities, such as the lower oxides, are carefully excluded. The commercial preparation after illumination shows, in addition to the greenish phosphorescence characteristic of the pentoxide, a pale glow, due probably to oxidation of the lower oxides present. The spectrum of the light emitted by the pure pentoxide is continuous, with a maximum intensity in the green, and the phosphorescence is much more intense at lower temperatures.
J. C. P.

Relation between the Constitution and Fluorescence of some Substances. By JOHN THEODORE HEWITT (*Zeit. physikal. Chem.*, 1900, 34, 1—19).—A fluorescent substance absorbs light of one wave-length, and emits light of another wave-length, so that two distinct sets of vibrations are involved. The author points out that for a compound which can exist in two tautomeric forms, and thus oscillates between two positions, the condition of fluorescence will most probably be satisfied. The most favourable cases would be those where there is a doubly symmetrical tautomerism, and consideration of a number of these shows that such compounds exhibit strong fluorescence. The various classes of fluorescent substances are considered in the order adopted by Meyer in his paper on the same subject (*Abstr.*, 1898, ii, 105). There are substances which, whilst possessing the requisite constitution, show no fluorescence; in such cases, it is possible (1) that the light emitted is beyond the visible part of the spectrum, or (2) that there is a secondary tautomerism which hides the primary. On the other hand, there are fluorescent substances which do not possess a doubly symmetrical tautomeric structure; in such cases, there may be a high velocity of transition from the one form to the other.
J. C. P.

Uranium Radiation. By HENRI BECQUEREL (*Compt. rend.*, 1900, 130, 1583—1585).—Part of the photographically active radiation from uranium is deflected in a magnetic field in the same direction as cathode rays.

When a small quantity of a barium salt is added to a uranium solution and then precipitated in the form of sulphate, the precipitate shows marked radioactivity, and hence it would follow that uranium commonly contains small quantities of a highly radioactive substance, probably actinium. At the same time, the most carefully purified uranium and its compounds still show radioactivity, and the extreme products of a long series of fractionations of uranium nitrate by Lecoq de Boisbaudran show identical radioactivity, whether it is measured by photographic effect or by its influence in promoting electrical discharge.
C. H. B.

Uranium Radiation. By HENRI BECQUEREL (*Compt. rend.*, 1900, 131, 137—138. Compare preceding abstract).—When solutions of uranium salts were treated with barium chloride and the barium subsequently precipitated as sulphate, the precipitate carried down a radioactive substance emitting rays which are deviated in the magnetic field. On repeating the precipitation, further quantities of this product were removed from the uranium solution, the amount decreasing with each successive operation. The uranium salt, when thus treated, was found to be less active, but the diminution in its activity decreased as the precipitations were repeated until, after the twelfth operation, its emissive power became approximately constant. The precipitations were still continued, but the variations were now found to be irregular, the uranium obtained after eighteen operations being decidedly less active than that from the twelfth. The rays emitted from the crude salt penetrate aluminium more readily than glass, whereas the converse holds with the radiations derived from the

purified compound. The electrical conductivity of air, as induced by the rays from uranium, is diminished by one-half after twelve precipitations, and its value is only one-sixth of the original after the eighteenth operation.

Photochemical Effects produced by the Hertzian Radiating Wire. By THOMAS TOMMASINA (*Compt. rend.*, 1900, 130, 1462—1465).—Luminous effects were observed about the radiating wire and these were photographed by placing the wire in direct contact with the sensitised gelatin plate. Illustrations are given showing the peculiar nature of the luminous radiations, and of the effect on them of iron and other metals, as well as of the differences resulting when the wire is sufficiently tense to also produce sound vibrations.

L. M. J.

Modification of Metallic Surfaces under the Influence of Light. By H. BUISSON (*Compt. rend.*, 1900, 130, 1298—1300).—It is well known that metals exposed to ultra-violet radiations rapidly lose negative charges of electricity, being in this respect far more active when freshly cleaned. Light, however, causes a decrease of this activity, which is regained when the metal is kept for some time in the dark; this effect is very marked for amalgamated zinc. There is also a difference of potential between the surfaces of a darkened and illuminated metal, which may reach 0.125 volt. Most metals are more electro-negative after illumination, but the reverse obtains for platinum, whilst gold, silver, and iron are not affected. Red or yellow glass cuts off the rays effecting this change, but colourless glass does not, whilst ultra-violet rays have a reverse effect, so that the electric arc has little effect if not screened by colourless glass. The wavelength of the rays which separate the radiations thus acting in opposite directions is, for zinc, about 0.310μ . The action is not affected by the external atmosphere, similar results being obtained in hydrogen, carbon dioxide, &c. Amalgamated zinc, exposed to light through a screen and then exposed to iodine vapours, was also found to be least attacked in the illuminated portions, and hence to give an image of the screen.

L. M. J.

Brazilin and Hæmatoxylin as Photographic Developers. By ROBERTO LEPETIT (*Bull. Soc. Chim.*, 1900, [iii], 23, 627—631).—Hæmatoxylin and brazilin, dissolved in aqueous sodium hydroxide, rapidly absorb atmospheric oxygen; the relative rapidity of absorption in the case of pyrogallol, quinol, hæmatoxylin, brazilin, and catechol is, with equal concentrations, given by the numbers 5:15:25:30:40. The rapidity with which the substances develop a photographic plate under similar conditions is determined by a similar ratio; pyrogallol, however, although more rapid than quinol, leaves the plate under developed to a greater extent than the latter. Catechol is wholly unsuitable for use as a developer.

W. A. D.

Refutation of [Poynting's Theorem]. By P. S. WEDELL-WEDELLSBORG (*Zeit. physikal. Chem.*, 1900, 33, 631—635. Compare *Abstr.*, 1898, ii, 61).—A continuation of the author's previous papers on this subject, in which he holds that Poynting's theorem is erroneous on the following grounds. It is not in accord with the fundamental

laws of energy, with experimental results, with the laws of induction, and with modern theories of electrolysis. L. M. J.

Thermodynamics of Normal Cells. I. By ERNST COHEN (*Zeit. physikal. Chem.*, 1900, 34, 62—68).—On the basis of the equation $E = E_c/ne_0 + T.dE/dT$, and from the electrical measurements of Kahle, Jaeger and Wachsmuth, and of Callendar and Barnes, the author shows that the usual way of representing the process that goes on in the Clark cell is inadequate. Instead of $\text{Zn} + \text{Hg}_2\text{SO}_4 \rightleftharpoons 2\text{Hg} + \text{ZnSO}_4$, the essential change is represented by the equation

where A is the number of water molecules present for every one of ZnSO_4 in the saturated solution. If this is regarded as the true mechanism of the reaction, then thermochemical data give $E_c = 81127$ cal., whilst the electrical measurements give $E_c = 81490$ cal. Similarly, in the case where the zinc sulphate is present as hexahydrate, E_c from thermochemical sources is shown to be 75159 cal., whilst the electrical measurements lead to the value 75677 cal. J. C. P.

The Weston Cell as a Transition Cell and as a Standard of Electromotive Force, with a Determination of the Ratio to the Clark Cell. By H. T. BARNES (*J. Physical Chem.*, 1900, 4, 339—348).—The E.M.F.'s. of a number of Weston cells were determined at temperatures varying from 0 to 40°. Above 15°, the values of the temperature were in good accord with the formula $E_t - E_{15} = -0.086(t - 15^\circ)$, the values being in millivolts. Below 15°, the values were not concordant; the curves representing the E.M.F. as a function of temperature, however, all converged to 15° and agreed above this temperature. Experiments to see if a sudden change in the E.M.F. may occur below 15° led to varying results; in some cells, a rapid increase occurred in the neighbourhood of 2°, in others the rise of the E.M.F. was continuous. The ratio of the E.M.F. of the Weston cell at 20° to that of the Clark cell at 15° was found to be 1.40658, agreeing very closely with the ratio 1.40663 found by Dr. Kahle for the standard cells in the possession of the Reichsanstalt. L. M. J.

New Electrolytic Cell for Rectifying Alternating Currents. By W. L. HILDBURGH (*J. Amer. Chem. Soc.*, 1900, 22, 300—304).—The cell $\text{Cu} | \text{H}_2\text{SO}_4 | \text{Pt}$ allows currents of low voltage to pass if the copper is employed as the anode, but if the current is reversed owing to the high polarisation, no current passes if the voltage is not too great, and hence such a cell may be used as a rectifier for low voltage alternating currents. This is not a very efficient arrangement, however, and a better form consists of a plate of platinised platinum (A), partly in sulphuric acid, partly in hydrogen, and a platinum wire (P) sealed into glass under the acid; the whole is contained in a sealed vessel. Currents may pass from A to P, generating hydrogen at P, which escapes in bubbles joining the gas above the acid; in the opposite direction, however, polarisation occurs, P becoming coated with a film of oxygen. For high E.M.F.'s, a number of these cells in series may be employed. L. M. J.

Reversible Electrodes of the Second Order with Mixed Depolarisers. By A. THIEL (*Zeit. anorg. Chem.*, 1900, 24, 1—64).—The electrodes dealt with are of silver, and the depolarisers used are (1) mixed silver chloride and bromide, (2) mixed silver bromide and iodide. The equilibrium between silver chloride and bromide when precipitated together from mixed solutions of potassium chloride and bromide by a quantity of silver nitrate insufficient for complete precipitation has been studied by Küster (Abstr., 1899, ii, 205); the author has now made a similar investigation with mixed bromide and iodide. He concludes that silver chloride and bromide mix in all proportions, whilst silver bromide and iodide are miscible only within certain limits. In agreement with this, an electrode of the second order, with mixed silver chloride and bromide as depolariser, shows a 'mixed potential,' that is, a potential between the values obtained when the depolariser is pure chloride or bromide; the absolute value of the potential depends on the relative proportions of chloride and bromide. When the depolariser, on the other hand, is mixed bromide and iodide, the electrode shows the potential corresponding with the more soluble depolariser, so long as it is present. The values obtained for the solubility of the silver halogen salts agree well with those of Goodwin (Abstr., 1894, ii, 305). J. C. P.

Determination of Electrical Conductivity with Direct Current Instruments. By J. LIVINGSTON R. MORGAN and W. L. HILDBURGH (*J. Amer. Chem. Soc.*, 1900, 22, 304—307).—By the use of the rectifier described by Hildburgh (this vol., ii, 520), the resistance of electrolytes may be found, using a galvanometer or ammeter in place of the telephone. The method described by the authors is a substitution method; an alternating current passes through the liquid of which the resistance has to be determined, then through a set of resistance coils the terminals of which are also connected through the rectifier and a galvanometer. The reading of this instrument is noted, and the electrolyte replaced by a variable resistance which is adjusted until the same reading is observed. A more sensitive arrangement may be obtained by a differential wound galvanometer, one set of coils being in circuit with one rectifier, and the second similar opposed coils in circuit with a rectifier in the opposite direction. L. M. J.

Electrolytic Deposition of Metals from Non-aqueous Solutions. By LOUIS KAHLBERG (*J. Physical Chem.*, 1900, 4, 349—354).—In order to test whether Faraday's law is valid for non-aqueous solvents, solutions of silver nitrate in pyridine, aniline, phenyl cyanide, and quinoline were electrolysed, and the weight of silver deposited compared with that deposited from an aqueous solution in the same circuit; the weights respectively were as follows, those from the aqueous solutions being given first: 0.7836 gram, 0.7819 gram; 0.1788 gram, 0.1780 gram; 0.1612 gram, 0.1603 gram; 0.2501 gram, 0.2452 gram. In the quinoline solution, there was evidence of a complicated reaction, as the silver was carbonaceous; in the other solvents, it was firm and white. Experiments with lead and antimony gave very similar results. The work must be con-

sidered as preliminary, but it certainly tends to show that Faraday's law is valid for the non-aqueous solutions. It was found also that silver can be completely deposited in a compact white form from solutions in pyridine, or in aqueous pyridine by a current of density of from 0.17 to 0.25 ampere per 100 sq. cm. cathode area.

L. M. J.

Electrolysis of the Alkali Salts of Organic Acids. By JULIUS PETERSEN (*Zeit. physikal. Chem.*, 1900, 33, 99—120, 295—325, 698—720).—Compare Abstr., 1898, i, 352.

J. C. P.

Electrolysis through Semipermeable Membranes. By B. MORITZ (*Zeit. physikal. Chem.*, 1900, 33, 513—528).—The system, cathode | CuSO_4 solution | membrane 1 | K_4FeCy_6 solution | membrane 2 | CuSO_4 solution | anode, was electrolysed, and the polarisation was determined at membrane 2, where the semipermeable ferrocyanide was formed. The polarisation for primary currents of less than 0.3 milliampere was found to steadily increase and reach a maximum of 0.22 volt; with stronger currents, however, much higher values are attained. A formula is given for the polarisation as a function of time and its final maximum value, and is seen to satisfactorily reproduce the experimental values. A maximum of 1.006 volt was obtained for a primary current of 7.95 milliamperes per square centimetre, and the relative rates of change of polarisation and primary currents were found for various currents. Changes in the concentration of the solutions have but little effect on the polarisation, both in the above system and in that in which zinc sulphate replaces the copper sulphate. At first the copper ferrocyanide forms as a colourless film, this being most probably a supersaturated solution, and with weak currents this may remain for some hours, then becoming coloured brown with precipitation of the ordinary salt, whilst later, if the primary current exceeds about 0.2 milliampere per sq. cm., copper is precipitated. In the case of the zinc salt, however, this precipitation of the metal was not found to occur.

L. M. J.

Conductivity of Aqueous Solutions of Hydrochloric and Sulphuric Acids. By JAMES BARNES (*Trans. Nova Scot. Inst. Sci.*, 1900, 10, 129—138).—The author has calculated, by the method described by MacGregor (this vol., ii, 332), the conductivity of mixed solutions of hydrochloric and sulphuric acids, the assumption being made that the latter in moderately dilute solutions, as it does in very dilute solutions, dissociates into H and SO_4 ions. In the case of the solutions of from N to $2N$ concentrations, the calculated values are greater than those directly determined, whilst the reverse obtains for dilute solutions, but the differences in the latter case being almost within the experimental errors, the author considers that to seminormal concentrations the conductivity can be accurately calculated by Macgregor's method.

L. M. J.

Degree of Dissociation and Dissociation Equilibrium of Highly Dissociated Electrolytes. By HANS JAHN (*Zeit. physikal. Chem.*, 1900, 33, 545—576).—The determination of the degree of

dissociation by conductivity experiments involves the assumption that the ion velocities are independent of concentration: an assumption which has not been experimentally justified. The ion concentrations may, however, be compared by E.M.F. determinations, and in this case variations of velocity produce no effect. The author therefore determined the ion concentrations in solutions of potassium chloride, and by use of Kohlrausch's values for the conductivity obtained the ratios of the ion velocities at different concentrations. The velocity was found to decrease on dilution, so that ion concentrations calculated by the dilution law are necessarily too high, and values for E.M.F.'s calculated from the conductivity are considerably higher than the experimental values. The velocity had not reached its minimum at the concentration $N/300$, so that the ratio μ/μ_{∞} as a measure of dissociation is only valid for exceedingly dilute solutions. The values for the dissociation constant, as calculated from the conductivity values, also on this account decrease with dilution, but assuming complete dissociation at $N/600$, the values found from the E.M.F. determinations give a fairly constant value for the dissociation constant, the numbers varying irregularly from 0.14 to 0.10. Similar experiments were made and similar results obtained for solutions of sodium chloride and hydrogen chloride, and these elucidate the cause of the divergences from Ostwald's dilution law in the case of strong electrolytes.

L. M. J.

Electrochemical Equivalent of Carbon. By SIDNEY SKINNER (*Proc. Camb. Phil. Soc.*, 1900, 10, 261—267).—When a solution of potassium permanganate is electrolysed with a carbon anode, 77—86 per cent. of the gas liberated at the anode consists of carbon dioxide, the rest being carbon monoxide and oxygen. The total volume of gas liberated is nearly the same as the volume of oxygen liberated by the same current in a dilute sulphuric acid voltameter; the permanganate ion persists in solution even although a quantity of electricity more than sufficient for its complete decomposition is passed through the cell. The author finds the electrochemical equivalent of carbon to be three times that of hydrogen.

A cell may be constructed with a carbon rod in potassium permanganate, and a lead peroxide plate in dilute sulphuric acid, the two electrolytes being separated by a porous pot: the E.M.F. is 0.33 volt, and acts externally from the lead peroxide to the carbon. In this self-acting system, carbon is consumed at the ordinary temperature.

J. C. P.

Thermo-electrical Properties of Alloys. By ÉMILE STEINMANN (*Compt. rend.*, 1900, 130, 1300—1303).—The thermo-electromotive forces of junctions of pure lead with various alloys were determined, the alloys employed being ten varieties of nickel-steel, four of platinum-iridium, three of aluminium-bronze, five of bronze, five of brass, and four of German silver. The determinations were made with the hot junction at 55°, 95°, 140°, 195°, and 260°, the cold junction being in all cases at 0°. Tables of the values contained are given, and it is seen that the curves of the E.M.F. of the alloys would always lie either entirely within or entirely without those of the pure components, but the

position of the curve cannot be calculated from the percentage composition. No simple rule appears to connect the E.M.F. with the composition, and very small quantities of one metal may change very considerably the E.M.F. of another, this being very marked in the case of the addition of nickel to iron.

L. M. J.

Thermo-electricity of Certain Alloys. By ÉMILE STEINMANN (*Compt. rend.*, 1900, 131, 34).—Nickel steel containing 36.1 per cent. of nickel has between 0° and 100° an E.M.F. of -2461 microvolts; the E.M.F. developed from a specimen containing 28 per cent. of this metal between 20° and 260° is 385—386 microvolts, lead being in both cases the standard of comparison.

G. T. M.

Transparency of various Liquids to Electric Oscillations. By A. DE HEEN (*Compt. rend.*, 1900, 130, 1460—1461).—The liquids examined may be thus divided with regard to their transparency to electric oscillations: opaque—water, ethyl alcohol, amyl alcohol, aldehyde, carbon disulphide, ethyl bromide; transparent—ether, petroleum, benzene, xylene, butyric acid, valeric acid. For pure liquids there appeared to be no gradation, the liquid being either almost completely opaque or completely transparent, but with mixtures gradation may be obtained; 8 per cent. of alcohol reduces the transparency of ether to one-half, and 30 per cent. renders it quite opaque.

L. M. J.

Electromagnetic Rotation of the Plane of Polarisation in Solutions of Salts and Acids. By J. FORCHHEIMER (*Zeit. physikal. Chem.*, 1900, 34, 20—30).—Perkin has found that with falling concentration the molecular rotation of sulphuric acid solutions diminishes, whilst that of hydrochloric acid solutions increases. Oppenheimer (*Abstr.*, 1899, ii, 139) has shown that the molecular rotation of alkali bromides and chlorides is independent of the concentration of the solution. The author confirms Perkin's observations as to the acid solutions, and finds that the molecular rotation of ammonium, sodium, and magnesium sulphates is independent of the concentration, whilst that of lithium sulphate increases with falling concentration. Lithium chloride, as noticed by Perkin (*Trans.*, 1894, 65, 20), and confirmed by the author, behaves in a similar fashion. The molecular rotation of cadmium bromide and iodide does not vary with the concentration of the solutions, and is therefore independent of the electrolytic dissociation.

J. C. P.

Permanent Change and Thermodynamics. By PIERRE DUHEM (*Zeit. physikal. Chem.*, 1900, 33, 641—697).—A mathematical paper not suitable for abstraction.

J. C. P.

Specific Heats of Metals and the Relation of Specific Heat to Atomic Weight. By WILLIAM A. TILDEN (*Phil. Trans.*, 1900, A, 194, 233—255).—The specific heats of pure cobalt and pure nickel have been determined in Joly's steam calorimeter. The atomic weights and densities of these metals are close together, but the mean specific heat of cobalt between 15° and 100° is 0.10303, and that of nickel 0.10842. If 58.55 and 58.24 are taken as the atomic weights of

cobalt and nickel respectively, the corresponding atomic heats are 6.03 and 6.31. In the case also of gold and platinum, two metals whose atomic weights and densities are not very different, the atomic heats have quite different values, so that Dulong and Petit's law is not strictly applicable.

Determinations of the specific heat of various specimens of iron and copper show that the presence of a non-metallic impurity raises the specific heat of a metal; a non-metal as impurity has much more influence than a metal which produces little effect until the quantity is large enough to make itself felt through the difference in atomic weight.

A series of experiments have been made with cobalt and nickel at the temperatures of solid carbon dioxide (-78.4°), and boiling oxygen (-182.5°). The mean specific heats of the two metals for the various ranges of temperature are as follows:

Range.	Specific heat.	
	Cobalt.	Nickel.
100° to 15°	0.10303	0.10842
15° „ -78.4°	0.0939	0.0975
15° „ -182.5°	0.0822	0.0838
By calc. -78.4° „ -182.5°	0.0712	0.0719

It is seen that the specific heat of nickel falls more rapidly than that of cobalt, and that the two specific heats approach each other. For the range last given, the mean atomic heat of both metals would be 4.

J. C. P.

Specific Heats of Fluids. By ÉMILE H. AMAGAT (*Compt. rend.*, 1900, 130, 1443—1447).—The pressure coefficient of the specific heat at constant volume is given by the expression $dc/dp = -AT.d^2v/dt^2$, and from the complete set of isothermals for carbon dioxide between 0° and 260° , and from 1 to 1000 atmos., the author has constructed the curves for d^2v/dt^2 for various temperatures and pressures from which the variations of the specific heat at constant volume can be deduced. The curves show that this constant increases with pressure, reaches a maximum, and then decreases, the pressure at which the maximum occurs increasing with temperature. Below the critical temperature, the curve consists of two separated portions, and the author gives a form of expression for the calculation of the difference between the specific heats in the liquid and gaseous states.

L. M. J.

Thermal Conductivity of Nitrogen Peroxide as affected by Change of Temperature and Pressure. By GAETANO MAGNANINI and V. ZUNINO (*Gazzetta*, 1900, 30, i, 405—435. Compare Magnanini and Malagnini, *Abstr.*, 1898, ii, 282).—The former experiments (*loc. cit.*) on the thermal conductivity of air, hydrogen, carbon dioxide, and nitrogen peroxide are extended to pressures greater than that of the atmosphere. The results show that, as before, air, hydrogen, and carbon dioxide obey Newton's law, the expression $1/t \cdot \log.(d_1 - d_0/d - d_0)$ having a constant value. For nitrogen peroxide, which dissociates on heating, this is not the case, but the numbers obtained are in complete accord with the kinetic theory of gases. Thus, at high temperatures,

the conductivity of nitrogen peroxide is less than that of hydrogen, whilst for temperatures at which the change in the amount of dissociation is greatest, the conductivities of the two gases are about equal.

T. H. P.

Effect of very Low Temperatures on the Colour of Compounds of Bromine and Iodine. By J. H. KASTLE (*Amer. Chem. J.*, 1900, 23, 500—505).—On cooling to the temperature of liquid air, a marked decrease occurs in the intensity of colour of lead iodide, phosphorus pentabromide and heptabromide, mercuric bromiodide, iodoform, benzenedibromosulphonamide, tribromophenol bromide, mercuric iodide, bromine, iodine in solution in alcohol or carbon disulphide, sulphur, red-phosphorus, chrome alum, manganous chloride, chromic chloride, and alkaline alcoholic solutions of phenolphthalein and *p*-nitrophenol: the colour in many cases disappears altogether. No change was observed in the colour of solid iodine and of hydrated copper sulphate.

T. M. L.

Minimum in the Molecular Lowering of the Freezing Point of Water, produced by Certain Acids and Salts. By VICTOR J. CHAMBERS and JOSEPH C. W. FRAZER (*Amer. Chem. J.*, 1900, 23, 512—520. Compare Jones and Chambers, *this*, vol., ii, 262).—Minima in the molecular lowering of the freezing point of water occur in the case of phosphoric acid at about 0.5*N*, hydrochloric acid and sodium acetate between 0.1*N* and 0.2*N*, zinc chloride and strontium iodide at about 0.1*N*, and a less defined minimum in the case of copper sulphate at about 0.9*N*.

T. M. L.

Depression of the Freezing Point by Mixtures of Electrolytes. By JAMES BARNES (*Trans. Nova Scot. Inst. Sci.*, 1900, 10, 139—161).—In order to test Macgregor's formulæ (this vol., ii, 332), the author has compared the freezing point depressions in the case of mixtures of potassium, sodium, and hydrogen chlorides with those obtained by calculation by Macgregor's method. The details of the experiments are given, and it is seen that the author's results for the separate solutions agree well with those of Loomis. The values found for double and triple mixtures agree well with those calculated, and hence indicate the availability of the formulæ in question. L. M. J.

Heat of Neutralisation of Hydrogen Peroxide by Lime. By ROBERT DE FORCAND (*Compt. rend.*, 1900, 130, 1250—1251. Compare *this* vol., ii, 277).—The heat production, due to the addition of a solution of lime to solutions of hydrogen peroxide of varying concentration, was determined. Curves for heat produced against concentration of hydrogen peroxide were found to consist of three straight lines meeting at points corresponding with $\text{CaO}, 2\text{H}_2\text{O}_2$ and $\text{CaO}, 10\text{H}_2\text{O}_2$. The former indicates the production of the peroxide $\text{CaO}_2, \text{H}_2\text{O}_2$, or $\text{Ca}(\text{O} \cdot \text{OH})_2$, and the heat of formation is calculated as 7.42 Cals.

L. M. J.

Heat of Dissolution of Hydrogen Peroxide: Thermal Value of the Hydroxyl Function; Influence of Hydrogen and Carbon. By ROBERT DE FORCAND (*Compt. rend.*, 1900, 130, 1620—1622).—Hydrogen peroxide solutions containing from 35.31 to

85.93 per cent. of the peroxide gave heats of dissolution ranging from +0.071 Cal. to +0.403 Cal., and the curve representing these results shows that there is a definite hydrate of the composition $\text{H}_2\text{O}_2 + \text{H}_2\text{O}$, whilst the heat of dissolution of the pure peroxide is +0.46 Cal. It follows that

The heat of fusion calculated from that of water is -2.70 Cal., and the same value is obtained by taking the mean heat of fusion of water and glycerol.

Combining these results with the known results of the action of hydrochloric acid on sodium hydroxide and peroxide and the action of sodium on water, it follows that

$\text{H}_2\text{O}_2 \text{ sol.} + \text{Na}_2 \text{ sol.} = \text{H}_2 \text{ gas} + \text{Na}_2\text{O}_2 \text{ sol. develops } +63.15 \text{ Cal.}$, and hence the mean thermal value of the hydroxyl function in the solid state is +34.07 Cal. Comparison with the corresponding values in the case of glycol leads to the conclusion that this value is affected by the proximity of various elements, or groups of elements, in the same molecule.

C. H. B.

Acidity of Alcohols. By ROBERT DE FORCRAND (*Compt. rend.*, 1900, 130, 1768—1761. Compare preceding abstract).—In a former communication, the author expresses the acidic functions of water, hydrogen peroxide, and glycol in terms of the heat developed when the hydroxylic hydrogen is replaced by metallic sodium, the values for H_2O , $\frac{1}{2}\text{H}_2\text{O}_2$, and $\frac{1}{2}\text{C}_2\text{H}_4(\text{OH})_2$ being +31.19, +34.07, and +31.32 Cal. respectively. By subtracting the second of these constants from the third, the number -2.75 is obtained; this quantity is characteristic of the group CH_2 , and is called its "coefficient of influence."

The coefficients of influence of carbon, hydrogen, methyl, and methenyl CH are deduced in a similar manner, their values being +3.01, -2.88, -5.63, and +0.13 Cal. respectively.

By applying this reasoning to the homologous series of alcohols, the coefficients +28.4, +25.69, and $(28 - 2.75 \times n)$ are obtained respectively for the first two members and the general term. It follows from this that the C_4 alcohol should not possess any acidity; this, however, is not the case, and the anomaly probably arises from the fact that the calculated coefficients of the two lowest members are less than the experimental values. Moreover, in straight chain compounds, the influence of a radicle probably diminishes as the distance from the hydroxyl group increases. The latter hypothesis is confirmed by a thermochemical study of the acidity of trimethylcarbinol and malonic and succinic acids. The calculated difference between the acidities of malonic and succinic acids is 1.375 Cal., whereas the actual difference is only 0.730 Cal., or 1.375×0.535 Cal. Similarly, the difference between the observed acidity of trimethylcarbinol and the calculated value for $\text{C}\cdot\text{OH}$ should be 3×5.63 Cal.; it is, however, only $3 \times 5.63 \times 0.585$ Cal. Taking 0.56 as the mean factor of correction, this quantity is employed in accordance with the following rule.

When an acidic group is situated in an open chain compound, the

influence of any other radicle of the compound on the acidity is only 0.56% of what it would be if this radicle were directly attached to the acidic group.

When this correction is applied to the alcohols, the calculated values of the coefficients of acidity approximate fairly closely to those obtained by direct experiment. G. T. M.

General Theory of Acidity. By ROBERT DE FORCRAND (*Compt. rend.*, 1900, 131, 36—40. Compare preceding abstracts).—In extending the generalisations put forward in two previous communications, the author calculates the "coefficients of acidity" and "influence" for a series of organic and inorganic radicles. The calculated coefficients agree fairly closely with those determined experimentally, and although this theory of acidity is still incomplete, it should be possible, knowing the constitution of any compound containing acidic hydrogen, to deduce by the aid of the "coefficients of influence" either the acidity or the heat of fusion of the substance. The coefficients of acidity of carboxyl and hydroxylic hydrogen are +52.62 and +18.43 Cal. respectively; the coefficients of influence of carbonyl, hydroxylic oxygen, sodium, and sodoxyl, NaO, are +18.55, +15.54, -45.70, and -30.16 Cal. respectively. The calculated acidities of (solid) propionic, *n*-butyric, and *n*-valeric acids are +49.32, +49.23, and +49.20 Cal. respectively, whilst the experimental values for the first two in the liquid state are +52.46 and +52.36 Cal. The experimental and calculated values for malonic, succinic, and glyoxylic acids are practically identical. The coefficients of influence of sulphur, nitrogen, and phosphorus in their oxy-acids are +16.79, +2.25, and +30.39 Cal. respectively. The acidity of formic and oxalic acid is abnormally high, the calculated values of this constant being +51.01 and +52.62, whilst the experimental numbers are 53.69 and 57.70, respectively. This abnormal acidity may be due to association. The theory of acidity cannot, however, be applied to cyanogen derivatives and hydracids.

G. T. M.

Temperature Coefficient of Ester Hydrolysis. By T. SLATER PRICE (*Öfvers. K. Vet. Akad. Stockholm*, 1899, 56, 921—934).—The rate of hydrolysis of a number of esters in presence of *N*/4 hydrochloric acid has been determined at various temperatures from 0° to 50°. The results obtained agree closely with those required for the formula $\log k = -A/T + B$, and are summarised in the following table:

Ester.	Value of <i>A</i> .	<i>k</i> at 40°.
Methyl acetate.....	8663	0.006397
Ethyl acetate	8695	0.006485
Propyl acetate	8586	0.006497
<i>iso</i> Butyl acetate	8746	0.006461
Methyl propionate	8273	0.006898
Propyl formate	7409	0.01554

The value of *A* for esters of the same acid is the same; for esters of the same alcohol, *A* varies (compare Hemptinne, *Abstr.*, 1894, ii, 274; Löwenherz, *Abstr.*, 1895, ii, 107). J. C. P.

Vapour Pressure Relations in Mixtures of Two Liquids. I. and II. By A. ERNEST TAYLOR (*J. Physical Chem.*, 1900, 4, 290—305 and 355—369).—The boiling points and composition of the vapour were determined for mixtures of acetone and water at various pressures. The first paper contains only an account of the methods employed. The author shows that superheating is very difficult to avoid, and considers that sufficient precautions have not been taken in the past, especially as the superheating can frequently only be detected by varying the conditions of the experiment. A mixture of garnets with platinum or silver tetrahedra was found to be most effective for preventing superheating, but these, or any other substance used for the same purpose, must be present in large quantities, their volume being at least one-half that of the liquid.

The second paper contains solely the vapour pressure curves and the numerical data for mixtures of acetone and water, all theoretical considerations and the discussions being postponed to a later paper. Some points are, however, noticeable; for example, the great steepness of the acetone curve compared with that of water, so that the curves are much closer at low temperatures and spread out as the temperature rises. Further, the composition of the vapour at low concentrations is markedly different from that of the solution. Thus, when the solution contains about 10 per cent. of acetone, the vapour contains 80 per cent. These points, however, will probably be fully discussed in later papers. L. M. J.

Absorption of Nitrogen and Hydrogen by Aqueous Solutions of Dissociating Substances. By LEONHARD BRAUN (*Zeit. physikal. Chem.*, 1900, 33, 721—739).—The author has determined the absorption coefficients of nitrogen and hydrogen at temperatures between 5° and 25° for aqueous solutions of the non-electrolytes, carbamide, and propionic acid, and the electrolytes, sodium and barium chlorides. The relation $C_1/C_2 = 1$, where C_1 is the molecular concentration of the gas in pure water, C_2 that in the solution of an indifferent substance, at the same temperature and partial pressure, is satisfied in the case of carbamide and propionic acid, but is quite inapplicable to sodium and barium chlorides. For the solutions of the latter compounds, the empirical relation $(\alpha - \alpha')/Gm^{2/3} = \text{const.}$ is found to hold; here α and α' are the absorption coefficients in water and solution respectively, whilst Gm is the number of gram-molecules per unit of volume.

Compare the results obtained by Steiner (Abstr., 1894, ii, 345), Gordon (Abstr., 1896, ii, 154), and Roth (Abstr., 1898, ii, 18).

J. C. P.

Temperature of Maximum Density of Solutions of Ammonium Chloride, Lithium Bromide, and Lithium Iodide. By LOUIS C. DE COPPET (*Compt. rend.*, 1900, 131, 178. Compare Abstr., 1899, ii, 590).—The results are exhibited in tabular form. G. T. M.

Isohydic Solutions. By WILDER D. BANCROFT (*J. Physical Chem.*, 1900, 4, 274—289).—It is commonly considered that by the mixing of isohydric solutions, no dissociation change occurs, and similar considerations have been applied to dissociation in gases, that

is, the dissociation is supposed to be unaltered by the addition of one of the products of dissociation at the same pressure as its partial pressure in the system, also termed "isohydric." These considerations have, however, only limited validity as considered from the point of view of the mass-action law; it is shown that by the addition of "isohydric" hydrogen to a dissociated system of hydrogen iodide, the dissociation is decreased, whilst the addition of isohydric carbon dioxide to ammonium carbamate causes an increase of dissociation. The general case is investigated, and it is deduced that if the dissociation is represented by $aA = bB + cC + \dots mM$, and isohydric B is added, the dissociation is unchanged, decreased, or increased according as a is equal to, greater, or less than $b + c + \dots m - b$. Similar considerations hold for electrolytic dissociation; if the dissociation be $A_1 = bB_1 + cC_1 + eE_1$, and $A_2 = fB_1 + gC_2 + \dots hM_2$, then the dissociation will be unchanged if $b + c + \dots e = 1$ and $f + g + \dots h - f = 1$, but if either of these expressions be greater than unity, the dissociation of the corresponding salt will be increased, and conversely. In the case of strong electrolytes, the mixture of isohydric solutions must generally be accompanied by dissociation changes. It is calculated that by the mixture of equal volumes of $N/100$ solutions of potassium and sodium chlorides, a decrease of dissociation should occur for each salt; conductivity experiments, however, showed an increase of dissociation. This is apparently not in accord with Arrhenius' results (this vol., ii, 201), but the discrepancy is explicable in view of the results obtained by Jones and Knight, which prove that dissociation is decreased by the mixture of strong solutions, but increased by the mixture of dilute solutions of potassium and ammonium chlorides (Abstr., 1899, ii, 628). The results are still not in accord with the theoretical deductions, and it is possible that the explanation has to be sought for in the effect of the undissociated products on dissociation.

L. M. J.

Solubility of Mixtures of Salts having one Common Ion. By CHARLES TOUREN (*Compt. rend.*, 1900, 130, 1252—1254).—The solubility curve of potassium chloride in solutions of potassium bromide is not identical with that for the solubility in solutions of potassium nitrate, so that the two latter salts have not equal effects on the solubility of the chloride. The solubility curve for potassium bromide in solutions of potassium chloride was also determined, and it was found that these curves do not cut, but form one continuous curve. There is hence no point at which the two salts are in equilibrium with the solution, and but one solid phase exists at all concentrations, that is, mixed crystals of the two compounds are formed. The author points out that solubility determinations may hence be of value in cases of doubtful isomorphism (this vol., ii, 396).

L. M. J.

Solubility of Hydrated Mixed Crystals. III. By WILLEM STORTENBEKER (*Zeit. physikal. Chem.*, 1900, 34, 108—123).—A study of the mixed salts, cadmium and ferrous sulphates, and copper and manganese sulphates, on the lines of the author's previous work (Abstr., 1896, ii, 13; 1897, ii, 250). The limits for cadmium and ferrous sulphates are found to be:

	$(\text{CdFe})\text{SO}_4 \cdot 2\frac{1}{2}\text{H}_2\text{O}$.	$(\text{CdFe})\text{SO}_4 \cdot 7\text{H}_2\text{O}$.
Solution...	100—79·8 mol. per cent. Cd.	79·8—0 mol. per cent. Cd.
Crystals...	100—99·1 " "	36·6—0 " "

Similarly, for copper and manganese sulphates, the limits are:—

	$(\text{CuMn})\text{SO}_4 \cdot 5\text{H}_2\text{O}$.	$(\text{CuMn})\text{SO}_4 \cdot 7\text{H}_2\text{O}$.
Solution	100—15·9 and 10·27—0 mol. per cent. Cu.	15·9—10·27 mol. per cent. Cu.
Crystals	100—22·9 and 10·5 —0 " "	23·5—16·0 " "

In the last case, the solubility isotherms cut each other in two points.
J. C. P.

Separation in Alloys. By G. NANNES (*Öfvers. K. Vet. Akad. Stockholm*, 1899, 56, 735—744).—When a molten alloy of equal parts of lead and tin is kept in a bath so that the two ends of the containing tube are at different temperatures, the concentration of the tin increases at the cooler end. This phenomenon is observed in both vertical and horizontal tubes, although in the former the point of equilibrium is reached more rapidly, and the final difference in concentration is somewhat greater than in the latter. The melting point curve of lead-tin alloys shows that in a 50 per cent. alloy the lead is to be regarded as the solvent; the observations, therefore, agree with Soret's rule that, in a homogeneous solution, the parts of which are kept at different temperatures, the warmer part becomes more dilute and the cooler part more concentrated with regard to the solute. On the other hand, the final concentrations at the ends of the tube are not exactly in the inverse ratio of the absolute temperatures, as required by van't Hoff's theory.
J. C. P.

Formation of Oceanic Salt Deposits, particularly of the Stassfurt Beds. XVIII. Gypsum and Anhydrite. I. The Hydrate $\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$. By JACOBUS H. VAN'T HOFF and E. F. ARMSTRONG (*Sitzungsber. K. Preuss. Akad. Wiss.*, 1900, 23, 559—576).—The hydrate $\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$ is conveniently prepared by warming 20 grams of gypsum with 50 c.c. of nitric acid of sp. gr. 1·4 for 18 hours at 40°; the crystals obtained are freed from acid by decantation, washed with alcohol, and dried.

The relative stability of the hydrates $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ and $\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$ can be deduced theoretically from their vapour tension curves, but previous researches have shown that the extreme slowness with which equilibrium is reached prevents an accurate and trustworthy determination of the vapour tension. The process may, however, be accelerated by the agency of solutions of sulphuric acid, nitric acid, sodium chloride, and magnesium chloride. The results obtained with solutions of sulphuric acid are not so satisfactory, probably owing to the comparative insolubility of calcium sulphate in the acid.

When sodium chloride is gradually added to water in the presence of gypsum, the boiling point rises regularly to the temperature at which the gypsum is converted into the hydrate $\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$. Further addition of sodium chloride at this point produces no further rise of temperature until the conversion is complete. A similar constant level in the boiling point curve is obtained when a concentrated solution of sodium chloride and the hydrate $\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$ is diluted.

In this way, the conversion temperature is determined to be 101.45° , at which point the vapour tension of the hydrate $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ is equal to an atmosphere. At 77.1° , by a similar experiment under reduced pressure, the tension is found to be 238 mm. At 25° , by moistening with magnesium chloride solutions of various concentrations, the tension is found to be 9.1 mm. From two of these values, and with the help of the equation $\log(p_g/p_w) = -q/2T + \text{const.}$, the vapour tension of the hydrate $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ is calculated for intermediate temperatures; in this equation, p_g and p_w are the vapour tensions of the hydrate $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ and water respectively; q is the heat liberated when 18 kilograms of water unite with the hydrate $\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$ to form gypsum.

It is a consequence of the above equation that at 107° $p_g = p_w$, and this point has been experimentally determined by the help of a dilatometer. Gypsum is therefore a compound whose melting point (107°) lies above its boiling point (101.45°). The conversion of $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ into $\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$ accounts for the apparent diminished solubility of gypsum above 100° .

J. C. P.

Equilibria in the Partition of an Acid between Ammonia and Sparingly Soluble Metallic Hydroxides. By W. HERZ (*Zeit. anorg. Chem.*, 1900, 24, 123—126).—Beryllium hydroxide is apparently insoluble in ammonium salts, and therefore unsuited for investigation on the lines of the author's previous work (Abstr., 1899, ii, 752; 1900, ii, 68 and 337).

The equilibrium represented by the equation $\text{Cd}(\text{OH})_2 + 2\text{NH}_4\text{NO}_3 \rightleftharpoons \text{Cd}(\text{NO}_3)_2 + 2\text{NH}_4\text{OH}$, has been studied, and the results are similar to those obtained in the case of zinc (*loc. cit.*). An empirical expression of the type formerly employed fits in better with the experimental results than the expression deduced from the law of mass action.

J. C. P.

Molecular Transformation of Cinchonine: An Addition to the Theory of Catalytic Action. By RUDOLF WEGSCHEIDER (*Monatsh.*, 1900, 21, 361—387).—It is shown that the transformation of cinchonine by means of halogen acids into α -isocinchonine (Skraup, Abstr., 1899, i, 961) is an example of the case of auxiliary reactions considered by the author (this vol., ii, 199), but the mathematical discussion does not lend itself to abstraction. The author puts forward the view that catalytic acceleration of a chemical reaction in a homogeneous solution can be explained by assuming that there is a continuous succession of intermediate stages, which the catalytic agent is able to influence by reversible reactions with the substances present, and so bring about or accelerate the main reaction.

R. H. P.

Theory of Catalytic Reactions. By HANS EULER (*Öfvers. K. Vet. Akad. Stockholm*, 1899, 56, 309—333).—A general discussion of reaction velocity and the part played by catalytic agents. It is pointed out that there are no grounds for making a distinction between electrolytes and non-electrolytes, and the author regards all chemical substances as electrolytes. The study of the influence of the solvent and the temperature makes it probable that substances hitherto

regarded as non-electrolytes react through intermediary ions. Every catalysis is supposed to consist in an increase in the number of the ions concerned in the accelerated reaction. The author applies his theories to the special case of ester formation and decomposition.

J. C. P.

The Driving Tendency of Physicochemical Reaction and its Temperature Coefficient. By THEODORE W. RICHARDS (*J. Physical Chem.*, 1900, 4, 383—393).—The paper contains essentially a slightly modified treatment of the van't Hoff equation. It is pointed out that the study of pressure affords a more direct method of analysing the progress of a reaction than that of volume or concentration. The author uses the term 'reaction-metatherm' to indicate the relation between pressure and temperature in the equilibrium ratio. In the expression, which is of the form $d/dT \log p_1^{n_1} \dots T^U / p_2^{n_2} \dots = U/RT^2$, U represents the actual heat evolved, and is hence an expression of the theorem of Le Chatelier. The expression $\log p_1^{n_1} \dots / p_2^{n_2} \dots = k$ is that which represents the reacting tendency of the reaction at a certain temperature, and receives the name of the "driving tendency" of the reaction.

L. M. J.

G. Linck's Crystallographic Views. By WILHELM MUTHMANN (*Ber.*, 1900, 33, 1771—1774).—A criticism of Linck's proposal to correct the atomic weights of elements by the aid of crystallographic considerations (compare Abstr., 1899, ii, 415).

W. A. D.

Additive Nature of the Properties of Atoms. By STEFAN MEYER (*Ber.*, 1900, 33, 1918—1919).—According to the author, only those compounds whose molecular volumes are the true sum of the atomic volumes of their constituent elements possess properties which are the actual sum of the atomic properties of their constituents. When, in the formation of the compound, volume contraction or dilatation occurs, other physical constants, for example, magnetisation number (Abstr., 1899, ii, 587; 1900, ii, 7, 143, 385), molecular heat (Abstr., 1900, ii, 464), &c., vary from the true sum in the direction of the maximum or minimum of the atomic volume curve.

J. J. S.

Second Report of the Committee of the German Chemical Society on Atomic Weights. By the Members of the Committee: HANS LANDOLT, WILHELM OSTWALD, and KARL SEUBEERT (*Ber.*, 1900, 33, 1847—1883. Compare Abstr., 1899, ii, 86).—This report deals with the conclusions arrived at by the International Commission formed to consider atomic weights (*Ber.*, 1898, 31, 2949). The members of the Commission agree almost unanimously that the atomic weight of oxygen shall be taken as the standard, and equal to 16.00; the advantages of this value are dealt with in detail in the report. The atomic weights are to be given with so many decimals that the last figure is *certainly* correct to less than half a unit; calculations made with these weights will thus be of permanent value, and subject to no alteration as additional accuracy is obtained in future determinations.

W. A. D.

True Atomic Weights of Ten Elements Deduced from Recent Researches. By GUSTAVUS HINRICHS (*Compt. rend.*, 1900, 131, 34—36. Compare preceding abstract).—The author states that by employing his method of calculation (*Abstr.*, 1893, ii, 317), the exact atomic weights of hydrogen, carbon, oxygen, sulphur, chlorine, bromine, sodium, silver, barium, and boron are found to be very close to the values in ordinary use. The values of these constants published by the German Committee on atomic weights are incorrect, and by employing these data Gautier has introduced an error into his determination of the atomic weight of boron. G. T. M.

Thiele's Theory of Partial Valencies in the Light of Stereochemistry. By EMIL KNOEVENAGEL (*Annalen*, 1900, 311, 194—240).—An attempt to place a stereochemical interpretation on Thiele's theory of partial valencies (*Abstr.*, 1899, i, 554). The author's speculations involve the hypothesis that the difference between a double and a single linking depends on the intramolecular movements of the atoms concerned. M. O. F.

The Steric Aspect of Partial Valencies. By JOHANNES THIELE (*Annalen*, 1900, 311, 241—255).—A criticism of the foregoing paper, in which the author regards the Wunderlich model, employed by Knoevenagel in his discussion, as unsuitable for the further development of valency relations. M. O. F.

Lecture Experiments. Reversible Chemical Reactions. By W. LASH MILLER, and FRANK B. KENRICK (*J. Amer. Chem. Soc.*, 1900, 22, 291—300).—A number of incomplete reactions capable of being employed for lecture experiments illustrative of reversible reactions are described. An orange solution of ferric chloride with ammonium thiocyanate in equivalent quantities becomes dark red by the addition of excess of either compound, and colourless by addition of ammonium chloride, whilst the same solution also may be used to illustrate the effect of dilution. The reactions between bismuth chloride and water, and of ammonium with salts of copper or silver, are also suitable for lecture purposes. The dissociation of water vapour may be shown by heating platinum wire by means of an electric current in the neck of an ordinary distilling flask, and ammonia may be similarly dissociated. The change from sodium sulphate to sodium chloride and *vice versa* by the addition of the respective acids may be conveniently shown on the screen, the crystallisation taking place on lantern slides. The reaction between antimony chloride and hydrogen sulphide is also suitable for lecture purposes, and in this case the effect of temperature and pressure is also well seen. The authors describe a form of pressure pump for use in connection with the water mains by means of which a gas can be brought to the pressure of the mains in three or four strokes of the pump without coming into contact with any liquid. L. M. J.

Method for Testing Weights. By THEODORE W. RICHARDS (*Zeit. physikal. Chem.*, 1900, 33, 605—610).—An account of the method in use in the author's laboratory for testing and correcting for the relative value of weights employed in quantitative work. The

author does not claim any originality for the method, but insists strongly on its necessity in all quantitative determinations.

L. M. J.

Receiver for Fractional Distillation in a Vacuum. By LUCIEN FOGETTI (*J. Amer. Chem. Soc.*, 1900, 22, 360—361).—The new receiver consists of three separator funnels sealed together, each of the three bulbs being furnished with a side stopcock, the uppermost having an additional one which is connected with the vacuum pump. The condenser tube enters into the top bulb, connection being made by a ground glass joint or a rubber stopper if desired. The two stopcocks of the bottom funnel are closed, also the side stopcock of the middle funnel and the left side stopcock of the top funnel. The other stopcocks are opened and the second side stopcock of the top funnel is connected with the vacuum pump. When the first fraction has collected in the lower funnel, the stopcock of the middle funnel is closed and the second fraction is collected; the stopcock of the middle one is then closed and the third fraction collected in the top funnel.

The bottom funnel is emptied by opening both stopcocks. The lower one being again closed, the side one is connected with a second pump and the vacuum is restored. By opening the stopcock of the middle funnel, its contents flow into the bottom one and the operation is then repeated.

L. DE K.

Inorganic Chemistry.

Hydrogen Peroxide. By JULIUS WILHELM BRÜHL (*Ber.*, 1900, 33, 1709—1710).—The explosive substance previously described (*Abstr.*, 1896, ii, 163) cannot be acetic peroxide as suggested by Nef (*Annalen*, 1897, 298, 290, 327), and again by Bach (*Ber.*, 1900, 33, 1506), since its boiling point is much too high, and its instability is the only point of resemblance. The view that hydrogen peroxide is $\text{HO}\cdot\text{OH}$ is supported by its high dielectric constant (92.8 at 18°) and by the absence of electrical absorption.

T. M. L.

Action of Iodides and of Hydriodic Acid on Sulphur Dioxide. By ARMAND BERG (*Bull. Soc. Chim.*, 1900, [iii], 23, 499—501. Compare this vol., ii, 398).—When aqueous solutions of sulphur dioxide and potassium iodide or hydriodic acid are mixed, a yellow coloration is produced which is probably due to the formation of an unstable compound; it is not caused by free iodine. On keeping, and especially under the influence of light and heat, the yellow colour gradually disappears and one-third of the total sulphur present is deposited, whilst the remaining two-thirds is converted into sulphuric acid. A small quantity of iodide is thus able to bring about the decomposition of a large quantity of sulphur dioxide, without itself undergoing any permanent change.

N. L.

Action of Oxidising Agents on Alkali Iodides. By E. PÉCHARD (*Compt. rend.*, 1900, 130, 1705—1708. Compare Abstr., 1899, ii, 473).—The liberation of iodine from alkali iodides by oxidising agents is probably due to an intermediate formation of periodate. A cold solution of monosodium periodate interacts with iodides in the following manner: $3\text{NaIO}_4 + 2\text{NaI} + 3\text{H}_2\text{O} = \text{NaIO}_3 + 2\text{Na}_2\text{H}_3\text{IO}_4 + \text{I}_2$. The reaction is not instantaneous, the liberation of iodine being still incomplete after an interval of one hour. Moreover, the following reverse action, $\text{Na}_2\text{H}_3\text{IO}_4 + \text{I}_2 = 3\text{NaIO}_3 + \text{NaI} + 3\text{H}_2\text{O}$, occurs when a solution of disodium periodate is left in contact with iodine, the mixture, which at first is alkaline, gradually becoming neutral. The amount of periodate is estimated by means of standard potassium manganate, prepared by treating an alkaline solution of permanganate with potassium iodide (compare Job, *Compt. rend.*, 1899, 128, 1453). The liberation of iodine from an alkali iodide by ozone follows a similar course, periodate is produced and the ratio between the amounts of free and combined iodine corresponds with that required by the first equation. When slightly acidified hydrogen peroxide is added to potassium iodide solution, iodine and oxygen are liberated, and the mixture becomes alkaline; after 24 hours, however, the alkalinity disappears, and the amount of free iodine diminishes perceptibly. These phenomena are explained in the following manner: the peroxide oxidises the iodide and the solution becomes neutral, the action following the course indicated by the first of the equations given; this results in the formation of the alkaline disodium salt in the presence of which hydrogen peroxide decomposes rapidly, and after 24 hours the solution again becomes neutral in accordance with the second equation. G. T. M.

Viscosity of Sulphur at Temperatures above the Point of Maximum Viscosity. By C. MALUS (*Compt. rend.*, 1900, 130, 1708—1710).—The rate of crystallisation of sulphur rendered viscous by heating at 357° for 10 minutes and then maintained for some time at 100° , depends on the rate of cooling and the time of exposure to the latter temperature; it decreases as the latter increases to a minimum value of 5.25 seconds, which is attained after 5 to 6 hours. This limiting value is identical with that obtained for sulphur rendered viscous by heating at 357° for 3 hours, the rate of crystallisation for this modification of sulphur being invariable.

Sulphur maintained for some time either at 100° or 357° passes into the liquid state, but the tendency to regain the viscous condition which is absent from the sulphur heated at 357° persists in that modification which has lost its viscosity at the lower temperature.

G. T. M.

Caro's Reagent. By EUGEN BAMBERGER (*Ber.*, 1900, 33, 1959—1961).—The formula H_2SO_7 is suggested for 'Caro's reagent,' in accordance with Bach's view (this vol., ii, 470) that it is a compound of hydrogen tetroxide and sulphuric acid. On adding a copper salt and then sodium hydroxide to a solution of Caro's reagent, a brownish-black precipitate is produced which is regarded as copper peroxide.

By adding strong sulphuric acid to a cold solution of potassium percarbonate, a solution is obtained which oxidises aniline to nitrosobenzene,

and probably contains the same oxidising agent as a mixture of sulphuric acid with a persulphate or with hydrogen peroxide. T. M. L.

Isomorphism of Selenium and Tellurium. By JAMES F. NORRIS and RICHARD MOMMERS (*Amer. Chem. J.*, 1900, 23, 486—494).—The isomorphism of tellurium with selenium on the one hand, and with platinum on the other hand, has only been established in the case of certain compounds crystallising in the cubic system. Tellurium dimethylamine bromide and selenium dimethylamine bromide are, however, isomorphous, since they both form mixed crystals with tellurium dimethylamine chloride, although none of the crystals have been measured. The corresponding platinum dimethylamine bromide, which belongs to the orthorhombic system, does not form mixed crystals.

The following double salts of tellurium have been prepared, and resemble in composition a number of selenium salts :

Double salts containing tellurium and dimethylamine perbromide could not be prepared. T. M. L.

Combustible Gases of the Atmosphere: Air of Towns. By ARMAND GAUTIER (*Compt. rend.*, 1900, 130, 1677—1684).—The paper contains a detailed account and sketch of the apparatus employed by the author in estimating the amount of hydrogen and carbon present in the atmospheric gases.

The mean of a series of analyses of the atmosphere of Paris, made at different seasons of the year, indicates that this air contains 12·45 mg. of carbon and 3·96 mg. of hydrogen per 100 litres, the ratio of carbon to hydrogen being 3·1. Comparative experiments made with purified air containing traces of methane give the ratio as 2·4, indicating that, under these conditions, the hydrogen burns faster than the carbon. It follows from these results that it is still an open question as to whether the combustible gas of the atmosphere consists wholly of methane or of a mixture of this substance with hydrogen and hydrocarbons richer in carbon than the paraffins. G. T. M.

Combustible Gases of the Atmosphere: Air of Forests and High Mountains. By ARMAND GAUTIER (*Compt. rend.*, 1900, 131, 13—18. Compare preceding abstract).—The atmosphere of a forest in July contains only half as much carbon as the air of Paris, whilst the amount of hydrogen is somewhat smaller; the ratio C/H is 2·2, being less than that obtained with air containing traces of methane. Analyses of the air of Mt. Canigou, Pyrenees, indicated a still greater diminution in the amount of carbon, the ratio C/H being only 0·33; the hydrogen present is, therefore, almost entirely uncombined. These results indicate that the hydrocarbons existing in appreciable quantities in the air of towns and woods are, in all probability, emanations from the animals, plants, and humus present in these regions. G. T. M.

Combustible Gases of the Atmosphere: Air of the Sea. Existence of Free Hydrogen in the Terrestrial Atmosphere. By ARMAND GAUTIER (*Compt. rend.*, 1900, 131, 86—90. Compare preceding abstracts).—Examination of the air at the Roches-Douvres lighthouse, 40 kilometres from the coast of France, showed the almost complete absence of hydrocarbons, whilst free hydrogen was present in the proportion of 19.45 c.c. per 100 litres, the same amount as previously found in mountain air. These results confirm the conclusion that air normally contains about 1/5000 of its volume of free hydrogen together with variable quantities of hydrocarbons, the latter being due to the action of vegetable and animal life, to industrial operations, &c.
N. L.

Formation of Nitric Acid during the Combustion of Hydrogen. By MARCELLIN P. E. BERTHELOT (*Compt. rend.*, 1900, 130, 1662—1677. Compare this vol., ii, 474).—When compressed mixtures containing equivalent amounts of hydrogen and oxygen are exploded in the presence of nitrogen, neither ammonia nor nitric acid is produced, a similar result being obtained when the first of these gases is in excess.

When the mixtures contain excess of oxygen, the amount of nitric acid produced increases as the pressure is augmented. Equal volumes of oxygen and hydrogen were exploded in the presence of nitrogen under pressures of 2, 4, and 20 atmospheres; the amounts of nitrogen oxidised were respectively 25, 33, and 45 per cent. by weight of the total hydrogen consumed. When oxygen and hydrogen unite in the oxy-hydrogen blowpipe in an atmosphere of oxygen containing about 7 per cent. of nitrogen, the quantity of nitric acid produced is much smaller than in the preceding experiments. If the partial pressure of the hydrogen is kept constant, whilst the amount of oxygen is gradually increased, the ratio between oxidised and total nitrogen increases to 6.3 per cent. when the mixture contains 1 vol. of hydrogen to 2 vols. of oxygen, and then rapidly diminishes, becoming negligible when the mixture contains 5 vols. of the latter gas.

Experiments made with highly compressed mixtures (8—30 atmospheres) indicate that the yield of nitric acid increases with the pressure, and also to a certain extent with excess of oxygen. When larger quantities of nitrogen are employed, the yield of nitric acid increases considerably, the maximum being attained with the mixture $H_2 : O_2 : N_2 = 1 : 1.7 : 1.3$ under a pressure of 16 atmospheres; further dilution with this gas diminishes its oxidation, a mixture of 1 vol. of hydrogen and 4.5 vols. of air under a pressure of 5.5 atmospheres yielding only a trace of acid. The amount of nitric acid produced during the burning of a feeble jet of hydrogen in air is extremely small.

The paper contains the complete data of each determination of nitric acid, and concludes with a theoretical discussion of the results, which cannot be suitably abstracted.
G. T. M.

Supposed Allotropism of Phosphorus Pentabromide. By J. H. KASTLE and L. O. BEATTY (*Amer. Chem. J.*, 1900, 23, 505—509).—In attempting to determine the transition point from

yellow, rhombic phosphorus pentabromide into the red, prismatic variety, it was found that the latter is probably a perbromide of the formula PBr_7 . Its formation by subliming the yellow pentabromide at 90° is probably due to a partial decomposition into heptabromide and tribromide; phosphorus tribromide reconverts it into the yellow pentabromide. Bromine vapour converts the yellow pentabromide into the red compound, whilst when left in contact with bromine absorbents the reverse change takes place. In contact with water, phosphorus pentabromide gives a colourless solution of phosphoric and hydrobromic acids, whilst the red compound liberates free bromine.

On mixing phosphorus pentabromide and bromine in mol. proportions in a sealed tube and subliming at 90° , bright red, transparent crystals were obtained which gave $P = 5.40$, $Br = 96.20$, the calculated values for PBr_7 being 5.25 and 94.75.

T. M. L.

The Lower Oxides of Phosphorus. By ADOLPHE BESSON (*Bull. Soc. Chim.*, 1900, [iii], 23, 582—585).—A criticism of the work of Michaelis and Pitsch (this vol., ii, 137), whose experiments, it is considered, neither justify the conclusions drawn from them nor invalidate the author's previous proofs of the existence of an oxide of phosphorus of the composition P_2O .

N. L.

True Atomic Weight of Boron. By GUSTAVUS HINRICHS (*Compt. rend.*, 1900, 130, 1712—1714).—A note on Gautier's determination of the atomic weight of boron (compare this vol., ii, 14, 15). The mean value of this constant calculated by the author's method from Gautier's data is 11.004, that adopted by the latter investigator being 11.016.

G. T. M.

Expansion of Fused Silica. By HENRI LE CHATELIER (*Compt. rend.*, 1900, 130, 1703—1705).—Amorphous silica, prepared by fusion in the electric furnace, has between 0° and 1000° a mean coefficient of expansion 0.0000007; this constant is lower than that of any other substance. The melting point of this substance is lowered by the addition of the oxides of the alkali and alkaline earth metals and alumina, but the mixtures have greater coefficients of expansion, the increase being least in the case of the product $10SiO_2, Al_2O_3, 2Li_2O$.

G. T. M.

Preparation and Properties of the Silicon Borides SiB_3 and SiB_6 . By HENRI MOISSAN and ALFRED STOCK (*Compt. rend.*, 1900, 131, 139—143).—A mixture of 1 part of boron and 5 parts of crystallised silicon is heated for about 1 minute in a vessel of refractory clay by means of an alternating current of 600 amperes and 45 volts. The cooled mass is treated with a mixture of nitric and hydrofluoric acids in order to remove excess of silicon, and the crystalline portion of the residue after heating with moist potassium hydroxide is extracted with dilute nitric acid and hot water and dried at 130° . The product consists of a mixture of two borides, SiB_3 and SiB_6 , containing about 80—90 per cent. of the latter.

The hexaboride is readily oxidised by boiling nitric acid, whereas the triboride is only slowly attacked by this reagent; the latter compound,

on the other hand, is decomposed by fused potassium hydroxide, whilst the former remains unchanged.

The triboride forms black, rhombic plates which, when very thin, appear yellowish-brown by transmitted light; its density is 2.52.

The hexaboride is always obtained in thick, black, opaque crystals with somewhat irregular faces; its density is 2.47.

These silicon borides, like the boride and silicide of carbon, are very hard, being intermediate between the diamond and ruby in the scale of hardness; they are soluble in fused silicon and conduct electricity.

When gently heated, they are decomposed by fluorine and are attacked at higher temperatures by chlorine and bromine, but not by iodine or nitrogen. They become superficially oxidised by heating in air or oxygen. They are not affected by the haloid acids, but are slowly decomposed by boiling concentrated sulphuric acid, and rapidly dissolved by fused potassium carbonate or by a mixture of this compound with potassium nitrate; the latter salt alone has no action on them.

G. T. M.

Krypton. By ALBERT LADENBURG and C. KRÜGEL (*Sitzungsber. K. Preuss. Akad. Wiss.*, 1900, 212—217).—The least volatile portion of a large quantity (850 litres) of liquid air was freed from oxygen and nitrogen; the 3.5 litres of gas thus obtained were condensed in a bath of liquid air and under slightly increased pressure; the liquid formed was then allowed to boil, and the gas collected in separate vessels. The greater part came off at -181.2° ; the temperature then rose rapidly to -153° , when the rest of the liquid evaporated; a crystalline residue melted at -147° , and was rapidly vaporised. The first gas (boiling point -181.2°) showed a complete argon spectrum; that obtained from the crystalline residue showed a bright krypton spectrum, and careful investigation pointed to the absence of argon. The density of this krypton was found to be 58.81, and subsequent sparking with oxygen did not alter this value appreciably. The authors suggest that the new atmospheric elements should be placed before Group I of the periodic system, thus: He=4 before lithium, Ne=20 before sodium, A=39 before potassium, and Kr=59 before copper.

J. C. P.

Sodium and Potassium Amalgams. By ANTOINE GUNTZ and JULES FÉRE (Compt. rend., 1900, 131, 182—184).—The solution obtained by adding a mixture of sodium and mercury containing 3.5 per cent. of the former to the fused amalgam Hg_6K at 200° , deposits prismatic needles of the amalgam Hg_5K on cooling to 140° ; the mother liquor solidifies at 96° , and consists of the substance Hg_6K . When either of these substances is submitted to a pressure of 200—1200 kilos. per sq. cm., a saturated solution of sodium in mercury is expressed, and the residue consists of a new amalgam, Hg_4Na .

The ordinary potassium amalgam, $Hg_{12}K$, when compressed, is converted into a new amalgam, $Hg_{10}K$. A solution of potassium in mercury, when cooled to -19° , yields crystals of another potassium amalgam, $Hg_{18}K$; this substance, on warming, yields crystals of $Hg_{12}K$ and a saturated solution of potassium in mercury.

G. T. M.

Impossibility of the Direct Formation of Potassium Chlorate by Electrolysis. By ANDRÉ BROCHET (*Compt. rend.*, 1900, 130, 1624—1627).—When a solution of potassium chloride mixed with potassium hydroxide is electrolysed in presence of finely divided cobalt oxide, practically no chlorate is formed, and since the chlorate is not decomposed by cobalt oxide, the author regards this result as conclusive proof that the chlorate produced by electrolysis is always a secondary product from the hypochlorite, and is never a primary product, even in a solution so strongly alkaline that the intermediate formation of hypochlorite cannot be detected by analysis.

C. H. B.

Compound of Silver Fluoride with Ammonium Fluoride. By BRUNO GRÜTZNER (*Arch. Pharm.*, 1900, 238, 1—3. Compare von Helmolt, *Abstr.*, 1893, ii, 373).—By dissolving moist, freshly precipitated silver oxide in cold concentrated aqueous ammonium fluoride, and cooling with ice, a small quantity of a double salt, $2\text{NH}_4\text{F} \cdot \text{AgF} \cdot \text{H}_2\text{O}$, was obtained; this compound is not hygroscopic.

C. F. B.

Physicochemical Relations of Aragonite and Calcite. By H. W. FOOTE (*Zeit. physikal. Chem.*, 1900, 33, 740—759).—From experiments on the decomposition of aragonite and calcite by potassium oxalate, and on the conductivity of solutions of these two in water saturated with carbon dioxide, the author concludes that at the ordinary temperature calcite is more stable than aragonite, although the solubility curves deduced from the conductivity experiments approach each other with rising temperature. It seems probable, from the results obtained by the author and others, that under atmospheric pressure calcite remains the more stable form up to its melting point. The transformation of aragonite into calcite is accompanied by a slight evolution of heat.

J. C. P.

Formation of Marine Anhydrite. By HEINRICH VATER (*Sitzungsber. K. Preuss. Akad. Wiss.*, 1900, 269—294).—After reviewing the work done by others on the formation of anhydrite, the author describes experiments showing that at the ordinary temperature calcium sulphate crystallises from a saturated sodium chloride solution as gypsum and not as anhydrite; this holds also when the sodium chloride solution contains 3 per cent. of magnesium chloride. From saturated magnesium chloride solutions, calcium sulphate crystallises as gypsum at the ordinary temperature, and as the compound $2\text{CaSO}_4 \cdot \text{H}_2\text{O}$ at 40° .

J. C. P.

Solubility of Tricalcium Phosphate in Natural Waters in the Presence of Carbonic Acid. By TH. SCHLÖSING (*Compt. rend.*, 1900, 131, 149—153).—Hydrated tricalcium phosphate, $\text{Ca}_3(\text{PO}_4)_2 \cdot \text{H}_2\text{O}$, prepared by neutralising an aqueous solution of phosphoric acid with calcium hydroxide, is almost insoluble in distilled water at the ordinary temperature; it dissolves to a far greater extent in solutions of carbonic acid, but is much less soluble in water containing this acid together with an amount of calcium hydrogen carbonate corresponding with the pressure of the dissolved carbon dioxide. Since the latter condition usually obtains in surface waters, it follows that the carbon

dioxide present exerts but little solvent action on the calcium phosphate present in artificial manures.

The paper contains two tables showing the solubility of the phosphate in carbonic acid and calcium hydrogen carbonate solutions of varying strengths. G. T. M.

Influence of Temperature and Concentration on the Saline Constituents of Boiler Water. By CECIL H. CRIBB (*Analyst*, 1900, 25, 169—183).—The author communicates the analyses of a large number of boiler waters before and after boiling at different pressures and for different periods; the results are given in eleven tables.

Magnesium chloride, which is not decomposed by mere boiling with water, decomposes, however, at a higher temperature, and deposits magnesium hydroxide or even oxide. Calcium sulphate is not rendered insoluble at 150°, as has been stated.

Many obscure points have been noticed which want investigation before a clear idea is obtained as to what really takes place with the dissolved salts when waters are heated under pressure. L. DE K.

Solubility of Cupric Chloride in Organic Media. By WILLIAM ECHNER DE CONINCK (*Compt. rend.*, 1900, 131, 58—60).—A qualitative and quantitative study of the solubility of anhydrous and hydrated cupric chloride in a variety of organic liquids. G. T. M.

Copper Carbonate. By MAX GRÖGER (*Zeit. anorg. Chem.*, 1900, 24, 127—138).—The greenish-blue precipitate obtained by precipitating a solution of sodium carbonate with copper sulphate at the ordinary temperature is colloidal, and contains more or less absorbed sodium carbonate; when equivalent quantities of the two solutions are employed, the copper carbonate contains cupric oxide and carbon dioxide in the ratio $\text{CuO} : \text{CO}_2 = 2 : 1$. The amount of carbon dioxide in the precipitate decreases with the increase of excess of sodium carbonate, and with excess of copper sulphate the precipitate contains basic copper sulphates. The amount of water in the precipitate is variable, as is the case with all colloids. When the precipitate is allowed to remain in contact with the mother liquor, it becomes crystalline, and then has the composition expressed by the formula $6\text{CuO} \cdot 3\text{CO}_2 \cdot 4\text{H}_2\text{O}$; this change takes place more slowly as the excess of sodium carbonate increases, and with a large excess of sodium carbonate blue crystals of sodium copper carbonate, $\text{Na}_2\text{CO}_3 \cdot \text{CuCO}_3 \cdot 3\text{H}_2\text{O}$, are formed together with a small quantity of a dark brown copper carbonate.

The precipitate obtained from sodium hydrogen carbonate and copper sulphate at low temperatures is also colloidal, contains absorbed sodium hydrogen carbonate, has the ratio $\text{CuO} : \text{CO}_2 = 8 : 5$, and is not altered by drying at the ordinary temperature. When dried over sulphuric acid, it has the composition $8\text{CuO} \cdot 5\text{CO}_2 \cdot 7\text{H}_2\text{O}$. When precipitated in the presence of excess of copper sulphate, it contains basic copper sulphates, and when allowed to remain in contact with the mother liquor is gradually converted into the crystalline com-

pound $6\text{CuO}, 3\text{CO}_2, 4\text{H}_2\text{O}$. An excess of sodium hydrogen carbonate accelerates the change. E. C. R.

Distillation of Amalgams and the Purification of Mercury. By GEORGE A. HULETT (*Zeit. physikal. Chem.*, 1900, 33, 611—621).—The purity of mercury may be very accurately found by E.M.F. determinations; thus the E.M.F. of the chain $\text{Zn} | \text{electrolyte} | \text{Hg}$ is very greatly altered by the addition of small quantities of zinc to the mercury. Mercury may be conveniently distilled by means of an ordinary distilling flask fitted to an exhaust pump, as for the distillation of other liquids under reduced pressure, if a capillary tube be passed down into the mercury so that a fine stream of air or nitrogen passes through the metal during the distillation. Contrary to general statements, mercury is completely freed from zinc and cadmium by distillation, these metals not distilling over so long as the surface is bright. If, however, a film of oxide forms on the surface, some of this may be mechanically carried over. Determinations of the zinc indicate that at 210° the vapour tension of mercury is at least 3×10^7 times that of zinc. L. M. J.

Decomposition of Metallic Chlorides. By WILLIAM ECHSNER DE CONINCK (*Compt. rend.*, 1900, 130, 1627—1628).—When a dilute aqueous solution of mercuric chloride is filtered through animal charcoal, the salt is absorbed somewhat rapidly, but not completely, and it may be regarded as stable unless exposed to a very bright light. Cadmium chloride and aluminium chloride are somewhat slowly absorbed, and may be regarded as very stable, but stannic chloride, like the stannous salt, is rapidly decomposed with formation of an oxychloride. The rapid alteration of the stannous and stannic salts seems to show that the charcoal exerts an oxidising action. With ferric chloride solution, the charcoal seems to act as a dialyser, the whole of the iron being removed whilst the chlorine remains in solution. C. H. B.

Direct Formation of Crystallised Mercuric and Mercurous Iodides. By F. BODROUX (*Compt. rend.*, 1900, 130, 1622—1624).—If a somewhat concentrated aqueous solution of a mercuric salt, preferably the acetate, is mixed with a small quantity of methyl iodide and allowed to remain at the ordinary temperature, mercuric iodide gradually separates in red lamellæ as much as 10 mm. in breadth. Some of the first crystals are yellow, but gradually change to red. Other alkyl iodides behave similarly, but the yield is not so good.

Mercurous iodide can be obtained abundantly in yellow, lustrous plates by adding ethyl or methyl iodide to a cold saturated solution of mercurous nitrate. C. H. B.

Mercury Antimonide. By ALFRED PARTHEIL and E. MANNHEIM (*Arch. Pharm.*, 1900, 238, 166—184).—See this vol., i, 479.

Mercury Phosphide and Phosphonium Compounds. By ALFRED PARTHEIL [with A. VAN HAAREN] (*Arch. Pharm.*, 1900, 238, 28—42).—When hydrogen phosphide, prepared from sodium hypo-

phosphite, zinc, and hydrochloric acid, and therefore mixed with much hydrogen, is passed through dilute alcoholic mercuric chloride, a yellow precipitate of $\text{PHg}_2\text{Cl}, \text{HgCl}_2, 1\frac{1}{2}\text{H}_2\text{O}$ is obtained. When comparatively pure hydrogen phosphide, prepared from zinc phosphide and hydrochloric acid, is passed into a $2\frac{1}{2}$ per cent. solution of mercuric chloride in alcohol, a dark brown precipitate is obtained eventually, almost free from chlorine, but having approximately the composition $\text{P}_2\text{Hg}_3\text{O}_4$; this is unstable and readily evolves hydrogen phosphide. When hydrogen phosphide is passed over dry mercuric chloride, the hydrogen chloride liberated does not correspond with the formation of P_2Hg_3 .

Mercury phosphide, P_2Hg_3 , was prepared eventually, as a brown powder, by Granger's method (Abstr., 1892, 1398), and heated with ethyl iodide at 160° for 4—5 hours; in addition to mercuric iodide, a yellow *tetraphosphonium mercuriodide*, $\text{PEt}_4\text{I}, 2\text{HgI}_2$, was obtained. By digesting this in alcoholic solution with silver oxide, and evaporating the alkaline filtrate, a crystalline mass, doubtless of *tetraphosphonium hydroxide*, was obtained; from this, the crystalline, hygroscopic *chloride* was prepared by neutralisation with hydrochloric acid. The *mercurichloride*, $\text{PEt}_4\text{Cl}, 2\text{HgCl}_2$, *aurichloride*, $\text{PEt}_4\text{Cl}, \text{AuCl}_3$, melting at 179° , and *platinichloride*, $2\text{PEt}_4\text{Cl}, \text{PtCl}_4$, were also prepared. Some of these compounds were also prepared, for the sake of comparison, from triethylphosphine; the products were identical with those described already. The precipitate obtained by mixing tetraphosphonium iodide and mercuric iodide in alcoholic solution at the ordinary temperature has the composition $2\text{PEt}_4\text{I}, \text{HgI}_2$, but it is converted into the compound described above when it is heated at 160° with mercuric iodide and ethyl iodide.

By heating mercury phosphide with methyl iodide at 140 — 150° , some analogous compounds were obtained. *Tetramethylphosphonium mercuriodide*, $\text{PMe}_4\text{I}, 2\text{HgI}_2$, melting at 172° ; *mercurichloride*, $\text{PMe}_4\text{Cl}, \text{HgCl}_2$, melting at 249° ; *platinochloride*, $2\text{PMe}_4\text{Cl}, \text{PtCl}_4$, and *aurichloride*, $\text{PMe}_4\text{Cl}, \text{AuCl}_3$, were prepared.

C. F. B.

Ceric Sulphates. By WILHELM MUTHMANN and L. STÜTZEL (Ber., 1900, 33, 1763—1765).—When ceric oxide is dissolved in concentrated sulphuric acid and the solution evaporated, a yellow salt is first obtained, which is normal ceric sulphate, $\text{Ce}(\text{SO}_4)_3, 4\text{H}_2\text{O}$. The mother liquors often, but not always, yield a second salt, forming large, reddish-brown crystals, which are readily decomposed by water, with formation of insoluble basic substances. This substance has the composition $\text{Ce}_2(\text{SO}_4)_3, 2\text{Ce}(\text{SO}_4)_3, 20\text{H}_2\text{O}$, and is the only ceric sulphate which could be obtained in addition to the normal salt.

A. H.

Luminescence Spectra. By WILHELM MUTHMANN and E. BAUR (Ber., 1900, 33, 1748—1763).—The authors regard the luminescence spectra yielded by certain of the rare earths as of considerable value for their identification, in spite of the fact that these spectra are much affected by the presence of small quantities of other substances, such as lime, gypsum, &c. Detailed measurements and diagrams are given for lanthanum oxide, yttrium oxide, yttrium sulphates of various origins, and oxides and sulphates obtained from monazite and commercial thorium nitrate. The spectra of the yttrium sulphates, and of

the oxides and sulphates derived from monazite and thorium nitrate, are essentially made up of lines due to yttria and gadolinia, to the latter of which the authors ascribe four bands. By fractionation of a crude yttrium earth by ammonia, and crystallisation of the formate, each operation being repeated 50 times, an earth containing very little erbia is obtained, which shows strong lines of yttria and gadolinia. When this material is divided into about 20 fractions by means of potassium dichromate, the last of these contains only traces of erbia and very little gadolinia. Further fractionation with ammonia removes the remainder of the erbia, whilst the gadolinia accumulates in the last fractions. Thoria itself gives no luminescence spectrum, the spectra actually observed with the oxides and sulphates derived from monazite and commercial thorium nitrate being due to yttria and gadolinia.

The authors have not observed the independent disappearance of the single bands of the yttria and gadolinia spectra in the manner described by Crookes (*Trans.*, 1889, 55, 270), whilst, on the other hand, Crookes has not described spectra corresponding with those ascribed by the authors to almost pure yttria and gadolinia respectively.

A. H.

Natural and Artificial Pozzuolana. By GIOVANNI GIORGIS and Ugo ALVISI (*Gazzetta*, 1900, 30, i, 436—508. Compare this vol., ii, 348).—A discussion is given of the literature of the setting of hydraulic materials, followed by a bibliography of the subject.

T. H. P.

Chemical Constitution of Steels; Influence of Tempering on the State of Combination of Elements other than Carbon. By ADOLPHE CARNOT and GOUTAL (*Compt. rend.*, 1900, 131, 92—96. Compare *Abstr.*, 1897, ii, 520, 555).—It has been shown (*Abstr.*, 1897, ii, 555) that in slowly cooled steel, the sulphur present combines with the manganese in preference to iron, since treatment with cupric potassium chloride solution leaves an insoluble residue of cupric sulphide containing sulphur equivalent to the manganese present, whereas iron sulphide is not attacked by the solvent in question. Precisely similar results are obtained with tempered steel, whence it follows that tempering has no influence on the condition in which sulphur exists in the metal. The same applies to phosphorus, present as iron phosphide, Fe_3P , which is left undissolved when the tempered or untempered steel is treated with cupric potassium chloride solution. On the other hand, arsenic, which exists in the free state in untempered steel, is found to be present mainly as an iron arsenide, Fe_3As , in the tempered metal, this arsenide being left undissolved by treatment with 7 per cent. sulphuric acid with exclusion of air. Copper is present chiefly in the uncombined state in both tempered and untempered steel, as was shown microscopically after digestion with dilute acid or with a mixture of hydrogen peroxide and ammonium chloride solution. Nickel in tempered, as in untempered, steel appears to exist in the metallic condition, either mixed with or dissolved in the iron.

N. L.

Iron Selenides. By HENRI FONZES-DIACON (*Compt. rend.*, 1900, 130, 1710—1712).—The combination of iron and selenium at high temperatures always gives rise to compounds containing an excess of selenium over that indicated in the formula FeSe . Amorphous products only are obtained by the action of hydrogen selenide or selenium vapour on red hot iron. Ferric selenide, Fe_2Se_3 , produced by the action of hydrogen selenide on ferric oxide heated to bright redness, forms a grey, microcrystalline powder with a blue reflex.

The *selenides*, Fe_3S_4 and Fe_7S_8 , are obtained in a similar manner from the peroxide or anhydrous ferric chloride at somewhat higher temperatures; these compounds are crystalline, and belong apparently to the cubic system.

Iron diselenide, FeSe_2 , prepared in a similar manner at a dull red heat, forms pseudomorphs after crystallised anhydrous ferric chloride; when heated in a current of oxygen, it is oxidised to ferric oxide and selenium dioxide.

The higher selenides are all converted into the monoselenide by reduction with hydrogen; the subselenide, Fe_3Se , however, could not be obtained by this process. When the monoselenide is heated in the electric furnace, a portion undergoes complete dissociation, whilst the residue remains unaltered. The stability of the selenides towards hydrogen chloride or a concentrated solution of this gas increases with the percentage amount of selenium, the diselenide not being attacked. The selenium in these compounds is readily replaced by chlorine, and fuming nitric acid converts them into selenites. G. T. M.

Behaviour of Potassium Cobaltocyanide and of Chromous Compounds towards Oxygen Gas. By WILHELM MANCHOT and JOHANNES HERZOG (*Ber.*, 1900, 33, 1742—1748).—When a solution of potassium cobaltocyanide is rapidly oxidised by atmospheric oxygen, it is found that twice as much oxygen is absorbed as is necessary for the conversion of the cobalto- into the cobalti-cyanide, according to the equation $2\text{K}_4\text{CoCy}_6 + \text{H}_2\text{O} + \text{O} = 2\text{K}_2\text{CoCy}_6 + 2\text{KOH}$.

At the close of the reaction, moreover, the whole of the oxygen absorbed is found to be present in the form of hydrogen peroxide. On the other hand, when the oxidation is carried out slowly, the oxygen absorbed is only slightly in excess of that required by the equation, and a correspondingly small amount of hydrogen peroxide is present. This is due to the fact that in the first case the direct oxidation proceeds so rapidly that the slower, indirect oxidation by means of hydrogen peroxide does not occur to an appreciable extent, whilst in the second case this factor becomes of importance. When a solution of potassium cobaltocyanide, prepared by adding potassium cyanide solution to a well boiled solution of cobalt sulphate, is simply boiled, hydrogen is evolved, the volume of which is equal to that of the oxygen absorbed during the rapid oxidation by air, and is chemically equivalent to the oxygen required according to the foregoing equation.

Solutions of chromous salts also evolve hydrogen when they are boiled or treated with platinised platinum, but no hydrogen peroxide is formed during their oxidation by atmospheric oxygen, and the amount of oxygen absorbed is simply that required for the oxidation.

The author therefore regards the oxidation of the chromous salts as due to the direct action of the oxygen of the air, whilst that of potassium cobaltocyanide is a spontaneous oxidation effected by the oxygen of the water present, the function of the absorbed oxygen being to unite with the liberated hydrogen, and thus destroy the equilibrium which normally exists between the cobaltocyanide, hydrogen, and cobaltocyanide.

A. H.

Ammonium Chromous Sulphate. By CHARLES LAURENT (*Compt. rend.*, 1900, 131, 111—113).—*Ammonium chromous sulphate*, $(\text{NH}_4)_2\text{Cr}(\text{SO}_4)_2 + 6\text{H}_2\text{O}$, prepared by concentrating in an atmosphere of carbon dioxide an aqueous solution of ammonium and chromous sulphates in molecular proportion, forms large, blue crystals resembling those of the double sulphates of the magnesium series. It is insoluble in alcohol, but readily soluble in water; 100 c.c. of the saturated aqueous solution at 20° contain 55 grams of the salt. When exposed to air, it is rapidly oxidised and converted into chromic salt.

N. L.

Permanganomolybdates. By CARL FRIEDHEIM and MINNA SAMELSON (*Zeit. anorg. Chem.*, 1900, 24, 65—107).—The authors have repeated the work of Rosenheim and Itzig (*Abstr.*, 1898, [ii, 154], Struve (*J. pr. Chem.*, 1854, 61, 449), and Péchard (*Abstr.*, 1897, ii, 498), and have prepared the following compounds.

Ammonium permanganomolybdate, $3(\text{NH}_4)_2\text{O} \cdot \text{MnO}_2 \cdot 9\text{MoO}_3 \cdot 7\text{H}_2\text{O}$, is obtained by adding 1.8 litres of a concentrated solution of ammonium paramolybdate (1 litre = 250 grams) to 100 c.c. of a solution of manganous chloride (1 litre = 875 grams) and then 800 c.c. of 2.5 per cent. hydrogen peroxide; the mixture is boiled for some time and filtered, when on cooling the salt separates in small, lustrous, red rhombohedra. It is necessary to employ solutions of the above strength, for under other conditions different salts are formed. The isomorphous mixture $4[(\text{NH}_4)_2\text{Mn}]_2\text{O} \cdot \text{MnO}_2 \cdot 11\text{MoO}_3 \cdot 8\text{H}_2\text{O}$ $[(\text{NH}_4)_2\text{O} : \text{MnO} = 8 : 1]$ is obtained by employing 20 per cent. more of a 3 per cent. solution of hydrogen peroxide in the above reaction. The salt, $2(\text{NH}_4)_2\text{O} \cdot \text{MnO}_2 \cdot 7\text{MoO}_3 \cdot 5\text{H}_2\text{O}$, is obtained by employing 18.5 per cent. solution of hydrogen peroxide in the above reaction.

The isomorphous mixture $4[(\text{NH}_4)_2\text{Mn}]_2\text{O} \cdot \text{MnO}_2 \cdot 10\text{MoO}_3 \cdot 6\text{H}_2\text{O}$ $[(\text{NH}_4)_2\text{O} : \text{MnO} = 17 : 3]$ is obtained by boiling a solution of the salt $3(\text{NH}_4)_2\text{O} \cdot 5\text{MoO}_3 \cdot 2\text{MoO}_4 \cdot 6\text{H}_2\text{O}$ with the equivalent quantity of manganous chloride. It crystallises in lustrous, red rhombohedra.

The *potassium salts*, $3\text{K}_2\text{O} \cdot \text{MnO}_2 \cdot 8\text{MoO}_3 \cdot 3\text{H}_2\text{O}$ and

are obtained in a similar manner by the action of hydrogen peroxide on mixed solutions of potassium paramolybdate and manganous chloride. *Potassium permanganomolybdate*, $3\text{K}_2\text{O} \cdot \text{MnO}_2 \cdot 9\text{MoO}_3 \cdot 5\text{H}_2\text{O}$, corresponding with the above ammonium salt, is obtained by adding a saturated solution of potassium chloride to the corresponding ammonium salt, or the salt $4(\text{NH}_4)_2\text{O} \cdot \text{MnO}_2 \cdot 10\text{MoO}_3 \cdot 6\text{H}_2\text{O}$. The isomorphous mixture $3[\text{K}_2(\text{NH}_4)_2]\text{O} \cdot \text{MnO}_2 \cdot 8\text{MoO}_3 \cdot 4\text{H}_2\text{O}$ $[\text{K}_2\text{O} : (\text{NH}_4)_2\text{O} = 4 : 1]$ is obtained by boiling mixed solutions of the salt

manganous chloride, and potassium chloride, and is a microcrystalline, orange-red powder.

A repetition of Struve's work resulted in the preparation of the following new salts. *Potassium manganese permanganomolybdate*, $2K_2O, MnO, MnO_2, 9MoO_3, 8H_2O$, is obtained by treating a solution of potassium trimolybdate and manganous sulphate with chlorine. *Ammonium permanganomolybdate*, $4(NH_4)_2O, MnO_2, 11MoO_3, 7H_2O$, is obtained in small quantities by prolonged boiling of pure hydrated manganese dioxide with a solution of ammonium paramolybdate. The salt, $3(NH_4)_2O, MnO_2, 9MoO_3, 8H_2O$, is obtained when hydrated manganese dioxide containing manganous oxide is employed in the preparation of the preceding salt.

A repetition of Péchard's and Rosenheim and Itzig's work resulted in the preparation of the following salts. The isomorphous mixture $3[K_2(NH_4)_2Mn]O, MnO_2, 10MoO_3, 6H_2O$ [$K_2 : (NH_4)_2 : Mn = 2 : 20 : 5$] is obtained by the action of potassium permanganate on a mixture of ammonium paramolybdate and manganous chloride, and crystallises in lustrous, red rhombohedra. The mixture,

$3[(NH_4)_2Mn]O, MnO_2, 10MoO_3, 10H_2O$ [$(NH_4)_2 : Mn = 10 : 3$], obtained by the action of potassium permanganate on ammonium manganese molybdate, crystallises in beautiful, red rhombohedra. If the crystallisation of the preceding mixture is effected rapidly, it contains potassium salt in the proportion $(NH_4)_2 : K : Mn = 12 : 1 : 1$. The isomorphous mixture $4[K_2(NH_4)_2Mn]O, MnO_2, 10MoO_3, 5H_2O$ [$(NH_4)_2 : K_2 : Mn = 20 : 5 : 1$] is obtained by reducing a boiling solution of potassium permanganate and ammonium molybdate with alcohol until the violet colour is changed to red. When excess of ammonium molybdate is employed, the salt $3[(NH_4)_2Mn]O, MnO_2, 10MoO_3, 8H_2O$ [$(NH_4)_2 : Mn = 20 : 1$] is formed.

The salts described above form a new series of compounds as shown by the formula $2R_2O, MnO_2, 7MoO_3$; $3R_2O, MnO_2, 8MoO_3$; $3R_2O, MnO_2, 9MoO_3$; $3R_2O, MnO_2, 10MoO_3$; $4R_2O, MnO_2, 10MoO_3$; $4R_2O, MnO_2, 11MoO_3$.
E. C. R.

Reduction of Tungsten Trioxide by Zinc. Preparation of Pure Tungsten. By MARCEL DELÉPINE (*Compt. rend.*, 1900, 131, 184—187. Compare this vol., ii, 8).—Tungsten is readily prepared by heating a mixture of tungsten trioxide or ammonium tungstate with powdered zinc in a gas or coke furnace. A product containing 94 per cent. of the element may be obtained from commercial zinc and crude tungsten trioxide, and the percentage is raised to 99.9 by extracting the substance with sodium hydroxide solution and drying the residue at red heat in a current of hydrogen. The metal is produced by this process in the form of a grey, crystalline powder which assumes a metallic lustre on compression or trituration; its density is 18.64, corresponding closely with the value obtained for the massive form. The heat of combustion of the metal to the trioxide is 196.44 Cal. at constant vol. and 197.3 Cal. at constant pressure; the heats of oxidation of WO_3 to WO_2 and W to WO_2 at constant pressure are 64.9 and 132.4 Cals. respectively.

Tungsten trioxide may be readily reduced by hydrogen at temperatures below the fusing point of glass. G. T. M.

Crystallisation of Gold. By ALFRED DITTE (*Compt. rend.*, 1900, 131, 143—149).—When a sheet of gold is heated for several hours in contact with a mixture of sodium chloride and sodium pyrosulphate, the surface of the metal becomes eroded by the action of the pyrosulphuryl chloride produced, and the gold chloride which results subsequently dissociates, leaving this element in a crystalline form. The same result is obtained by employing a mixture of ferrous sulphate and sodium chloride, and although the temperature attained is below the melting point of gold, the metal produced from the chloride is found in the form of rhombic plates, small prisms, six-rayed rosettes, and fern-like aggregates; a portion is also obtained in non-crystalline filaments indicating incipient fusion. These appearances resemble those presented by the gold of auriferous minerals. When quartz fragments are introduced with the mixtures employed in the preceding experiments, it is found that the gold crystals and filaments are deposited at the surface and in the fissures of the mineral.

The aqueous extract of the salts after fusion contains sodium sulphide, produced by the action of the oxides of sulphur on the fused sodium chloride; when the oxides of iron or other metals are present, the corresponding sulphides are produced by double decomposition. These reactions are comparable with those occurring in nature and explain the presence of the sulphides in auriferous quartz.

A mixture of sodium chloride and pyrosulphate attacks platinum in a similar manner, the fused mass containing detached particles of the metal and traces of its chlorides. G. T. M.

Gold-Aluminium Alloys. By CHARLES T. HEYCOCK and FRANCIS H. NEVILLE (*Phil. Trans.*, 1900, A., 194, 201—232).—Addition of aluminium to gold lowers the freezing point of the latter metal, and an alloy containing 21.5 atomic per cent. of aluminium freezes as low as 525°. Further addition of aluminium raises the freezing point until a maximum is reached at 625°, corresponding with an alloy of the composition Au_2Al . The freezing point curve then falls again, reaching another minimum or eutectic point at about 570°, corresponding with 40 atomic per cent. of aluminium. From that point, the curve rises rapidly to 1060°, the freezing point of the alloy AuAl_3 , the purple compound discovered by Sir W. Roberts-Austen. After passing this maximum, the curve falls again and has a minimum close to the freezing point of pure aluminium. This curve, on which a large number of points have been determined, shows the existence of the compounds Au_2Al and AuAl_3 , whilst other singularities, less well marked than those mentioned, point to the formation at various stages of less stable compounds, probably Au_4Al , Au_5Al_2 (or Au_8Al_3), and AuAl . As the curve is followed, the different substances that crystallise out may be traced in the changing colour of the alloys, which are at first yellow, owing to the presence of free gold, then white, then purple, and finally white again as the aluminium end of the curve is reached.

These results are fully borne out by a microscopic study of the
VOL. LXXVIII. ii.

alloys. In particular, the alloys which are approximately of the composition Au_2Al and AuAl_2 show the structure which is characteristic of a nearly pure substance; polygonal sections of the crystals cover the surface, divided only by fine boundary lines; as the composition of the alloy departs from that of the pure compound, so these boundary lines increase in size. The results given by slowly cooled alloys are the same in kind as those obtained from quickly cooled alloys. A number of photomicrographs illustrate this part of the paper.

J. C. P.

Mineralogical Chemistry.

Ankerite from Missouri. By AUSTIN F. ROGERS (*Kansas Univ. Quart.*, 1899, 8, A, 183).—The material analysed consists of salmon coloured, crystalline masses, with minute crystals lining crevices; it occurs with hematite, chalybite, calcite, and amethyst, near Rolla, Phelps Co. The formula agrees closely with that for normal ankerite, namely, $2\text{CaCO}_3, \text{MgCO}_3, \text{FeCO}_3$:

CaO.	MgO.	FeO.	CO ₂ .	Total.	Sp. gr.
28.41	10.20	17.22	44.21	100.04	2.99
					L. J. S.

Origin of Nitrates in Cavern Earths. By WILLIAM H. HESS (*J. Geol.*, 1900, 8, 129—134. Compare Abstr., 1896, ii, 529).—The considerable deposits of nitrates in the great limestone caves of Virginia, Kentucky, and Indiana are often supposed to have been formed by bats; but this, it is pointed out, is probably incorrect. The author supposes that the nitrates in the surface soil have been carried by percolating water (surface drainage) into the caves below, where, in cases in which evaporation exceeds inflow, the nitrates are deposited. In support of this theory are given analyses of cave earth, bat guano, and of the water which drips from the roof of the Mammoth Cave, Kentucky. The same explanation would also apply to the deposits of nitrates found under rock ledges.

L. J. S.

Composition of Sulphohalite. By SAMUEL L. PENFIELD (*Amer. J. Sci.*, 1900, [iv], 9, 425—428).—From the single partial analysis that has been made of sulphohalite, the formula was deduced as $3\text{Na}_2\text{SO}_4, 2\text{NaCl}$ (Abstr., 1889, 217). Recent attempts by de Schulten and by van't Hoff and Saunders to prepare this compound artificially have failed, and the existence of sulphohalite has consequently been doubted; a new analysis was therefore desirable. The following are the new results obtained with carefully purified material from a portion of the same optically isotropic, rhombic dodecahedral crystal used for the previous analysis:

SO ₃ .	Na ₂ O.	K ₂ O.	Na.	Cl.	F.	Ignition.	Total.	Sp. gr.
41.79	32.37	0.10	11.60	9.10	4.71	0.15	99.82	2.500

This gives the formula $2\text{Na}_2\text{SO}_4, \text{NaCl}, \text{NaF}$. The presence of fluorine is unexpected, but may be explained by the borax deposits of Borax Lake, San Bernardino Co., California, having been formed by fumerole action. Sulphohalite is intimately associated with hanksite, a mineral also containing three acid constituents, $9\text{Na}_2\text{SO}_4, 2\text{Na}_2\text{CO}_3, \text{KCl}$, (Abstr., 1897, ii, 49).
L. J. S.

Melilite Group of Minerals. By FERDINAND FOUQUÉ (*Bull. Soc. franç. Min.*, 1900, 23, 10—15).—In the analysis of silicate rocks by Deville's method, in which the material is fused with lime, it is found that the fused mass on cooling sometimes consists almost entirely of a crystalline mass of a mineral of the melilite group. Thin sections under the microscope show tetragonal crystals which are sometimes arranged in spherulitic groups 1 mm. in diameter; the crystals are always optically positive with marked birefringence, but are often nearly isotropic in the centre. Analyses I and II are of the products obtained by fusing an andesite and a basalt respectively with about an equal amount of calcium carbonate.

	TiO ₂	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	FeO	CaO	MgO	Na ₂ O	K ₂ O	Total	Sp. gr.
I.	0.23	36.47	18.00	2.22	2.98	42.18	0.89	2.44	0.46	100.82	2.95
II.	0.56	32.55	12.49	1.48	4.67	42.08	8.86	2.35	0.63	100.62	2.99

Vogt has considered the members of the melilite group to consist of mixtures of the two end members gehlenite and the non-aluminous åkermanite, which are optically negative and positive respectively. According to this theory, a member with 12 per cent. of alumina should be optically negative and almost isotropic, but this is opposed to the present observations.
L. J. S.

Gadolinite from Batum. By G. P. TOCHERNIK (*J. Russ. Phys. Chem. Soc.*, 1900, 32, 252—266).—Gadolinite occurring in the form of a cement occurs with flesh-red feldspar in a coarse-grained granite from the bed of the river Chorok. The mineral, which has a hardness slightly less than 7 and a sp. gr. 4.205, shows no cleavage, the fracture being conchoidal. It has a dark resinous-black colour with a distinct greenish shade and a fatty lustre, and is opaque even at the edges of very thin fragments; from external examination, it appears to be amorphous. It does not melt in the blowpipe flame, but readily breaks up and increases slightly in volume; on cooling, it becomes greyish-green in colour. Concentrated hydrochloric acid and aqua regia readily attack, but do not completely decompose it, whilst sulphuric acid acts less energetically. Analysis:

Y ₂ O ₃	Er ₂ O ₃	CaO	FeO	BaO	Nb ₂ O ₅	TiO ₂	CaO
28.38	11.01	0.53	10.02	4.22	1.05	5.08	4.92
		LaO	DiO	SiO ₂	H ₂ O	Total	
		4.86	4.99	22.20	0.73	98.87	

with traces of MgO, MnO, Al₂O₃, K₂O, Na₂O and P₂O₅. The Nb₂O₅, which is probably due to the presence of some other mineral, possibly contains small quantities of Ta₂O₅.
T. H. P.

Manganocalcite and Angolite. By EDUARD BREUSING (*Inaug. Diss. and Jahrb. Min.*, 1900, Beil.-Bd., 13, 265—330).—Mangano-

calcite from Schemnitz, Hungary, was described by Breithaupt as an orthorhombic carbonate of manganese, calcium, &c., belonging to the aragonite group. It was afterwards shown by Des Cloiseaux (Abstr., 1886, 320) to be a mixture of carbonate and an anorthic hydrated silicate of manganese, and this is confirmed by the present author, who gives the name angolite (angolith) to the latter. The angolite can only be separated from the mixture by mechanical means, since it is readily decomposed by acids; it is flesh-red to rose-coloured, with a vitreous lustre; $H = 5$; sp. gr. 3.054—3.067; there is a cleavage parallel to the length of the fibres, and the pure material contains no carbon dioxide, calcium or magnesium. The mixture occurs in globular aggregations with a radial structure, and it varies considerably in composition; the mean of several analyses is given under I. After deducting a variable amount of carbonates (14.90 per cent. in the mean), the composition (II) of the angolite agrees with the formula $H_2Mn_3(SiO_3)_4, H_2O$. Angolite is a zeolite related to apophyllite or heulandite, and perhaps to inesite.

	SiO ₂	FeO.	MnO.	CaO.	MgO.	CO ₂	H ₂ O.	Total.
I. 41.89		1.23	35.79	7.51	0.90	6.49	6.30	100.11
II. 49.21		43.39		—	—	—	7.40	100.00

L. J. S.

Corundum-bearing Rocks of Eastern Ontario. By WILLER G. MILLER (*Amer. Geologist*, 1899, 24, 276—282).—Corundum occurs in Eastern Ontario in syenites, syenite-pegmatites, nephelite-syenites, and anorthosites, which as large masses are intrusive in the gneiss of the region; these occurrences are similar to those of India and the Urals (Abstr., 1899, ii, 763). A specimen of the anorthosite free from corundum from South Sherbrooke gave analysis I (by W. Lawson); the felspar (bytownite, Ab, An₄) from the same rock gave II, and the hornblende gave III (in III also a trace of MnO).

	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	FeO.	CaO.	MgO.	Na ₂ O.	K ₂ O.	CO ₂	H ₂ O.	Total.	Sp. gr.

II.	48.12	34.54	0.86	—	16.30	trace	1.91	0.15	—	nil	101.38	2.731
III.	41.40	15.39	7.01	7.17	12.53	10.31	3.58	1.56	—	0.81	99.76	3.13

L. J. S.

Meteorite from Oakley, Kansas. By H. L. PRESTON (*Amer. J. Sci.*, 1900, [iv], 9, 410—412).—This stone, which weighs 27.9 kilograms, was found 15 miles south-west of Oakley, Logan Co., Kansas, in 1895. The material is greyish-black with darker blotches and numerous grains of metallic iron and troilite. Under the microscope, it shows condrioles of olivine and enstatite set in a very irregularly granular ground-mass of the same materials. Sp. gr. 3.7. The metallic portion (14.44 per cent. of the whole) contains Fe, 89.16; Ni, 10.84 per cent.

A list is given of eleven meteorites reported from Kansas, and it is suggested that five of these belong to the same fall. L. J. S.

Analyses of French Mineral Waters. By ADOLPHE CARNOT (*Ann. des Mines*, 1899, [ix], 16, 33—94).—A collection is given of 122 analyses of mineral waters from France and her colonies which

have been performed since 1894 in the Laboratory of the National School of Mines. Previous collections of 255 and 207 analyses were published in 1884 and 1894 respectively.

L. J. S.

Physiological Chemistry.

Digestion in Birds. By L. PAIRA-MALL (*Pflüger's Archiv*, 1900, 80, 600—627).—In pigeons and hens, during hunger, the gastric cells are laden with granules of ferment or zymogen. These granules are believed to be converted into the enzyme by the acid formed. The amount of pepsin obtainable from the mucous membrane continuously diminishes during digestion, reaching its minimum 6 to 8 hours after the meal. Restoration begins 2 or 3 hours later. The gizzard does not form pepsin. The gullet and crop secrete only mucus. The so-called middle-stomach of crows and magpies forms pepsin in the same way as described above. The histological changes in the cells of the pancreas are similar to those described by Heidenhain in the dog. This gland forms both proteolytic and amylolytic enzymes.

W. D. H.

Peptic Digestion. By EMIL SCHÜTZ and KARL H. HUPPERT (*Pflüger's Archiv*, 1900, 80, 470—526).—The experiments were conducted with egg-albumin freed from globulin; ovo-mucoid is not affected by gastric digestion, or may be removed by boiling with neutral ferric acetate. Determinations, mainly by the polarimeter, were made after digestion with artificial gastric juice of (1) acid-albumin, (2) primary proteoses, (3) secondary proteoses. The results are given in tables, and show the influence of temperature, of the degree of acidity, of the amount of albumin originally taken, of the length of time of digestion, of the volume of the fluid, and of the amount of pepsin on the relative quantities of the three groups of products just mentioned.

W. D. H.

The Bile as a Digestive Juice. By G. G. BRUNO (*Chem. Centr.*, 1900, i, 916; from *Arch. Sci. biol. St. Petersburg*, 7, 87—142).—The flow of bile ceases when the stomach is empty; it begins to flow with the entrance of food into the stomach. Water, proteid, or carbohydrate does not intensify the rate of secretion, but fat does.

The bile contains a proteolytic and a fat-splitting enzyme. It also assists the pancreatic juice in all its activities.

W. D. H.

Secretion of the Pancreas. By A. A. WALTER (*Chem. Centr.*, 1900, i, 916; from *Arch. Sci. biol. St. Petersburg*, 7, 1—86).—The secretion of pancreatic juice in dogs is stimulated by the hydrochloric acid of the stomach, and this largely depends on the appetite of the animal. The amount of secretion runs parallel with the amount of water in the food. Food rich in proteid, carbohydrate and fat calls forth respectively an increase of trypsin, amylpsin, and steapsin.

High acidity of the gastric is accompanied by high alkalinity of the pancreatic juice. The signal for all these reflex effects is the stimulation of the nerve-endings of the intestinal mucous membrane.

W. D. H.

Metabolism in Horses. By THEODOR PFEIFFER (*Landw. Versuchs-Stat.*, 1900, 54, 101—112. Compare *J. Landw.*, 1890, 38, 258).—A criticism of Zuntz and Lehmann's methods and conclusions (*Abstr.*, 1889, 911; *Landw. Versuchs-Stat.*, 1891, 38, 340; and *Landw. Jahrb.*, 1894, 23, 125, and 1898, 27, *Ergänzungsbd.*, iii). Respiration experiments during short periods furnish data as regards the direction of metabolism under different conditions, but cannot show exactly the absolute extent of the effects of the feeding.

N. H. J. M.

Influence of Extract of Ovaries on the Changes Produced in Nutrition During Pregnancy. By ALBERT CHARRIN and GUILLEMONAT (*Compt. rend.*, 1900, 130, 1787—1789).—During pregnancy, the activity of the organs of nutrition is notably diminished, less oxygen being consumed, and smaller quantities of carbon dioxide and urea eliminated. Injections of extracts of liver, spleen, and muscle do not stimulate these organs to any appreciable extent, whereas the extract of one or two ovaries, obtained by digesting these glands with a dilute solution of glycerol and sodium chloride, has a marked effect in increasing the excretion of urea. This result can only be maintained, however, by repeating the injection at least once in three days.

G. T. M.

Action of Increased Osmotic Pressure on the Ovum. By E. BATAILLON (*Compt. rend.*, 1900, 130, 1480—1482).—By placing the egg-cells of *Petromyzon* in isotonic solutions of salt or sugar, the separation of the blastosphere into its early segmentation spheres is accelerated, and may even result in a complete division, and formation of two embryos. Similar mechanical processes may possibly explain the occurrence of double monsters, or other abnormalities, in the higher animals.

W. D. H.

Relationship between the Nitrogen and Chlorides of the Stomach-contents. By JUSTIN WINTER and FALLOISE (*Compt. rend.*, 1900, 130, 1646—1648).—Attention is drawn to a fixed relationship which exists between the chlorine of the gastric juice and the amount of nitrogenous substances which pass into solution. This ratio is expressed by a mathematical formula.

W. D. H.

Thiocyanate in Human Saliva. By LAFAYETTE B. MENDEL and E. C. SCHNEIDER (*Proc. Amer. Physiol. Soc.*, 1900, vii—viii; *Amer. J. Physiol.*, 4).—The saliva of non-smokers and smokers shows an average of 0.0029 and 0.0134 of potassium thiocyanate per cent. respectively. The parotid saliva is uniformly richer in this substance than the submaxillary saliva.

W. D. H.

Action of Anti-leucocytic Serums on Blood-coagulation. By O. DELEZENNE (*Compt. rend.*, 1900, 130, 1488—1490. Compare this vol., ii, 423).—Further experiments are brought forward to show that certain serums like 'peptone' when injected intra-

venously lead to the liberation of an anti-coagulating substance. The importance of the liver as well as of the leucocytes is insisted on. Probably, when the leucocytes disintegrate, two substances are liberated, one assisting, the other hindering, coagulation of the blood; the former is retained by the liver, the latter remains in the blood.

W. D. H.

Iodine in the Blood. By EUGÈNE GLEY and PAUL BOUBOET (*Compt. rend.*, 1900, 130, 1721—1724).—In the blood of the dog, iodine combined with nucleo-proteid is present normally in solution. Its amount, like that of iodine in the thyroid, is variable. In the analyses quoted, the amount of iodine in the thyroid varied from 0.18 to 1.06, and in a litre of blood from 0.013 to 0.11 milligram.

W. D. H.

Artificial Production of Normal Larvæ from Unfertilised Eggs of the Sea Urchin. By JACQUES LOEB (*Amer. J. Physiol.*, 1900, 3, 434—471).—The paper describes in full a large number of experiments which show that the eggs of the sea urchin will develop with somewhat imperfect embryos even though fertilisation has not occurred. To promote this, 'physiologically balanced salt solutions' were used similar to those employed previously in the study of muscular contraction and other vital contractile phenomena.

W. D. H.

Organic Substance of the Shells of *Mytilus* and *Pinna*. By G. WETZEL (*Zeit. physiol. Chem.*, 1900, 29, 386—410).—The organic basis of the shells of *Mytilus* and *Pinna* is mainly conchiolin. On being decomposed by sulphuric acid, it yields tyrosine, leucine, and glycine. The occurrence of phenylaminopropionic acid or other phenyl-amino-acids is not probable. It contains also a 'hexon' nucleus; the yield of bases places it between casein and egg-albumin. The quantity of nitrogen split off as ammonia amounts to 3.47 per cent. of the whole. The organic residue of the mother-of-pearl substance of the mussel shell differs from that obtained from the rest of the shell by a smaller percentage of carbon.

W. D. H.

Mucin. By ISAAC LEVIN (*Amer. J. Physiol.*, 1900, 4, 90—95).—Mucin prepared from connective tissue, when injected into the blood-stream of dogs and rabbits, produces a depressive effect on the central nervous system, which is chiefly shown by a fall of blood-pressure. It is, however, not fatal unless the animal has been previously deprived of its thyroid. Mucinæmia may be one of the pathological conditions resulting from the absence of the thyroid function.

W. D. H.

Chemistry of Paranucleo-compounds. By P. A. LEVENE and C. L. ALSBERG (*Proc. Amer. Physiol. Soc.*, 1900, xi; *Amer. J. Physiol.*, 4).—The ichthulin of the cod-fish egg differs from that described by Walter in its percentage composition and in containing no carbohydrate radicle in its molecule. On treatment with alkalis, both ovo-vitellin and ichthulin yield substances akin to true nucleic acids, but differing from them in the absence of purine bases, and in containing proteid in their molecule. This proteid does not resemble the protamines, as can be concluded by the yield of 'hexon' bases. Iron

enters into the molecule of the paranucleins in a combination probably similar to that of the ethereal acids. W. D. H.

Chemistry of the Lymphatic Glands. By LAFAYETTE B. MENDEL and R. NAKASEKO (*Proc. Amer. Physiol. Soc.*, 1900, xii; *Amer. J. Physiol.*, 4).—In view of a possible compensatory action of the lymphatic glands after splenectomy (an operation which does not lessen uric acid excretion), the Horbaczewski-Spitzer experiments were repeated with these organs. At most, only traces of uric acid were obtained by treatment of 100—300 grams of material. Xanthine bases were found in larger quantity. The glands are rich in nucleic acid, the study of which is being continued. W. D. H.

Urea in Human Milk. By BERNHARD SCHÖNDORFF (*Pflüger's Archiv*, 1900, 81, 42—47).—Polemical. The values for urea in human milk given previously are maintained to be correct, and those given by Camerer and Söldner incorrect, and much too small W. D. H.

Xanthine Bases in Fæces. By WILLIAM H. PARKER (*Amer. J. Physiol.*, 1900, 4, 83—89).—From experiments on man, it is found that under normal conditions on a diet containing no nuclein there is a constant excretion of combined xanthine bases derived from the cells of the alimentary canal. The amount excreted is about 30 milligrams a day, and is about equal to that which leaves the body by the urine under the same conditions. The amount is nearly doubled with a mixed diet. This increase may not be necessarily due to the nuclein and alloxuric substances in the food, but may arise indirectly from an influence exerted on the processes of metabolism and secretion. W. D. H.

Excretion of Sulphur after Extirpation of the Liver. By S. LANG (*Zeit. physiol. Chem.*, 1900, 29, 305—319).—After the extirpation of the liver in birds, the amount and relationships of the various forms of sulphur in the urine show no noteworthy departure from the normal. The liver plays practically no part in the formation of sulphuric acid from the sulphur of the food. W. D. H.

Albumin in Normal Urine. By A. BELLOCQ (*J. Pharm.*, 1900, [vi], 11, 478—482).—After carefully defining what shall be considered as "normal" urine, the author states that the latter produces a faint turbidity with Tanret's iodo-mercuric reagent in presence of a saturated solution of citric acid. This turbidity, although almost unnoticeable alone, is distinctly visible when compared with the original limpid urine. Finely-divided manganese dioxide carries down from normal urine the whole of its albumin, the latter being recovered as a whitish mucilage; on dissolving the dioxide in a saturated solution of sulphurous acid, adding 30 per cent. of alcohol of 85° containing citric acid, and filtering, ordinary albumin contaminated with uric acid is obtained. W. A. D.

Decrease of Water in the Central Nervous System of the Growing White Rat. By HENRY H. DONALDSON (*Proc. Amer. Physiol. Soc.*, 1900, v—vi; *Amer. J. Physiol.*, 4).—In the spinal cord of rats,

the percentage of water decreases from 85 at birth to 70 in old age; in the brain the numbers respectively are 88 and 77.5. The most rapid stage of loss of water is from the tenth to the fiftieth day of life, the period during which the process of myelination of the nerve fibres is proceeding most rapidly.

W. D. H.

Physiological Action of Extracts of Sympathetic Ganglia. By ALLEN CLEGHORN (*J. Boston Soc. Med. Sciences*, 1900, 4, 239—242. Compare Abstr., 1899, ii, 569, and this vol., ii, 423).—The idea that choline is the substance responsible for the fall of blood-pressure produced by the injection of extracts of sympathetic ganglia is combated. The extracts in the present experiments were made with alcohol; this was evaporated off, and the residue dissolved in saline solution. Choline is admittedly present, but after the removal of choline by platinic chloride and filtering, the filtrate was evaporated to dryness, and the residue extracted with saline solution. Injection of this still produced a fall of blood-pressure. Moreover, it is stated that the depressor effect of the ganglionic extract is not abolished by atropine.

W. D. H.

The Anti-rennin of Serum in Pathological Conditions. By CH. ACHARD and A. CLERC (*Compt. rend.*, 1900, 130, 1727—1729).—Previous observers have shown that normal blood-serum contains some substance which hinders the action of rennin on milk. In the present research, thirty-four human serums from various cases of disease were examined, with the general result that the anti-rennin substance diminishes in grave pathological disorders.

W. D. H.

Analysis of the Liquid contained in a Mesenteric Cyst. By A. RICHAUD and R. BONNEAU (*J. Pharm.*, 1900, [vi], 11, 535—541).—The liquid had a sp. gr. 1.025, an alkaline reaction, and did not deposit fibrin after 18 hours; it contained 94.14 per cent. of water, 4.15 per cent. of proteid material (precipitated by alcohol acidified with acetic acid), 0.45 per cent. of fat, 0.77 per cent. of extractives, and gave a solid residue of 5.86 per cent., and 0.49 per cent. of ash. The ash contained sulphates, chlorides, and carbonates, but no phosphates. On adding an excess of alcohol of 95°, a viscous, fibrous mass of proteids was precipitated; this mass shared the character of both the true and the pseudo-mucins, since on heating with dilute sulphuric acid for 1 hour at 115—120° it yielded a substance having reducing properties (reaction of true mucin), and yet on peptic digestion gave an ash rich in phosphorus (characteristic of pseudo-mucin). Finally, it is noteworthy that the secretion contained only minute quantities of serin, globulin, or casein.

W. A. D.

Action of Diphtheria Toxin on the Motor Cells of the Spinal Cord. By H. RAINY (*J. Pathol. and Bacteriol.*, 1900, 6, 435—458).—Diphtheritic paralysis is associated, not only with changes in peripheral nerves, but also with alterations in the cord itself, namely, moderate chromatolysis and vacuolation of the protoplasm of the motor cells.

W. D. H.

Diphtheritic Paralysis and Antitoxin. By F. RANSOM (*J. Pathol. and Bacteriol.*, 1900, 6, 397—414).—Experiments on animals

show that with suitable doses, the administration of antitoxin prevents the development of paralysis caused by the diphtheritic toxin.

W. D. H.

The Lymph after Intravenous Injection of Tetanus Toxin and Antitoxin. By F. RANSOM (*Zeit. physiol. Chem.*, 1900, 29, 349—372).—After the injection of the tetanus poison into the bloodstream, an important part of it passes rapidly into the lymph, and after 26 hours, the amounts in blood and lymph are about equal. If the thoracic duct is opened before the injection of the toxin, so that the lymph drains away, the toxic value of the blood remains, for at least 6 hours, higher than that of the lymph. Much the same is true for the antitoxic horse-serum, except that even 68 hours after the injection the blood still contains more antitoxin than the lymph. The toxin thus behaves like an inorganic constituent, and the antitoxin like a proteid constituent of the blood-lymph system.

W. D. H.

Interaction of Toxin and Antitoxin. By WALTER MYERS (*J. Pathol. and Bacteriol.*, 1900, 3, 415—434).—In cobra venom there are two poisons, one, *cobralysin*, acts hæmolytically, the other, *cobranesurin*, causes death by its action on the respiratory centre. The present paper relates principally to the first, and to the methods by means of which it may be estimated physiologically, and the amount of antivenene necessary to neutralise it. Ehrlich's methods appear to have guided the experiments, and the formation of toxoids is confirmed. This combines with antitoxin, but does not act on the blood corpuscles.

W. D. H.

Use of Alkaline Solutions in Surgical Shock. By WILLIAM H. HOWELL (*Proc. Amer. Physiol. Soc.*, 1900, xiv—xv; *Amer. J. Physiol.*, 4).—Conditions of shock in animals produced, for instance, by operations on the brain, are associated with heart failure and fall of blood pressure. This can be largely counteracted by the injection of 0.5 per cent. solution of sodium carbonate into the veins or into the rectum. If injection is made into the veins, care must be taken to use a moderate amount of solution, not more than sufficient to raise the alkalinity of the blood by 0.1 to 0.2 per cent. Rectal injections are safer. 'Shock-blood' contains no poisonous substances.

W. D. H.

Action of Phloridzin on Muscle. By FREDERIC S. LEE and C. C. HARROLD (*Proc. Amer. Physiol. Soc.*, 1900, ix—x; *Amer. J. Physiol.*, 4).—One gram of phloridzin was injected three times daily for two to four days into fasting cats. The course of fatigue in the *tibialis anticus* muscle was then studied, when the animals were killed. Instead of giving 800 to 1000 contractions, it gives only 200 to 400, and the curves obtained resemble those obtained in the last stages of normal fatigue. This is due to removal of carbohydrates; subsequent injection of dextrose largely restores the muscle. Phloridzinised muscle rapidly goes into rigor.

W. D. H.

Influence of Phloridzin Diabetes on Lactation. By GRAHAM LUSK (*Proc. Amer. Physiol. Soc.*, 1900, xi; *Amer. J. Physiol.*, 4).—In fasting goats, phloridzin diabetes stops milk formation. This is

probably the result of the diabetes, and not of the specific action of phloridzin on the gland. In sugar elimination, the fasting goat resembles the rabbit, since in the urine the ratio of dextrose to nitrogen is 2.8 to 1.

W. D. H.

Toxicity of Urine. By ALBERT CHARRIN (*Compt. rend.*, 1900, 130, 1724—1726).—Support is given to Bouchard's views of auto-intoxication, and that the toxicity of urine is, at any rate in part, due to products of katabolism.

W. D. H.

Action on the Heart of Toxic Products of the Typhoid Bacillus. By GEORGE T. KEMP and MISS S. L. DEWEY (*Proc. Amer. Physiol. Soc.*, 1900, viii—ix; *Amer. J. Physiol.*, 4).—The culture medium used was alkali-albumin prepared from egg white *plus* Ringer's solution in the proportion 1 : 10. This has no action on the heart. The cultures of the typhoid bacillus were filtered, and tested on terrapins' hearts. The heart is gradually weakened without being slowed, and it finally stops in diastole. If the poison has not acted too long, the heart can be revived by Ringer's solution. This property is associated with the presence of proteid (albumin or globulin); the alcoholic filtrate, which is proteid-free, when evaporated to dryness and dissolved in Ringer's solution, increases the strength of the heart-beat without affecting the rate; the proteid precipitate, dissolved in the same solution, gives the same effect on the heart as the culture, but is somewhat less powerful.

W. D. H.

Combination of Nucleins with Metallic Compounds, Alkaloids, and Toxins. By H. STASSANO (*Compt. rend.*, 1900, 131, 72—74).—Ammonium hydrosulphide has no immediate action on mercury and arsenic contained in the nuclein derived from animals poisoned with compounds of these metals. The mercury may be eliminated by electrolysis, but less rapidly than from solutions of its salts, and the separation is accompanied by the destruction of the nuclein by the electric current. An aqueous solution of hæmatoxylin, which is rendered turbid by mercuric chloride dissolved in water or serum, remains unaltered in nuclein solutions containing mercury. These results indicate that the metallic radicles are actually in combination with the nuclein.

Morphine and strychnine can be rapidly extracted by ether from alkaline mixtures of the nucleins; the alkaloids are also liberated by electrolysis, the action being attended by the decomposition of the nuclein. The separation of nucleins from animal tissues by peptic digestion requires two days, whereas the nucleo-albumins can be isolated in one hour; the alkaloids may be eliminated from the latter substances quite as readily as from the former.

The nucleo-albumins prepared from the liver, spleen, and kidneys of dogs poisoned with ricin or tetanin are subjected to the action of a feeble electric current until the decomposition of the nuclein compounds is complete. The toxin and proteids are then precipitated together by alcohol, and from the precipitate the base is extracted with brine.

G. T. M.

Chemistry of Vegetable Physiology and Agriculture.

Mechanism of Agglutination. By HAROLD C. ERNST and W. H. ROBEY, jun. (*J. Boston Soc. Med. Sciences*, 1900, 4, 219—228).—A discussion with experimental tests of the numerous theories put forward to explain agglutination. No satisfactory theory to account for all cases has yet been offered, although Bordet's, that an agglutinating agent (agglutinine) acting upon an agglutinable substance of at present uncertain nature, is regarded as most rational. The reaction occurs, not only with bacteria, but with many other elements, globules, casein, and various precipitates.
W. D. H.

Antiseptic Value of Certain Chemicals in Milk. By S. MOULTON BABCOCK, H. L. RUSSELL, and ALFRED VIVIAN (*15th Ann. Rep. Agr. Expt. Stat. Univ. Wisconsin*, 1898, 98—103).—For the purpose of experiments on the enzymes of milk, it was desired to obtain an antiseptic which would act on the organised ferments without materially affecting the enzymes. Benzene, chloroform, ether, toluene, xylene, aniline, arsenious acid, thymene, phenol, sodium fluoride, oil of cloves, oil of cassia, oil of Ceylon cinnamon, oil of mustard, and turpentine were the substances tried.

It was found that the antiseptic efficiency of many substances is much less in milk than in liquids which do not contain substances like fat, which combines with the antiseptic and thus diminishes its power. Only four, chloroform, ether, benzene, and toluene, are to be recommended in studying the enzymes, and a distinction has to be made between curdling and the proteolytic action; ether retards curdling, whilst scarcely any difference exists in the time of curdling with the other three substances. Chloroform and ether seem to affect the digestive changes least. Chloroform is the best agent, and 2—3 per cent. keeps milk perfectly. Owing to its high sp. gr. and its affinity for fat, the cream is submerged, and this renders sampling more accurate.
N. H. J. M.

Boric Acid and Formaldehyde as Milk Preservatives. By SAMUEL RIDEAL and A. G. R. FOULERTON (*Exper. Stat. Record*, 1900, 11, 582; from *Public Health*, 1899, 11, 554—568).—The minimum amounts of the substances to preserve milk for 24 hours were found to be 1 in 50,000 for formaldehyde, and 0.05 per cent. of a mixture of boric acid and borax. These amounts have no appreciable effect on the proteolytic action of the peptic and pancreatic enzymes. The boric acid mixture distinctly retarded the amylolytic action of saliva, but it is doubtful if this is of importance; the action of formaldehyde was much less marked.

The results of experiments with kittens, a rabbit, and guinea-pigs indicated that the amount of formaldehyde required to preserve milk has no marked effect on proteid metabolism. Fishes were not appreciably affected by being kept for 6 days in water containing 1 part of

formaldehyde in 50,000, and a less dilute solution (1:20,000) did not seem to affect frogs in 2 hours.

The conclusions are drawn that the two substances, in the quantities as given, are effective preservatives for milk for 24 hours, and that they have no appreciable effect on the digestibility of the milk.

N. H. J. M.

Boric Acid and Formaldehyde as Food Preservatives. By OTTO HEHNER (*Exper. Stat. Record*, 1900, 11, 582—583; from *Brit. Food Jour.*, 1899, 1, 132).—The experiments of Rideal and Foulerton (preceding abstract) are criticised, on the ground that there were no control animals. The author is inclined to infer from the results that the preservatives, in the amounts recommended, are injurious.

N. H. J. M.

Action of Dry and Moist Air on Plants. By EBERHARDT (*Compt. rend.*, 1900, 131, 193—196).—Germinating plants develop more rapidly in air saturated with moisture than in dry or normal air; the stem is longer, but has a smaller diameter; the number of leaves is greater, but the production of rootlets is greatly diminished. Dry air decreases the development of the stem and leaves, the former, however, having a greater diameter than that of the plant grown under normal conditions; the foliage surface is diminished, whilst the number of rootlets is increased.

G. T. M

Can Strontium and Barium replace Calcium in Phænogams? By U. SUZUKI (*Bul. Coll. Agr. Tokyo Imp. Univ.*, 1900, 4, 69—79).—Sand culture experiments with buckwheat and barley, and water culture experiments with *Phlox paniculata*, *Rubus Idaeus*, and *Coreopsis tinctoria* are described. It was found that neither strontium nor barium can replace calcium, and that their salts are both strongly poisonous. Haselhoff's statement that strontium can replace calcium (*Abstr.*, 1894, ii, 207) is therefore incorrect.

The poisonous effects of barium and strontium are diminished by the presence of calcium.*

The author considers that Loew's view as to the rôle of calcium (*Abstr.*, 1899, ii, 789) agrees best with his observations.

N. H. J. M.

Distribution of Cane Sugar in Plants. By JUSTUS ANDERSEN (*Zeit. physiol. Chem.*, 1900, 29, 423—428).—The wide distribution of cane sugar in the vegetable world has been pointed out by Schulze. His investigations relate chiefly to the higher plants. The cryptogams still require to be investigated, and in the present paper it is shown that cane sugar is present in a number of ferns.

W. D. H.

Reserve Carbohydrate of the Seed of *Trifolium Repens*. By HENRI HÉRISSEY (*Compt. rend.*, 1900, 130, 1719—1721. Compare *Abstr.*, 1899, i, 839, and this vol., ii, 233).—The carbohydrate obtained from the seeds of *Trifolium repens* by extraction with cold water con-

* Haselhoff (*Abstr.*, 1896, ii, 267) found that very small amounts of barium are injurious, and suggested that addition of lime would lessen its effects.

taining lead acetate and precipitation of the filtered solution with alcohol, is a *mannogalactan*, for on hydrolysis with dilute sulphuric acid or seminase it yields galactose and mannose; a 1 per cent. solution gives $[\alpha]_D$ 81.1°.

G. T. M.

Composition of the Albumen of the Seed of the American Bean (*Gleditsia triacanthos*). By MAURICE GORET (*Compt. rend.*, 1900, 131, 60—63).—The albumen of the seed of the American bean (*Gleditsia triacanthos*) when hydrolysed at 110° with excess of 2 per cent. sulphuric acid yields 94.20 per cent. of reducing sugar; the soluble ferment seminase obtained from lucerne (Bourquelot and Hérissé, this vol., ii, 135, 233) has a similar hydrolytic action.

The reducing sugar contains about 70 per cent. of galactose and 23 per cent. of mannose; both constituents were isolated in a crystalline form, the former being estimated as mucic acid and the latter as mannose hydrazone.

It follows that this albumen is either a mannogalactan or a mixture of mannan and galactan (compare Abstr., 1899, i, 868, and ii, 301, 917).

G. T. M.

Arginine. By U. SUZUKI (*Bul. Coll. Agr. Tokyo Imp. Univ.*, 1900, 4, 1—24. Compare Schulze and Steiger, Abstr., 1886, 725; Schulze and Likiernik, *ibid.*, 1891, 1521; Hedin, *ibid.*, 1895, i, 160, and 1896, i, 193; Kossel, *ibid.*, 1896, i, 582; and 1898, i, 715; Schulze, *ibid.*, ii, 383 and 572; and 1898, ii, 179; Kutscher, *ibid.*, 1898, i, 161; Ellinger, *Ber.*, 31, 3183; and Gulewitsch, *Zeit. physiol. Chem.*, 27, 178).—The proteids obtained from the seeds of *Cryptomeria japonica*, *Pinus Thunbergii*, and *Ginkgo biloba* yielded much organic bases, chiefly arginine, when boiled with 20 per cent. hydrogen chloride (sp. gr. 1.10). The etiolated shoots of *Cryptomeria* and *Pinus* also contain much organic bases, chiefly arginine, but the shoots of *Ginkgo* yielded very little. It is probable that the chemical nature of the proteids of the shoots of coniferous plants is the same as that of the seed proteids, since both proteids furnish the same products of decomposition.

The method employed for the isolation of arginine is described.

N. H. J. M.

Formation of Arginine in Coniferous Plants. By U. SUZUKI (*Bul. Coll. Agr. Tokyo Imp. Univ.*, 1900, 4, 25—68. Compare E. Schulze, *Zeit. physiol. Chem.*, 22, 445).—The results of experiments with coniferous plants (*Pinus Thunbergii* and *Cryptomeria japonica*) showed that the arginine they contain is not only formed from the decomposition of proteids, but can be produced synthetically from ammonium salts and nitrates. This synthetical production of arginine takes place both in full and in diffused daylight, but it is not yet proved whether it proceeds in darkness.

There is a great accumulation of arginine in the shoots of coniferous plants in the dark, as well as in full daylight during the first stage of germination; it soon diminishes on further exposure to light, and gradually increases if the light is cut off. The transformation of arginine into proteids in presence of light is accelerated by the presence of mineral matter.

It is probable that arginine is directly used in regenerating proteids, but its relation to other amino-compounds requires further investigation. It seems, however, probable that there is a production of arginine from other amides.

From the results of experiments with *Brassica napa* and barley, the conclusion is drawn that in the case of plants other than coniferous, arginine is not formed from ammonium salts, asparagine being the only product.

N. H. J. M.

Amount of Alkaloids in the Bark of Java Pomegranates. By HEINRICH BECKURTS (*Arch. Pharm.*, 1900, 238, 8—9. Compare Ewers, *Abstr.*, 1899, ii, 457).—The percentage of alkaloids in bark from Java is found to be 0.92—0.98, that is, not much more than in the bark of roots from the South of France. In the titration of these alkaloids, iodeosin is to be preferred to methyl-orange as the indicator.

C. F. B.

[Composition of the Flowers of the] Hollyhock. By C. ZAY (*Landw. Versuchs-Stat.*, 1900, 54, 141—145).—The flowers of the hollyhock have the following percentage composition: Water, 13.15; crude fat, 2.29; crude fibre, 14.33; proteids, 6.56; nitrogenous matter other than proteids, 4.68; non-nitrogenous substances, 49.71; and ash, 9.28.

The flowers contain 0.67 per cent. of reducing sugar. The ethereal extract of the flowers yield a compound melting at 63.5—64°. It forms lustrous plates readily soluble in ether, petroleum, chloroform, or warm alcohol, and is not reddened by sulphuric acid.

N. H. J. M.

Composition of the Spores of *Aspergillus Oryzae*. By K. ASO (*Bul. Coll. Agr. Tokyo Imp. Univ.*, 1900, 4, 81—96).—The air-dried spores contained 57.485 per cent. of dry matter of the following percentage composition:

N.	Ether extract.	Alcohol extract.	Carbohydrates (as dextrose).	Crude fibre.	Ash.
6.380	0.377	27.666	20.017	8.994	5.151

Lecithin was detected in the ether extract, and the alcoholic extract which was obtained after extracting with ether was found to contain mannitol and trehalose.

The composition of the ash was found to be as follows:

K ₂ O.	Na ₂ O.	CaO.	MgO.	Fe ₂ O ₃ .	P ₂ O ₅ .	SO ₃ .	SiO ₂ .	Cl.
45.96	4.13	1.04	4.36	4.92	39.64	2.00	0.41	trace

N. H. J. M.

Metabolism in Full-grown Bullocks with Maintenance and Fattening Foods. By OSCAR KELLNER and A. KÖHLER (*Landw. Versuchs-Stat.*, 1900, 53, 1—16 and 398—474. Compare *Abstr.*, 1894, ii, 391, and *Landw. Versuchs-Stat.*, 1896, 47, 291 and 309).—In the experiments now described (see following abstracts), the effect of feeding with isolated foods, such as starch-meal, gluten-meal, oil, and cellulose, and of whole foods, as hay, cereal straw, and molasses, was determined by deducting the amounts of meat and fat produced

with a basal ration from the amounts obtained when the basal ration was employed in conjunction with the different foods.

Instead of adopting the usual method of calculating the results on 1000 lb. of live weight, the surface (compare Meek, *Zeits. Biol.*, 1879, 15, 425) of the beasts was taken into account, as it is on this that the losses of heat depend.

Among the factors which have to be taken into account in the experiments is the amount of water consumed. The raising of the temperature of the water to that of the body, and its elimination, cannot fail to be without influence. The amount of water consumed depends partly on the food; gluten-meal, molasses, hay, and straw increased, whilst starch-meal and oil diminished the consumption of water per kilogram of dry food.

As regards the production of hydrocarbons, 4.2 parts of methane were produced on the average from 100 parts of digested carbohydrate. Digestible protein and oil have no direct share in producing hydrocarbons; large amounts of oil hinder the production of hydrocarbons. The greatest quantity of hydrocarbon was obtained when wheat straw was employed. This is due, not only to the chemical composition of the straw, but to its physical nature and the fact that its digestion is slow.

Direct determinations of the heat of combustion of urine showed that, within certain limits of proteid-feeding, the amount of carbon in the urine is an approximately accurate measure of the heat value of the total dry matter of the urine, 1 gram of urine-carbon corresponding with about 10 Cal. With large amounts of gluten-meal, however, the carbon of the urine seems to be in compounds which yield more heat than was the case when the basal rations were employed alone. On the other hand, when the bullocks were fed with molasses, 1 gram of urine-carbon corresponded with less than 10 Cal., owing to the greater amounts of carbonates present.

By deducting the losses in urine and methane from the heat-value of 1 gram of digested organic matter, values are obtained indicating the amounts of heat produced by the decomposition of the digested substance in the organism, and also the relations in which the substances examined can replace each other in the maintenance food for bullocks. When starch is represented by 100, the following numbers show the isodynamic equivalents for the various foods: Earth-nut oil, 43; gluten protein, 76; extracted straw, 103; molasses, 103; hay, 103; oat straw, 100; and wheat straw, 113.

Owing to still greater losses than those due to formation of urine and methane, the values of the foods in producing flesh and fat are in every case below the "physiological values"—the heat value *minus* losses in urine and methane. The digestible organic matters of gluten-protein, starch, and molasses behave similarly, but the productive value of oil is decidedly higher, whilst in the case of hay and straw the values are lower than in the isolated components. The productive value of a substance depends therefore, not only on the amount of digestible matter it contains, but to an important extent on the nature of the tissues and on the amount of indigestible matter present.

Calculations of the amounts of digestible organic matter required to produce the same amounts of flesh and fat, over the minimum amounts required by the beasts, gave the following results: Starch meal, 100; gluten meal, 99; earth-nut oil, 45; extracted straw, 96; molasses, 97; hay, 147; oat straw, 157; and wheat straw, 374.

With full-grown bullocks, fattening rations with wide nutritive ratios can produce the same results as rations richer in proteids.

N. H. J. M.

Experiments with Gluten and Starch Meal. By OSCAR KELLNER, A. KÖHLER, F. BARNSTEIN, W. ZIELSTORFF, H. LÜHBIG, and F. MACH (*Landw. Versuchs-Stat.*, 1900, 53, 17—95).—In these experiments, which extended over some months, the amounts of food and water consumed, the changes in live weight, the amount and composition of the faeces and urine, and the amounts of carbon dioxide and hydrocarbon produced were determined; daily observations of the temperature of the stalls were also made.

When the amount of starch was increased so as to give a nutritive ratio of 1:15.95 or 1:16.21, considerable amounts of starch passed into the faeces, and the digestion of crude fibre was diminished.

Three concordant results showed that 86 per cent. of the crude proteid of gluten meal is digested.

In all the experiments, there was considerable production of hydrocarbon.

The production of fat by no means depends on proteid-feeding. Nitrogenous food produces for some time a greater increase of flesh than food poor in nitrogen, but the production of meat is not in proportion to the amount of digestible nitrogen in the food. Taking the average of both experiments, 1 kilogram of total food produced 219.7, 217.1, and 224.2 grams of flesh and fat when the nutritive ratios were 1:4, 1:10—11, and 1:16 respectively. The average amounts of increase produced by 1 kilogram of digestible food available for production by addition of gluten and starch were with (1) gluten meal, 229.7, and (2) starch meal, 250.6 grams.

The utilisation of the available energy of starch meal was on the whole higher than was the case with proteid.

N. H. J. M.

Experiments with Gluten, Starch Meal, and Oil. By OSCAR KELLNER, A. KÖHLER, W. ZIELSTORFF, FR. HERING, R. EWERT, and M. LEHMANN (*Landw. Versuchs-Stat.*, 1900, 53, 96—171).—During the first period of the experiments, the bullocks were fed with limited fattening food; in the second period, starch meal was given; in the third period, an amount of oil approximately isodynamic with the starch; and in the fourth period gluten meal.

The amount of carbon dioxide contained in the water consumed was determined.

The increase produced by 1 kilogram of the different foods was as follows: Starch meal, 215.8; earth-nut oil (reckoned as starch), 203.7; and gluten meal, 170.9 grams. As one part of oil is calculated to 2.27 parts of starch, the increase due to 1 kilogram of oil would be 462.4 grams.

N. H. J. M.

Experiments with Meadow Hay, Oat Straw, Starch Meal, and Molasses. By OSCAR KELLNER, A. KÖHLER, M. LEHMANN, FR. HERING, K. WEDEMAYER, and TH. METHNER (*Landw. Versuchs-Stat.*, 1900, 53, 172—277).—The results of experiments with two bullocks gave the following average amounts of increase for 1 kilogram of the food: Meadow hay, 149·7; oat straw, 148·7; starch meal, 255·8; earth-nut oil, 416·1; and molasses, 258·0 grams.

With exception of hay and oat straw, the numbers are not exact, and are, especially in the case of oil, too high.

Taking into account the alteration in live weight and surface, calculations are given of the percentage amounts of available energy in the increase. The results show that earth-nut oil takes the first place, (65·2—70·6 per cent.), then starch meal (65·2—66·0 per cent.) and molasses (60·3 per cent.). Meadow hay and oat straw gave much lower results (42·8—37·7 and 39·9—35·2 per cent.).

Hay, oat straw, and starch produced the greatest amounts of methane; oil, in some cases, diminished the amount of hydrocarbon produced from the other foods.

N. H. J. M.

Experiments with Meadow Hay, Wheat Straw, Starch Meal, Extracted Rye Straw, and Molasses. By OSCAR KELLNER, A. KÖHLER, M. LEHMANN, FR. HERING, K. WEDEMAYER, J. VOLHARD, H. PETERS, H. VON GILLERN, and O. ZAHN (*Landw. Versuchs-Stat.*, 1900, 53, 278—397).—The extracted rye straw was prepared by heating the straw (1 kilo.) under pressure with a solution (2070 c.c.) containing NaOH, 55; Na₂CO₃, 20; and Na₂S + Na₂S₂O₃, 22 grams per litre.

It was found that the cellulose of the extracted straw was of not less effect than starch, whilst the digestible matter of wheat straw, oat straw, and meadow hay produce much less increase. This difference is attributed to the presence, in the raw foods, of lignin-like substances. The raw foods require a greater expenditure of energy in chewing and digesting, and the passage of sparingly soluble matter into the lower intestines results in a loss of substance otherwise available for production of increase.

N. H. J. M.

Beet Molasses of Different Origin. By OSCAR KELLNER, H. PETERS, O. ZAHN, and A. STRIGEL (*Landw. Versuchs-Stat.*, 1900, 54, 113—123).—The molasses was in each case obtained from factories in which the diffusion process was employed. Molasses obtained directly from the juice contained more ash, nitrogen, and organic non-sugar than when the strontium process is used. The cane-sugar in the dry matter is about the same in both cases, but the dry matter of molasses from the strontium process contained 15·1 per cent. of raffinose.

The sp. gr. of the dry matter differed only slightly (1·679—1·709), and the results gave an average (1·692) almost identical with the number (1·69) obtained by Neubauer (*Landw. Versuchs-Stat.*, 1899, 51, 421).

N. H. J. M.

Milk and Artificial Foods for Fattening Calves. By D. DICKSON and L. MALPEAUX (*Ann. Agron.*, 1900, 26, 217—245).—Feeding with milk gives the best results both as regards amount and

quality. As regards substitutes for milk, starch and malt flour proved to be the best of the foods employed; but even with these it is an advantage to terminate the fattening with milk.

Decoction of linseed in conjunction with rice starch or flour gave good results as regards quality, whilst boiled malt flour mixed with skim milk also gives very good results. Margarine and sugar may be employed with milk from which the cream has been partially separated, and it is suggested that to separate the cream and replace it by margarine for calves is preferable to employing margarine for human consumption.

Many foods remain to be tried, and it is possible that some may furnish better results than those employed in the experiments described.
N. H. J. M.

Effect of Fatigue on the Quantity and Quality of Milk. By JOSEF L. HILLS (*12th Ann. Rep. Vermont Agr. Expt. Stat.*, 1898—1899, 309).—The cows had been driven about 10 miles, sent 70 miles by rail, the whole journey taking about 18 hours, during which time they were not milked. The amount (in lbs.) and percentage composition of the milk the day after arriving, and after 1 and 3 weeks, was as follows:

Amount (lbs.).			Total solids.			Fat.			Solids, not fat.		
1.	2.	3.	1.	2.	3.	1.	2.	3.	1.	2.	3.
122.5	122.3	131.4	15.19	13.73	14.10	5.94	4.43	4.32	9.25	9.80	9.28

The results show that milk should not be tested until the cows have recovered from the effects of fatigue.
N. H. J. M.

Effect of Food on the Hardness of Butter, and Composition of Butter Fat. By JAMES M. BARTLET (*14th Ann. Rept. Maine Agr. Expt. Stat.* for 1898, 97—113).—The object of the experiments was to ascertain the effect of different gluten meals on butter. Three kinds of meals were employed containing respectively about 15, 8, and less than 3 per cent. of fat. In one experiment with the meal containing the lowest percentage of oil, emulsified tallow was added to the food.

The results show that the hardness of butter can, to a great extent, be regulated by the food. Gluten products containing much oil produce soft butter; gluten meals with 3 per cent. of fat or less, and with high percentages of proteids, will make butter sufficiently hard when employed in conjunction with maize meal and bran. When freed from fat, the glutens will not, however, have the hardening effect of cotton seed meal.

The melting point of fat, as determined by the American official method, is not a true indication of the hardness; some fats of medium hard butters gave melting points practically the same as the softest butters. When, however, the melting point of the fat is low and the iodine number high, the butter is soft, and *vice versa*.

The production of soft butter cannot be attributed either to deficiency of nitrogenous food or to excess of fat; addition of 0.5 lb. of tallow to the ration caused the butter to become harder, and raised the melting point of the butter-fat. In some way, the properties of the food-fat are transmitted to the milk-fat.
N. H. J. M.

Effect of Feeding Fat on the Percentage of Fat in the Milk. By JAMES M. BARTLET (*14th Ann. Rep. Maine Agr. Expt. Stat.* for 1898, 114—117).—Albert and Maercker (*Landw. Jahrb.*, 1898, 27) found that rations rich in fat caused a decided increase in the fat of the milk; in another experiment it was found that in a longer period the yield of fat afterwards fell to about the same as it was previously with a ration poor in fat. The falling off was attributed to over-feeding with fat. Rhodin (*K. Landt. Akad. Handl.*, 1888, 37, 25), in experiments with emulsified oils also observed an increase of milk fat, followed by a fall to the normal amount.

The examination of the milk of cows fed with rations containing different amounts of fat (compare preceding abstract) showed a very decided increase in the percentage of fat in milk during the first two weeks of the period in which a ration rich in fat was fed; in the third week of the same period, the percentage of milk fat diminished. The following are the percentages of fat found each week. Period I (digestible fat, 0.36 lb. per day): (1) 5.34, (2) 5.21, (3) 5.66, (4) 5.94. Period II (0.86 lb. fat): (5) 6.39, (6) 6.43, (7) 6.05, (8) 6.15. Period III (0.55 lb. fat): (9) 5.64, (10) 5.78, (11) 5.96, and (12) 5.74. The decrease of milk-fat in the third period is attributed to the gradual return of the cows to their normal capacity.

N. H. J. M.

Effect of Emulsified or Non-emulsified Fat on [Milk] Production. By JOSEF L. HILLS (*12th Ann. Rep. Vermont Agr. Expt. Stat.* for 1898—1899, 269—275).—From the results of two years' experiments the following conclusions are drawn. Addition of cotton seed, maize, or linseed oils tends to increase the yield of milk per unit of dry matter consumed. With cotton seed oil there seems to be a fairly permanent increase of 0.2—0.3 per cent., in the fat of the milk, but maize and linseed oils, when fed as a regular diet, seem to lower the percentage of fat, although, when first given, all the oils produced marked gains in milk fat. The improvement in the quality of the milk under the influence of cotton seed oil took place both with emulsified oil and oil which had not been emulsified.

By feeding with oil, the butter is injured to an extent which far outweighs any possible benefit from increased yield and quality (compare following abstract).

N. H. J. M.

Effect of Food on the Quality of Butter. By JOSEF L. HILLS (*12th Ann. Rep. Vermont Agr. Expt. Stat.*, 1898—1899, 296—298. Compare this vol., ii, 236).—The rations contained hay and usually silage besides cotton seed, linseed and maize meals, and bran, in two different combinations; maize meal and bran; maize meal, bran, and buckwheat middlings; Buffalo gluten feed; Tucker oat feed. At times emulsified cotton seed, maize, and linseed oils were added to the maize and bran ration. The following average results were obtained with the butter:

Without oil.			Maize oil.			Cotton seed oil.			Linseed oil.		
Vola- tile	Iodine num-		Vola- tile	Iodine num-		Vola- tile	Iodine num-		Vola- tile	Iodine num-	
acids.	ber.	M. p.	acids.	ber.	M. p.	acids.	ber.	M. p.	acids.	ber.	M. p.
29.3	28.0	33.8°	17.8	44.7	34.3°	23.2	39.8	36.4°	20.2	47.8	34.1°

The effects of the oil, especially maize and linseed oil, were maintained for some time after the oil was discontinued. The cotton seed butter was hard and of good quality, the linseed butter very soft and sticky, whilst the maize oil butter was rather soft and oily, but of fair quality.

It is hardly safe to conclude that the oils actually migrate to the milk, but the results lend support to this view. N. H. J. M.

Composition and Food-value of the Salt Bushes. By MEJER E. JAFFA (*Univ. California Agr. Expt. Stat. Bul.*, 125, 1899, 24—30).—The percentage composition of two samples of *Atriplex semibaccata* grown at Tulare and Paso Robles was found to be as follows:

	Water.	Crude proteid.	N-free extract.	Crude fat.	Crude fibre.	Pure ash.
1.	78.03	2.75	10.41	0.48	3.75	4.58
2.	75.00	3.93	10.15	0.41	5.58	4.93

As regards digestibility, feeding experiments are required. In the meantime, the author would assign to the hay about the same digestive coefficients as for oat hay. Salt bushes should not be fed alone, owing to the high percentage of saline ingredients, and should be given in gradually increasing amounts. Sheep and cattle have, however, been fed exclusively with the material throughout an entire season.

The composition of the ash (of 1) is as follows:

Na_2O .	K_2O .	CaO .	MgO .	Fe_2O_3 .	Al_2O_3 .	Mn_2O_4 .	P_2O_5 .	SO_3 .	SiO_2 .	Cl.
85.39	11.42	5.79	3.23	1.38	1.95	0.22	2.30	2.64	16.24	24.33

Although the percentages of potash and phosphoric acid are low, the actual amounts are much greater than those yielded by an ordinary crop of hay. N. H. J. M.

Edible Earth from Fiji. By B. G. CORNEY, DAVID, and FREDERICK B. GUTHRIE (*Journ. and Proc. Roy. Soc. N.S. Wales*, 1900, 33, 224—227).—The sample of soil was obtained from the Island Vanua Levu, and consists of a very soft, pale pink, clayey material with small, white patches, and lumps of grey to reddish chalcedony. It contained a good many quartz crystals and numerous small, octahedral crystals of magnetite. It therefore seems likely that the rock was originally a quartz andesite (dacite), probably of tuffaceous origin. The following analytical results are given:

Loss at 120°.	Combined water.	Al_2O_3 .	Fe_2O_3 .	SiO_2 .
2.45	12.78	41.53	7.66	35.09

The substance contains no lime or magnesia, and would seem to be a silicate of the formula $\text{Al}_2\text{O}_3(\text{SiO}_2)_2(\text{H}_2\text{O})_2$, with ferric oxide as impurity. N. H. J. M.

Basic Constituents of Crops. By ROBERT WARINGTON (*Agr. Students' Gaz.*, 1899, [ii], 9, 133—138).—The author remarks that he had previously pointed out that the carbonates found in plant ashes must be in part a residue of nitrates. The bases of the nitrates remain, after the nitric nitrogen has been utilised by the plant, and probably become united with organic acids.* The results of calculations of the lime corre-

* Compare Lawes and Gilbert (*Journ. Roy. Agric. Soc. Eng.*, 1894, [iii], 5, 636—641; *Proc. Roy. Soc.*, 1899, 65, 329—332; and *Phil. Trans.*, 1900, 192, B., 150—174).

sponding with the whole of the nitrogen of various crops, and of the amounts of lime equivalent to the bases of the ash, after satisfying the phosphoric (assumed to be dibasic) and hydrochloric acids present, showed, in every case, with the exception of mangels, a great deficiency of bases on the assumption that most of the nitrogen enters into the plant in the form of nitrate. The results of Arendt's experiments with oat-plants which were analysed at different dates, from June 10 to July 31, showed a falling off in the salifiable base as percentage of nitrate base from 41—44 to 27.

Unless, therefore, cereals take up only about a quarter of their total nitrogen in the form of nitrates, it must be assumed, as is probably the case, that a loss of bases occurs. The differences in the amount and composition of barley straw harvested at Rothamsted in wet and dry seasons, indicated that losses occur owing to the washing out of withered stems and leaves in wet weather. There is probably also a loss of ash-constituents by diffusion into the soil, especially when the crop ripens and the sap becomes more and more concentrated. The diffusion into the soil would occur chiefly during the night.

N. H. J. M.

[Basic Constituents of Crops.] By EM. DEMOUSSY (*Ann. Agron.*, 1900, 26, 251—257).—With reference to the preceding paper, it is pointed out that, although plants do not take up much nitrogen in the form of ammonia, since the soil generally contains very little, any ammoniacal nitrogen taken up would further increase the deficiency of base by leaving the acid of the ammonium salt in the plant.

The deficiency of bases in plant ashes is attributed partly to a certain amount of nitrogen being taken up in other forms than nitrate, especially as organic compounds, and partly to losses in dead leaves both attached and fallen. The results of experiments with wheat showed that losses of dry matter, greater losses of total ash, and still greater losses of potash took place in July (compare Dehérain and Bréal, *Abstr.*, 1882, 419; Rouf, "Étude anal. sur la canne à sucre," *La Martinique*, 1879, and Dehérain, *Ann. Agron.*, 1879, 5, 271).

The possibility of losses of ash constituents by diffusion into the soil when the concentration of the sap increases was suggested by Marie-Davy and Albert Lévy (*Ann. Montsouris*, 1873 and 1876), but the results of experiments by the author and others indicate that living portions of plants retain with great vigour all the mineral matter absorbed. Knop's results were probably due to mutilated plants having been employed (compare *Abstr.*, 1894, ii, 153).

N. H. J. M.

Manurial Experiments with Fruit Trees. By STROBLICH (*Bied. Centr.*, 1900, 29, 292—296; from *Mitt. Deut. Landw. Ges.*, 1897, No. 4, 39).—The percentage amounts of food constituents in fruit trees increase from the root-wood to the fruit-wood, and are still greater in the leaves. The amount of nitrogen in the vegetative organs is always greater than that of the potash.

The yearly amounts of nitrogen, potash, lime and phosphoric acid required by fruit trees with stems 25 cm. in circumference have been estimated. The following results are given (in grams) for apple, pear,

cherry, and plum trees : N, 59, 37, (76) and (34) ; K_2O , 51, 40, 95, and 74 ; CaO , 109, 69, 209, and 75 ; P_2O_5 , 11, 7, 30, and 11. Provisional estimates were made of the manurial requirements of fruit trees for each cm. of circumference.

A large number of measurements and weighings have been made, the results of which show the relations of the amounts of total wood to the amount of stem wood, the average increase in circumference per annum, and the relation of the amount of foliage to the circumference of the trees, &c.

N. H. J. M.

Storage of Stable Manure. By FRIEDRICH HOLDEFLEISS (*Mitteil. Landw. Inst. kgl. Univ. Breslau*, 1900, Heft. 3, 49—55).—Three samples of manure from previous experiments (*ibid.*, Heft. 2) were employed. They contained 6415, 5532, and 5480 grams of total nitrogen respectively ; 7.35, 3.61, and 2.05 per cent. of the nitrogen were in the form of ammonia, and 88.2, 88.3, and 92.3 per cent. were in the form of proteids. The three lots were kept (1) without preservative, (2) with potassium salt, and (3) with superphosphate.

The percentage losses or gains of the different constituents were as follows :

	N.	N as NH_3 .	Proteid N.	Non-proteid organ. N.	Non-nitrog. extract.	Crude fibre.	Pentosans.
1.	-18	-64	-20.3	+105	-8.7	-27.5	-35.1
2.	-6.3	+48	-11.3	+32	-27.5	-6.9	-16.7
3.	-6.75	+306	-14.1	no change	-27.5	-9.4	-22.5

As regards nitrogenous constituents, the effect of preservatives was not only to diminish the loss of proteid nitrogen, but to increase considerably the amount of nitrogen in the form of ammonia.

Of the non-nitrogenous constituents, the pentosans and non-nitrogenous extract are the substances which decomposed most readily. In crude fibre *minus* pentosans there was only a loss in (1) amounting to 17.5 per cent. ; in (2) and (3) there were gains of 7.6 and 7.9 per cent.

N. H. J. M.

Analytical Chemistry.

Burette for Accurate Gas Analysis. By ALFRED H. WHITE (*J. Amer. Chem. Soc.*, 1900, 22, 343—349).—This is an improvement on the Hempel-Petterson apparatus. For working particulars, reference must be made to the original with its five illustrations.

The main body of the burette consists of 12 bulbs, each with a capacity of about 12 c.c. A line is etched on each constriction and the capacity of the bulb between these marks is determined ; no reading telescope is required, yet the volume of the gas may be read off within 0.02 c.c.

The other parts of the apparatus, which is enclosed in a water-jacket, consist of a side burette and of a manometer placed below

a specially constructed stopcock which prevents the escape of gas or entrance of outer air when connection is made with the absorption pipettes.

The burette in which mercury is employed compensates automatically for all changes of temperatures and pressure.

L. DE K.

Alkalimetry and Acidimetry in Volumetric Analysis. By A. ASTREUC (*Compt. rend.*, 1900, 130, 1636—1639).—The author summarises and discusses the various observations which have been made on the behaviour of phenols, amines, organic acids, and other carbon compounds with various indicators.

C. H. B.

New Methods of Mineral Analysis. By ADOLPHE CARNOT (*Ann. des Mines*, 1898, [ix], 14, 113—209).—A collection is given of 21 methods which have previously been published separately (*Abstr.*, 1898, ii, 349, &c.).

L. J. S.

Iodometric Estimation of Hydrogen Peroxide, Alkali Percarbonates and Persulphates. By ERWIN RUPF (*Arch. Pharm.*, 1900, 238, 156—158).—Hydrogen peroxide may be estimated with great accuracy by adding 1 c.c. of the sample to 20 c.c. of water mixed with 5 c.c. of dilute sulphuric acid and 1 gram of potassium iodide. After being kept for half an hour in a closed flask, the liberated iodine is titrated, as usual, with *N*/10 sodium thiosulphate. Percarbonates may be estimated in a similar manner. The process is also applicable to persulphates, but the time of reaction should be extended to 2 hours.

L. DE K.

Detection of Fluorine in Wine. By GIULIO PARIS (*L'Orosi*, 1900, 23, 1—3).—The ignited ash from 50 c.c. of the wine is mixed in a platinum crucible with one-third of its weight of precipitated silica and about 0.5 c.c. of concentrated sulphuric acid. The lid of the crucible, on the bottom of which is suspended a drop of distilled water, is then put on and a little ice placed on the upper surface. After heating the crucible with a very small flame for about 5 minutes, it is allowed to cool and the drop of water hanging from the lid is removed to a microscope slide, a small portion of which is covered with a thin uniform coating of Canada balsam. A few small crystals of sodium chloride are then added and after a lapse of half an hour to an hour the slide is examined under the microscope; if the wine contains fluorine, hexagonal crystals of sodium silico-fluoride are observable.

T. H. P.

Estimation of Ozone. By OTTO BRUNCK (*Ber.* 1900, 33, 1832—1842. Compare Ackermann, *Chem. Zeit.*, 1900, 24, 235).—In the estimation of ozone by the liberation of iodine from potassium iodide solution, trustworthy results can only be obtained when the solution is treated with the theoretical amount of sulphuric or acetic acid necessary to liberate hydrogen iodide. When a neutral solution of potassium iodide is employed, the amount of ozone always comes too low, probably owing to the formation of potassium peroxide which destroys part of the iodine and also to the interaction of ozone and hydrogen peroxide. In acid solutions, a slight error occurs when very

concentrated solutions are employed, owing to decomposition of the hydriodic acid, but this may be eliminated by making a blank determination. J. J. S.

Selenium and Tellurium. By EDWARD KELLER (*J. Amer. Chem. Soc.*, 1900, 22, 241—245. Compare Abstr., 1898, ii, 638).—*Quantitative Separation of Selenium and Tellurium.* The method is based on the fact that selenious acid dissolved in strong hydrochloric acid is reduced by sulphur dioxide; any tellurous acid may then be reduced by adding water and boiling. The process has been derived more particularly for the analysis of crude copper.

One hundred grams of copper with 2—4 grams of ferrous sulphate are dissolved in 400 c.c. of nitric acid (sp. gr. 1.42), the nitrous fumes expelled, and the solution diluted, cooled, and mixed with sufficient ammonia to redissolve the copper precipitate. After boiling and settling, the ferric hydroxide containing the selenium and tellurium is collected on a filter; as it always retains copper, it must be repeatedly redissolved in acid and reprecipitated with ammonia. The precipitate is then dissolved in just sufficient hydrochloric acid, saturated with hydrogen sulphide, and the precipitated sulphide after being well washed is digested with sodium sulphide, which dissolves the sulphides of selenium and tellurium. The filtrate is carefully acidified with nitric acid and evaporated to dryness; the residue now contains the dioxides of selenium and tellurium, besides sodium nitrate and some sulphur. Two hundred c.c. of strong hydrochloric acid are added and the whole is boiled until all nitro-hydrochloric acid is expelled and the two elements have been reduced to the lower state of oxidation. When cold, the liquid is passed through a Gooch filter and the residue washed with strong hydrochloric acid. A current of sulphur dioxide is now passed through the solution to precipitate the selenium which is washed first with dilute hydrochloric acid, then with water, and finally with alcohol, and is then dried and weighed. The filtrate containing the tellurium is diluted with an equal bulk of water and boiled to precipitate the tellurium, more sulphur dioxide being passed if necessary. It is then collected and treated in the same manner as the selenium. The results are quite satisfactory, notwithstanding Lenher's assertions that small quantities of selenium cannot be accurately estimated in the presence of much tellurium; the amount of hydrochloric acid should, however, be about 100 times that of the tellurium. L. DE K.

Distillation of Ammonia in the Estimation of Nitrogen. By FRANCIS GANO BENEDICT (*J. Amer. Chem. Soc.*, 1900, 22, 259—263).—When distilling dilute solutions of ammonia, this is generally expelled in a very short time, but still it is necessary to keep on distilling a considerable volume in order to wash out the ammonia adhering to the condensing tube. If the latter is not cooled, the ammonia is very soon expelled, but this causes other inconveniences, such as the possible overheating of the standard acid into which the ammonia is received.

The author now combines the two methods. The vapour passes through a vertical tin condensing-tube fixed into a galvanised iron tank filled with water, which may be drawn off by means of a tap. When the bulk

of the ammonia is supposed to have passed over, the refrigerating water is slowly withdrawn, thus allowing the tube to get hot.

L. DE K.

Rapid Method for the Estimation of Carbon in Iron or Steel by Combustion. By GEORGE W. SARGENT (*J. Amer. Chem. Soc.*, 1900, 22, 277—285).—This is a modification of the ordinary process of burning the carbonaceous residue of iron or steel in a current of air or oxygen. The air or oxygen employed is first passed over a red-hot spiral made from a platinum tube 17 inches long and $\frac{5}{8}$ inch in diameter; this gives four close coils $\frac{3}{4}$ inch in diameter, and leaves 4 inches extended on either side. The object is to fully oxidise any hydrocarbons which may be present in the air, and the carbon dioxide formed is then absorbed in a Geissler bulb apparatus. The carbon is placed in a porcelain boat heated inside a porcelain combustion tube, and the resulting gases are passed through a tube containing red-hot copper oxide to insure complete oxidation. It has been found that the same object is attained by passing the gases through a small glass tube in which two platinum wires were fused, so that a spark would be produced between the points, when a current from a Rhumkorff coil passed through the wires. As there is, however, always a danger of stoppage, the use of copper oxide is the safest. To retain traces of hydrochloric acid or chlorine, the gases are afterwards passed through a $\frac{1}{4}$ -inch glass tube 6 inches long, containing loosely-packed coarse wet sand held in place by two small discs of copper gauze placed at either end.

Precautions are taken to prevent overheating of the corks. The dried gases are then finely absorbed in a weighed Geissler apparatus of somewhat larger size than usual, and containing 30 c.c. of aqueous caustic potash of sp. gr. 1.27.

L. DE K.

Estimation of Carbon in Steel. By GEORGE AUCHY (*J. Amer. Chem. Soc.*, 1900, 22, 334—343).—The method of estimating the carbon by igniting the carbon sponge, and attributing 70 per cent. of the loss in weight to the presence of carbon, is said to be untrustworthy. No better results are obtained by treating the carbon sponge with nitric acid.

The colour tests are also untrustworthy, the same sample giving sometimes a difference of 0.1 per cent. of carbon.

Sources of error are pointed out in the moist and dry combustion process; as regards the latter, Shimer's apparatus will, in the author's opinion, eventually displace the old arrangement.

L. DE K.

Estimation of Carbon and Sulphur in Steel. By BEETRAM BLOUNT (*Analyst*, 1900, 25, 141—144).—The author has attempted to estimate carbon and sulphur in iron by direct combustion in pure oxygen. The sample is heated at about 1200° in a porcelain boat contained in a porcelain tube, and the products of combustion are passed into suitable absorbents. The process does not answer well for sulphur, and even for carbon it is not as yet preferable to the existing methods. It might be made more generally applicable if

means were found to completely oxidise the iron at a temperature not exceeding 800°.

L. DE K.

Estimation of Alkali Carbonates in Presence of Alkali Hydrogen Carbonates. By FRANK K. CAMERON (*Amer. Chem. J.*, 1900, 23, 471—486).—Alkali carbonates interact with potassium hydrogen sulphate to give sodium hydrogen carbonate and sodium potassium sulphate; since both the latter are neutral to indicators, the carbonates can be separately estimated by adding a standard solution of the acid sulphate until the pink coloration of the phenolphthalein disappears; the hydrogen carbonates are, however, unstable, and gradually decompose into carbonates and carbon dioxide. Salts of other weak acids, such as the borates, silicates, and phosphates, can be similarly estimated.

The hydrogen carbonates do not yield a CO_3 ion, except by decomposition into carbonates, and do not themselves precipitate silver salts; chlorides can therefore be titrated directly against silver nitrate in presence of hydrogen carbonates, if the decomposition of the latter is prevented by a very slight excess of acid sulphate.

T. M. L.

Estimation of Calcium and Sulphuric Acid by the Photometric Method. By J. I. D. HINDS (*J. Amer. Chem. Soc.*, 1900, 22, 269—274).—The author has extended his process (*Abstr.*, 1896, ii, 574) to the estimation of calcium in limestone. About 0.10 of the sample is dissolved in hydrochloric acid and a few drops of nitric acid, and evaporated to dryness over a free flame. The residue is dissolved in water with a little hydrochloric acid, neutralised with ammonia diluted to 150 c.c., and mixed with a little solid ammonium oxalate. The turbid liquid is then poured into the apparatus previously described until the image of the candle flame just disappears. The depth is read and the percentage of calcium in the liquid is calculated from the equations:

For calcium carbonate, $y = 0.0642/x - 0.3$; for calcium oxide, $y = 0.0360/x - 0.3$, in which x is the reading of the cylinder in cm. and y the percentage sought.

The percentage of calcium in the sample is then found by an easy calculation.

Small quantities of sulphuric acid in liquids may be similarly estimated by adding solid barium chloride and using the equations:

For H_2SO_4 , $y = 0.0590/x$; for SO_3 , $y = 0.0482/x$.

Tables are given to save the trouble of calculating.

L. DE K.

Estimation of Zinc by the Use of Standard Thiosulphate Solution. By RICHARD K. MEADE (*J. Amer. Chem. Soc.*, 1900, 22, 353—356).—The author recently proposed a new volumetric process for the estimation of magnesium (this vol., ii, 48), and has applied the same principle to the estimation of zinc. The strongly ammoniacal solution is mixed with sodium arsenate, and any precipitate due to calcium, magnesium, &c., is filtered off. The filtrate is nearly neutralised with nitric acid and then faintly acidified with acetic acid. After being washed, the precipitated zinc arsenate is dissolved in

dilute hydrochloric acid, potassium iodide added, and the liberated iodine titrated with standard sodium thiosulphate, addition of starch being superfluous.

Manganese, which is frequently present in zinc ores, must be first removed by treating the sample with nitric acid and potassium chlorate.

L. DE K.

Quick and Exact Test for Mercury in Urine. By ADOLF JOLLES (*Monatsh.*, 1900, 21, 352—360; *Zeit. anal. Chem.*, 1900, 39, 230—237).—The urine (100—150 c.c.) acidified with concentrated hydrochloric acid (5—10 c.c.) is heated with potassium chlorate (1.5—2 grams) until it no longer smells of chlorine, and then mixed with a dilute solution of stannous chloride; in this mixture, a gilt platinum foil is placed for 15 minutes; the foil is then treated with nitric acid and the solution evaporated to a small bulk and tested with stannous chloride or hydrogen sulphide. It is thus possible to detect 0.000066 gram of mercury in 100 c.c. of urine. A quantitative method is based on the same test, the yellow coloration produced by hydrogen sulphide in the dilute mercury solution being compared with that of solutions of known strength.

R. H. P.

Separation and Estimation of Mercury as Mercurous Oxalate. By C. A. PETERS (*Amer. J. Sci.*, 1900, [iv], 9, 401—406).—Mercury in solution as mercurous nitrate may be estimated volumetrically by adding a known weight of ammonium oxalate and titrating the excess of oxalic acid in the filtrate with standard solution of potassium permanganate. An attempt to estimate the oxalic acid in the precipitate proved unsuccessful.

In solutions containing from 2—5 per cent. of excess of nitric acid (sp. gr. 1.15), mercurous salts may be quantitatively separated from mercuric salts if the latter do not exceed 20 per cent. of the total mercury.

Instead of estimating the mercurous compound volumetrically, the precipitated mercurous oxalate may be weighed as such. As it is not stable at 100°, however, it should be collected on a weighed asbestos filter and dried over sulphuric acid to constant weight, which is generally accomplished in about 15 hours if the weight does not exceed a few decigrams.

L. DE K.

Estimation of Cerium. By GEORG VON KNORRE (*Ber.*, 1900, 33, 1924—1929. Compare Abstr., 1898, ii, 311; Job, Abstr., 1899, ii, 334).—Cerium in ceric salts may be readily estimated by reduction with excess of hydrogen peroxide and subsequent estimation of the excess of peroxide by standard permanganate. Hitherto, no good method has been described for the oxidation of cerous to ceric salts; the author finds, however, that extremely dilute solutions of cerous compounds which have been acidified with the smallest possible amount of sulphuric acid are readily oxidised by boiling for a few minutes with ammonium persulphate; the change in colour, from colourless to yellow, is very characteristic, and may possibly be the most delicate test for cerium. The subsequent estimation of the ceric compound is carried out as just described.

J. J. S.

Estimation of Alumina and Ferric Oxide in Natural Phosphates. By F. P. VEITCH (*J. Amer. Chem. Soc.*, 1900, 22, 246—258).—*Estimation of Alumina.*—One gram of the substance is treated in a platinum dish with 5—10 c.c. of hydrofluoric acid and after 2 or 3 hours the solution is evaporated to dryness on the water-bath; 2 c.c. of sulphuric acid are added, and the whole gently heated until the substance no longer flows in the dish. When cold, 10—20 c.c. of hydrochloric acid are added, and after warming a few minutes to soften the mass this is transferred to a small beaker and boiled for 15—30 minutes to dissolve all aluminium compounds. The liquid is then diluted and passed through a filter and the undissolved matter is well washed. To the filtrate are added 50 c.c. of a 25 per cent. solution of ammonium chloride, then ammonia until alkaline, and then enough hydrochloric acid to just redissolve the precipitate. When cold, the mixture is diluted to about 250 c.c., and a 50 per cent. solution of ammonium thio-sulphate is added drop by drop until the solution is colourless, adding in all 20 c.c.; the beaker is covered with a watch glass and the mixture is boiled for half an hour. The precipitate, after being drained, is washed back into the same beaker, redissolved in hydrochloric acid, mixed with 2 c.c. of a 10 per cent. solution of ammonium phosphate, and reprecipitated in the way described. The aluminium phosphate is washed 20 times with a 5 per cent. solution of ammonium nitrate and ignited over the blowpipe to constant weight.

Estimation of Ferric Oxide.—One gram of the substance is heated with 20 c.c. of sulphuric acid. The mixture is diluted with water and filtered; should organic matter be suspected, the solution is boiled for some time with addition of a little potassium chlorate. The mixture is then reduced with zinc in the ordinary way, and titrated with a standardised solution of potassium permanganate.

Part of the paper is devoted to a criticism of existing methods.

L. DE K.

Preparation of Potassium Xanthate for Nickel Estimations. By EDWARD D. CAMPBELL (*J. Amer. Chem. Soc.*, 1900, 22, 307—308. Compare Abstr., 1895, ii, 421).—As commercial potassium xanthate is often not sufficiently pure, it is advisable to prepare the salt specially. Fused potassium hydroxide is placed in a tightly stoppered flask and covered with absolute alcohol, of which 2.5 c.c. should be used for each gram of the hydroxide. When dissolved, the liquid is poured off from any undissolved carbonate into a beaker which is placed in ice-water until the temperature is reduced to 10° or less, and carbon disulphide is gradually added with constant stirring, using 1 c.c. for each gram of potassium hydroxide. The crystalline mass is collected on a Buchner funnel, using the suction-pump, washed once with a very little absolute alcohol, and then twice with a little ether. When properly dried at about 100°, the compound will keep for years.

L. DE K.

Colorimetric Estimation of Vanadium. By LOUIS MAILLARD (*Bull. Soc. Chim.*, 1900, [iii], 23, 559—563).—The method described is adapted for the estimation of small quantities of vanadium, and is

based on the red coloration, probably due to the formation of a per-vanadic acid, produced by the action of hydrogen peroxide on vanadic acid. 10 c.c. of the liquid under examination are placed in a graduated cylinder, 1—5 c.c. of hydrochloric acid and 3—10 c.c. of an ethereal solution of hydrogen peroxide added, the mixture well agitated, and water added until the aqueous layer measures 15 c.c. The operation is repeated with 10 c.c. of a 0.1 per cent. solution of sodium vanadate, and the two liquids examined and compared in a colorimeter. Experiments are cited to prove that the intensity of the coloration is strictly proportional to the amount of vanadic acid present, and is not affected by excess of acid and hydrogen peroxide, or by the presence of various salts. N. L.

Electrolytic Estimation of Bismuth. By DMITRY BALACHOWSKY (*Compt. rend.*, 1900, 131, 179—182).—An adherent deposit of bismuth, suitable for quantitative estimations, may be obtained by working with feeble currents (maximum current density $ND_{100} = 0.06$ ampere), roughened electrodes, and slightly acidic solutions, free from large quantities of haloid salts.

About 0.6 gram of the sulphate or nitrate, mixed with 3—4 grams of carbamide, and dissolved in 5—6 c.c. nitric acid, diluted with 150 c.c. of water, are electrolysed in a roughened Classen capsule for 6—8 hours at 60°, with a current density of 0.03—0.04 ampere, and a difference of potential 1.5—1.9 volts; towards the close of the electrolysis, the current density is increased to 0.08 ampere, and the E.M.F. to 2 volts.

Formaldehyde or acetaldehyde may be added instead of carbamide, and in this case the operation is finished by warming to 80—90°, and slightly decreasing the voltage and current density.

The precipitated metal is washed without stopping the current, and dried at 100°; the deposit is readily removed from the capsule by the action of nitric acid. The analytical results are exhibited in tabular form. G. T. M.

Bismuth Cobalticyanide. By JOHN A. MATHEWS (*J. Amer. Chem. Soc.*, 1900, 22, 274—277).—Further particulars are given about the constitution and properties of bismuth cobalticyanide (this vol., ii, 318). The results have not been favourable to the proposed use of potassium cobalticyanide in the analysis of pig-leads, but the salt may be used in the analysis of regular lead-bismuth alloys. It has been found that unless 1 c.c. of the liquid contains at least 0.0079 gram of bismuth, the precipitation is not complete in any circumstances. As a rule, the precipitation is favoured by operating at the boiling heat; once a precipitate is formed, it does not redissolve even in a quantity of water, which would have prevented its formation at the beginning. A large excess of the reagent also increases its insolubility, also the presence of free acetic acid. Bismuth cobalticyanide is crystalline, settles and filters well, and does not completely give up its water below 165°. The formula of the dry compound is $\text{BiCo}(\text{CN})_6$. When freshly thrown down, the precipitate looks white, but on the filter it acquires a greenish tint, which, on drying, changes

to blue; on exposure to the air, it reabsorbs water and assumes a pink colour.

L. DE K.

Determination of the Hardness of Water. By GIUSEPPE VENTUROLI (*L'Orosi*, 1900, 23, 39—43).—To obviate the inconveniences of the Clark method and its modifications for determining the hardness of water, the following process is recommended. 40 c.c. of the water are acidified with hydrochloric acid and evaporated to dryness, the residue being dissolved in distilled water, and the solution mixed with a measured volume (50 to 60 c.c.) in excess of standard sodium carbonate solution (0.429 gram of Na_2CO_3 per litre). After heating to boiling and adding methyl-orange (or another indicator), the excess of sodium carbonate present is determined by titration with an acid solution of strength equivalent to that of the sodium carbonate solution. This gives the total hardness, each c.c. of the sodium carbonate solution corresponding with 1 part of calcium carbonate per 100,000 parts of water. To obtain the separate proportions of lime and magnesia in the water, it is necessary to determine, besides the total hardness, (1) the hardness after the calcium salts have been precipitated with ammonium oxalate solution, this giving the total amount of magnesia; (2) the hardness after the water has been boiled, representing the lime and magnesia not combined with carbonic acid; (3) the hardness after the removal of the calcium salts from the boiled water by means of ammonium oxalate, this giving the amount of magnesia not in combination with carbonic acid.

T. H. P.

West Indian Sandalwood Oil. By ERNST DEUSSEN (*Arch. Pharm.*, 238, 149—156. Compare *Abstr.*, 1899, i, 924; this vol., i, 242, 401).—This oil may be identified by the large amount of santalol it contains. The percentage of this alcohol in sandalwood oil may be calculated from the equation $P = a \times 22.2/s - (a - 0.42)$, in which a represents the number of c.c. of normal alkali consumed, and s the number of grams of the acetylated oil used in the experiment. As the constitution of this oil is but little known, the author has subjected a genuine sample to fractional distillation, analysis and further research.

The oil boils at 265° under atmospheric pressure, undergoing slight decomposition, but on distilling under 23 mm. pressure 6 fractions were obtained, boiling respectively at 139 — 147° , 147 — 155° , 155 — 160° , 160 — 168° , 168 — 171° , and 171 — 174° , a small quantity of resinous matter remaining in the flask. Most of the oil was contained in fractions 2, 4, and 6. Of these, 2 and 4 were subjected to ultimate analysis, and their molecular weight was determined by the freezing point method; the results obtained showed that these fractions probably contain a mixture of a sesquiterpene alcohol and a sesquiterpene.

By treating a solution of the oil in twice its volume of dry ether with hydrogen chloride, bromide, or iodide, crystalline compounds were obtained which chemically and physically corresponded with those of cadinene. There is, therefore, little doubt that sandalwood oil contains cadinene, the amount being about 16 per cent.

L. DE K.

Valuation of Spirit of Camphor. By ALFRED PARTHEIL and A. VAN HAAREN (*Arch. Pharm.*, 1900, 238, 164—166).—See this vol., i, 507.

Assay of Creosote. By A. D. HALL (*Analyst*, 1900, 25, 148—151).—One hundred c.c. of the sample are put into a distilling flask and the measuring flask is rinsed with 5 c.c. of benzene which are afterwards deducted from the volume of the distillate. After distilling until nothing more comes over at 325° , the volume of the distillate is read off. This is then shaken with 100 c.c. of sodium hydroxide solution of sp. gr. 1.2 or 1.3, and the mixture put in a water-oven for at least 1 hour, being shaken from time to time; when cold, the volume of the alkaline solution is read off and the greater part is withdrawn by means of the tap attached to the graduated cylindrical receiver.

The soda solution is boiled for a few minutes to expel hydrocarbons. When cold, 10 c.c. are withdrawn by a pipette and introduced into a Leffmann-Beam milk bottle (specially calibrated for the purpose); dilute sulphuric acid is added to neutralise the alkali, and the bottle whirled in the machine for a few minutes. When cold, the volume of the tar acids is read off.

To the contents of the receiver 100 c.c. of dilute sulphuric acid (1:5) are now added, and the whole is heated and shaken as before. The volume of the acid is then read off and 10 c.c. are mixed with excess of alkali in a milk bottle, which on being whirled causes the liberated tar bases to collect in the neck, when their volume may be read off.

Technical experiments not yet concluded seem to point to the fact that the pyridine tar bases are quite as valuable for preservative purposes as the tar acids.
L. DE K.

Volumetric Valuation of Syrup of Ferrous Iodide. By ERWIN RUFF (*Arch. Pharm.*, 1900, 238, 159—160).—The process is based on the fact that on adding potassium permanganate to an acid solution of ferrous iodide the iodine is liberated. On adding potassium iodide, this dissolves and at the same time a further amount of iodine is liberated by the action of the ferric salt on the potassium iodide; the iodine may then be titrated with sodium thiosulphate. When dealing with syrup of ferrous iodide, the unavoidable excess of permanganate is rapidly decomposed by the sugar.

Five grams of the syrup, 5—10 c.c. of water, and 10 c.c. of dilute sulphuric acid are introduced into a 100 c.c. stoppered bottle and a 1 per cent. solution of potassium permanganate is slowly added until the liquid remains pink for a few seconds. After 3 hours, one or two grams of potassium iodide are added, and after remaining in the dark for another hour, the liberated iodine is titrated with *N*/10 sodium thiosulphate, using starch as indicator. A 5 per cent. solution of ferrous iodide consumes 24.2 c.c. of *N*/10 sodium thiosulphate.

L. DE K.

Relation of the Reducing Power of Normal Urine to the Amount of Certain Nitrogen Compounds Present. By JOHN H. LONG (*J. Amer. Chem. Soc.*, 1900, 22, 309—327).—The copper solution used

in the experiments was prepared by dissolving in water 8.166 grams of crystallised copper sulphate, 15 grams of 100 per cent. sodium hydroxide, 25 c.c. of glycerol, 350 c.c. of ammonia of sp. gr. 0.9 and diluting to 1 litre. Fifty c.c. are diluted with 50 c.c. of water and boiled in the well-known Pavy apparatus; to prevent too rapid an escape of ammonia, some paraffin wax is added, also a few fragments of pumice-stone, and the burette tip for discharging the sugar solution or the urine is made long enough to pass down the neck of the flask and below this paraffin. If the saccharine solution contains 0.2 per cent. of dextrose, then 1 mol. of this will reduce exactly 5.88 mols. of copper oxide. Using this solution with uric acid and creatinine, it was found that 1 mol. of the former reduces 2.98 and 1 mol. of the latter 1.998 mols. of copper oxide. Processes are given for the estimation of these substances in urine so as to be able to allow for their reducing power when estimating the reducing power of a sample of urine. This reducing power is larger than that caused by uric acid and creatinine, proving the presence of normally existing sugar and, possibly, other reducing substances.

Estimations of urea by the mercury and hypobromite methods and its relation to the uric acid are also given. L. DE K.

Estimation of Glycogen. By EDUARD PFLÜGER (*Pflüger's Archiv*, 1900, 80, 351—369, 527—532; 81, 1—7. Compare Abstr., 1899, ii, 529, 819).—Largely polemical. Austen's method of estimating glycogen consists in a preliminary digestion of the substance with Finkelberg's pepsin, and subsequent treatment according to Külz's method. The pepsin used, however, contains a variable amount of glycogen or a similar polysaccharide; the glycogen obtained contains nitrogen, and a loss of glycogen occurs in prolonged peptic digestion. The final result is too low. A protest is entered against the incomplete and incorrect account of the Pflüger-Nerking method given in Salkowski's recently published text-book. A number of new experiments are given to show that this method is the best at present in vogue. W. D. H.

Estimation of Chloral Hydrate and Chloroform in Toxicological Analysis. By CARL KIPPENBERGER (*Arch. Pharm.*, 1900, 238, 81—100).—When chloral is distilled with an alkali, a not inconsiderable portion of the chloroform formed is decomposed according to the equation $\text{CHCl}_3 + 3\text{KHO} = 3\text{KCl} + 2\text{H}_2\text{O} + \text{CO}$. The author now estimates this carbon monoxide by taking advantage of its reducing action on palladium chloride.

The material to be tested is, if necessary, rendered faintly acid, then mixed with a fairly large quantity of magnesium oxide and introduced into a distilling flask placed in a water-bath. The flask is provided with a doubly-perforated cork, one opening of which is connected by means of an india-rubber tube and clamp with a Woulf's bottle containing aqueous caustic potash. This arrangement allows of the transmission of air later on. Through the other opening passes a tube connected with a small condenser which in turn is connected with another Woulf's bottle, then with a wash bottle containing dilute hydrochloric acid, and finally with a Lunge's 10-bulb tube filled

with solution of palladious chloride and surrounded by hot water; to this bulb tube an aspirator is attached to draw a current of air through the apparatus when no more chloroform distils over.

On heating the flask, the chloroform and water vapour condense in the Woulf's bottle and the chloroform is separated mechanically and weighed. The little which remains dissolved in the water is afterwards estimated by one of the well-known methods, for instance, by means of Fehling's solution, by potassium permanganate, or by iodine. The carbon monoxide, after being freed from volatile impurities by passing through the acid, now enters the bulb tube and causes a precipitate of metallic palladium, which is then collected, ignited and weighed. One hundred parts of palladium correspond with 26.42 parts of carbon monoxide or 156.02 of chloral hydrate or 112.6 parts of chloroform.

L. DE K.

Acidity of Milk. By A. L. TOURCHOT (*Expt. Stat. Record*, 1900, 11, 578; from *Brit. Food Jour.*, 1899, 1, 199).—Determinations of acidity in a large number of milk samples showed that fairly constant results are obtained with milk less than 12 hours old, the amount of *N/10* soda required to neutralise 10 c.c. of milk being 1.4—1.6 c.c. Greater acidity indicates that the milk is contaminated or less fresh, or else that it was from cows which had recently calved. Up to two weeks after calving, cows yield milk which may require as much as 1.8 c.c. of *N/10* soda to neutralise 10 c.c.

When the amount of soda required exceeds 1.7 c.c. in summer, or 1.6 c.c. when the cows are stall-fed, the milk should be rejected as unfit for food. On the other hand, acidity represented by less than 1.2 or 1.4 c.c. of *N/10* soda, in winter and in summer respectively, indicates addition of water or the presence of an unhealthy cow in the herd.

N. H. J. M.

Examination of Brown and Taylor's Official Method of Identifying Butter. By JOHN A. HUMMEL (*J. Amer. Chem. Soc.*, 1900, 22, 327—329).—In the manufacture of renovated butter, the butter-fat is melted and then rapidly cooled in a stream of cold water; this induces a semi-crystallisation of the fat, which may be recognised by the microscope. A small piece of the sample is placed on a glass slide and pressed into a thin film with a cover glass; it is then at once examined with a polarising microscope magnifying 120—150 diameters. A selenite plate is placed between the slide and the lower Nicol's prism. In every case normal butters gave a uniform blue coloured field showing the entire absence of crystals, but the renovated samples gave a blue field mottled with yellow, which varied in intensity, but was very distinct in each case.

L. DE K.

Maize Oil. By ROWLAND WILLIAMS (*Analyst*, 1900, 25, 146—147).—A table is given containing the sp. gr., potash-absorption, free fatty (oleic) acids, bromine thermal value, iodine values according to Hübl (15 hours) and to Wijs (15 minutes), and unsaponifiable matters of 8 samples of maize oil. On the whole, the figures are fairly constant, particularly those of the potash absorption and the bromine thermal value.

Notwithstanding its high iodine value (120·85—127·27), it possesses but little drying power and is not likely to take the place of linseed and similar oils in the manufacture of paints and varnishes.

L. DE K.

Nature of Klunge's Aloin Reactions, and the Oxidising Action of Cupric Salts in the Presence of Cyanogen Compounds. By EDUARD SCHAEER (*Arch. Pharm.*, 1900, 238, 42—48).—It is pointed out that a close analogy exists between Klunge's reactions for aloin and those of the author for guaiacum; the same substances (haloid salts, hydrocyanic acid, ferrocyanides, thiocyanates, and nitroprussides) which produce a blue coloration when added to a mixture of barbaloin and copper sulphate in dilute solution also produce the amethyst to cherry-red coloration when added to guaiacum-resin (guaiaconic acid) and copper sulphate. In both cases, the coloration is due to an oxidation of the colouring matter; it is removed by various reducing agents. (See also this vol., i, 512).

C. F. B.

Estimation of Santonin. By JULIUS KATZ (*Archiv Pharm.*, 1900, 238, 100—102. Compare Abstr., 1899, ii, 619; this vol., ii, 122).—A controversy with Thäter on the estimation of santonin in *Flores cinæ*. Whilst, doubtless, Thäter's improved process yields a fairly pure santonin, yet it is absolutely useless for quantitative purposes, as loss of 23—56 per cent. of the total amount of santonin is caused by it.

L. DE K.

Volumetric Estimation of Alkaloids. By OTTO LINDE (*Arch. Pharm.*, 1900, 238, 102—135. Compare Abstr., 1899, ii, 534, 826).—When titrating alkaloids with standard acid and alkali, it is advisable to avoid an excess of the indicator, to have the solution as concentrated as possible, and to work at the ordinary temperature.

The following indicators may be used; they are classed according to their sensitiveness: Iodeosin, in water covered with ether; fluorescein and gallein, in water, covered with ether or in alcohol; luteol, in water or alcohol (ether or chloroform to be avoided); phenacetolin, in alcohol or water; lacmoid, in alcohol, less satisfactory in water with or without addition of ether; cochineal, in water or alcohol; tincture of brazilwood, tincture of logwood, hæmatoxylin, brazilin, azolitmin, and litmus, in water; phenolphthalein, in water (ether and chloroform to be avoided); rosolic acid, in water (ether and chloroform to be avoided); Congo-red (ether to be avoided); methyl-orange, in water; dimethyl-aminoazobenzene, in water (ether, alcohol, and light petroleum to be avoided); tropæolin, in water; tincture of turmeric and Poirrier's blue are useless.

L. DE K.

Estimation of Alkaloids by Means of a Titrated Solution of Iodine. By CARL KIPPENBERGER (*Arch. Pharm.*, 1900, 238, 135—148. Compare Abstr., 1895, ii, 467; 1896, ii, 282, 682).—A lengthy reply to Scholtz's criticism (Abstr., 1899, ii, 390). The author, although aware that the iodine process for the estimation of alkaloids does not belong to the more accurate analytical methods, still recommends it for practical purposes. Besides repeating previous experiments, fresh ones have been made with caffeine and aconitine; a solution of silver

iodide in potassium iodide is recommended as a catalytic liquid to promote the action of the iodine.

L. DE K.

[Estimation of Berberine.] By JULIUS TROEGER and OTTO LINDE (*Arch. Pharm.*, 1900, 238, 4—8).—See this vol., i, 515.

Gluten Constituents of Wheat and Flour, and their Relation to Bread-making Qualities. By H. A. GURRS (*J. Amer. Chem. Soc.*, 1900, 22, 263—268).—The following method of analysis is proposed :—
(a) Five grams of the finely-ground meal or flour are put into a 250 c.c. flask, and a 1 per cent. solution of salt is added from a pipette with sufficient pressure to prevent any tendency to clot; the flask is then filled to the mark, shaken at intervals for an hour, and left at rest for 2 hours. Of the clear filtrate, two duplicate portions of 100 c.c. are withdrawn, the proteids are precipitated with a few c.c. of a 10 per cent. solution of phosphotungstic acid, 50 c.c. of the clear filtrate evaporated with sulphuric acid, and the amide-nitrogen estimated in the usual manner.

(b) One gram of the sample is put into a 500 c.c. Kjeldahl flask, mixed with alcohol of sp. gr. 0.90, thoroughly shaken, placed in a water-bath maintained at a temperature slightly below the boiling point of the alcoholic mixture, and agitated every 10 minutes for an hour. After settling for an hour, the liquid is poured as far as practicable into a similar flask, taking care not to disturb the deposit; this is then treated four times in succession with 25 c.c. of hot alcohol to complete the extraction. The alcohol is distilled off, the nitrogen in the residue estimated, the amide-nitrogen subtracted, and the balance calculated to gliadin, using the factor $\times 5.7$.

(c) The residue from the alcohol extraction, when cold, is treated with 250 c.c. of a 1 per cent. solution of salt, and allowed to settle for an hour; after pouring off the liquid through a filter, the mass is again treated with another 250 c.c. of salt solution, shaken at intervals for an hour, and allowed to settle for 2 hours, when the liquid is decanted through the same filter. The filter and contents are added to the residue in the flask, and the nitrogen estimated and calculated to glutenin.

The results of the analyses of 104 samples are communicated in a table. At present, it cannot be said that there seems to be a true relation between the ratios of the various proteids and the practical value of the sample for bread making, but there is no doubt a direct and very intimate connection between them.

L. DE K. /

General and Physical Chemistry.

Origin of Certain Unknown Lines in the Spectra of Stars of the β -Crucis Type, and the Spectrum of Silicon. By JOSEPH LUNT (*Proc. Roy. Soc.*, 1900, 66, 44—50).—The three unknown lines present in the spectra of β -Crucis, ϵ -Canis Majoris, and stars of that type (Gill, *Abstr.*, 1899, ii, 718), have been obtained from pure helium and argon tubes with a highly disruptive spark, and are shown to be due to silicon. In the silicon spectrum from these tubes, the enhanced lines noted by Lockyer are less prominent than in the spectrum obtained from silicon tetrafluoride with an intensely disruptive spark; it therefore seems that great variations in the relative intensities of the silicon lines occur in stellar spectra. This behaviour of the silicon lines is important in the determination of relative stellar temperatures (compare Lockyer, this vol., ii, 181). J. C. P.

Liquid Absorption Spectra in the Ultra-Red. By L. PUCCIANI (*Nuovo Cimento*, 1900, [iv], 11, 241—278).—The absorption spectra of the following liquids in the ultra-red have been determined for wave-lengths of 2.75μ and less: Benzene, toluene, *o*-, *m*-, and *p*-xylene, ethylbenzene, methyl iodide, ethyl iodide, ether, alcohol, methyl alcohol, pyridine, allyl alcohol, carbon disulphide, and carbon tetrachloride. The results, together with those of Donath (*Ann. Phys. Chem.*, 1896, [ii], 58, 609), on oil of turpentine, oil of juniper, oil of rosemary, oil of lavender, safflower oil, oil of olives, and petroleum show that liquid compounds whose molecules contain carbon combined directly with hydrogen exhibit a maximum of absorption for the wave-length 1.71μ . Further, besides this maximum, all the benzene compounds examined, and also pyridine, have two other maxima of absorption in common, these being probably due to the peculiar structure of their molecules. The spectra of the three alcohols are very similar, and have maxima of absorption for a wave-length of about 2.10μ . The three isomeric xylenes show absorptions almost, although not quite, identical. At about 2.32μ , another maximum occurs for toluene, *o*-, *m*-, and *p*-xylene, ethylbenzene, ethyl iodide, ether, and methyl and ethyl alcohols. T. H. P.

Sensitiveness of Silver and of some other Metals to Light. By JAMES WATERHOUSE (*Proc. Roy. Soc.*, 1900, 66, 490—504).—The author confirms Moser's observation that silver, exposed under ordinary conditions, is distinctly sensitive to light; not only can an invisible, developable image be obtained, but by prolonged exposure printed-out impressions are produced which are clearly visible after exposure. Blue and violet rays are shown to be most active in producing this effect. It seems that heat does not play any active part in the production of the images, although higher temperatures may accelerate the action of light. When a pure silver plate has been raised to a red heat, plunged in dilute sulphuric acid, washed,

dried, and exposed, no image is produced. Of other metals, the only one that is similarly sensitive is lead. J. C. P.

Artificial Radio-active Barium. By A. DEBIERNE (*Compt. rend.*, 1900, 131, 333—335).—When a highly radio-active salt of actinium is added to a barium chloride solution, the latter becomes radio-active, and the results are more marked if the barium is precipitated as sulphate and reconverted into chloride, the actinium being separated by means of ammonium hydroxide. The radio-activity of the barium increases with the duration of its contact with the actinium salt, and may become several hundred times as great as that of uranium. The radiation thus induced in the barium resembles that of the radio-active barium obtained from pitchblende, is associated with the atoms of the metal, and persists through various chemical changes; it ionises gases, excites the phosphorescence of barium platinocyanide, and acts on photographic plates. Part of the radiation is deflected in a magnetic field, and the anhydrous chloride of the metal is self-luminous. Further, the barium chloride made radio-active by induction can be fractionated, and the radio-activity is more intense in the first crystals. On the other hand, the salts do not show the spectrum of radium, and the induced radio-activity gradually diminishes in intensity (compare this vol., ii, 351, 352, 480). C. H. B.

Spectrum of Radium. By EUGÈNE DEMARÇAY (*Compt. rend.*, 1900, 131, 258—259).—A specimen of radium chloride, prepared by Mme. Curie, and dissolved in hydrochloric acid, gave a spark spectrum in which the barium lines were feeble, and only the line 4554·4 had any marked intensity. On the other hand, it gave a brilliant radium spectrum, which did not contain any lines in addition to those already observed (this vol., ii, 83). Two bands described (*loc. cit.*) as faint and nebulous were, however, very distinct, with maximum intensity at about 4627·5 and 4455—4453·4 respectively. The line 4364·2, formerly attributed to radium, seems to be identical with the platinum line 4364·4, and the origin of the very feeble line 4600·3 is uncertain. In general character, the radium spectrum resembles the spectra of the alkaline-earth metals. The low intensity of the barium spectrum indicates that this specimen of radium chloride is practically pure. C. H. B.

Radio-activity of Uranium. By SIR WILLIAM CROOKES (*Proc. Roy. Soc.*, 1900, 66, 409—423).—In agreement with an observation of M. and Mme. Curie (this vol., ii, 82), the author finds that all radio-active minerals contain either uranium or thorium; pitchblende shows the most intense action, and gives an effect roughly proportional to the percentage of uranium it contains. In the preparation of pure uranium nitrate, it was observed (1) that solution of the nitrate in ether and subsequent crystallisation gave an inactive product; (2) that the active constituent was concentrated in the aqueous layer formed when crystallised uranium nitrate and ether are shaken up together. The portion insoluble in ether, when evaporated to dryness with nitric acid and crystallised from water, has the same appearance (1) as ordinary uranium nitrate, (2) as the product from the ethereal solution, evapo-

rated to dryness and crystallised from water. When the uranium nitrate from the portion insoluble in ether is submitted to fractional crystallisation, the radio-active substance is concentrated in the mother liquor. A highly active uranium nitrate obtained in this way was dissolved in water, and excess of ammonia added; the whole of the radio-activity was found to reside in the ammonium uranate formed. Another portion of active uranium nitrate was dissolved in water, and excess of ammonium carbonate added; the first formed precipitate almost entirely redissolved, but a light brown, fluorescent portion, remaining insoluble in excess, was found to contain almost the whole of the radio-active constituent. For this the author uses provisionally the symbol UrX , and shows that its action differs from that of polonium, inasmuch as the emanations from the latter cannot pass through glass, aluminium, or lead. UrX is further distinguished from polonium by its non-volatility and its chemical behaviour. It is not so easy to settle whether UrX is distinct from radium, although many considerations point to its not being this substance; thus radium sulphate is said to be insoluble in water and acids, whilst UrX dissolves easily to a clear solution in dilute sulphuric acid.

Similar experiments with thorium nitrate point to the possibility of separating a radio-active substance from thorium. J. C. P.

Behaviour of Radium at Low Temperatures. By O. BEHRENDSEN (*Ann. Phys.*, 1900, [iv], 2, 335—337).—The power of certain substances possessing radio-activity to discharge a metallic conductor has been previously shown (*Ann. Phys. Chem.*, 1896, [ii], 69, 220) to be diminished by lowering the temperature. The same behaviour has now been observed in the case of a radium preparation. J. C. P.

Velocity of the Ions produced in Gases by Röntgen Rays. By JOHN ZELENY (*Proc. Roy. Soc.*, 1900, 66, 238—241).—The author has determined the velocities of the ions produced in air, oxygen, carbon dioxide, and hydrogen by Röntgen rays. Moisture generally diminishes the ionic velocity, this effect being specially marked in the case of negative ions. Except for moist carbon dioxide, the velocity of the negative ion is greater than that of the positive ion (compare Rutherford, *Abstr.*, 1898, ii, 112; Townsend, *Abstr.*, 1899, ii, 729).

J. C. P.

Electrical Conductivity in Gases traversed by Cathode Rays. By J. C. McLENNAN (*Proc. Roy. Soc.*, 1900, 66, 375—378).—It has been shown that when a gas is traversed by Röntgen or uranium rays, positive and negative ions are produced; the author finds that this occurs also under the influence of cathode rays. When cathode rays of a given strength pass through a gas, the number of ions produced per second in 1 cub. cm. depends only on the density of the gas, and is independent of its chemical composition. Under rays of constant intensity, the ionisation in a particular gas varies directly as the pressure. It is shown that the values of relative ionisation in different gases by Röntgen rays of constant intensity agree well in most cases with those obtained for cathode rays.

J. C. P.

Electrical Effects due to Evaporation of Sodium in Air and other Gases. By W. CRAIG HENDERSON (*Proc. Roy. Soc.*, 1900, 66, 183—186).—When sodium is fused and boiled in an iron cylinder, an electrometer connected (1) with the cylinder, (2) with a copper plate suspended in the vapour, shows considerable electrification; this, however, is not observed when the air in the cylinder is replaced by coal gas, so that the electrification is due to oxidation, and not merely to evaporation.

J. C. P.

Electrolytic Reduction of Difficultly Reducible Substances in Sulphuric Acid Solution. By JULIUS TAFEL (*Zeit. physikal. Chem.*, 1900, 34, 187—228; also *Ber.*, 1900, 33, 2209—2224).—By comparing the volumes of hydrogen liberated (1) in a sulphuric acid voltameter, (2) at the cathode of a cell containing a reducible substance in sulphuric acid solution, it is possible to follow the course of the reduction. With an apparatus constructed on this principle, the author has determined under what conditions the process of reduction is a regular one. In the case of caffeine, the reducible substance mainly used in the experiments, no reduction takes place except when the cathode is of lead or mercury, the cathode potential of these metals being specially high. The addition of small quantities of other metals to the cathode liquid stops the reduction process, and there is a simultaneous fall in the cathode potential. In certain cases, the foreign metal is rendered harmless, and the reduction process started again by the addition of lead acetate. In view of these experiments, it is probable that the irregularities usually observed in the reduction process are due to small quantities of foreign metals. To obtain consistent results, it is further necessary that the lead electrodes should be prepared electrolytically, and have a superficial coating of finely divided peroxide. Rise of temperature accelerates the reduction of caffeine, but only to a small extent (compare Abstr., 1899, i, 268).

J. C. P.

Chromium Cell for the Rectification of Alternating Currents. By J. LIVINGSTON R. MORGAN and W. A. DUFF (*J. Amer. Chem. Soc.*, 1900, 22, 331—334).—Two electrodes, one of chromium and the other of platinum, are immersed in dilute sulphuric acid. When the platinum is made the anode, the current passes freely; but if the chromium is made the anode, no current goes through the cell. By using the chromium as anode and very gradually increasing the impressed E.M.F., it is possible to stop any current entirely until a pressure of about 75 volts is reached. When the increase in the E.M.F. is made so rapidly that the current passes from chromium to platinum, or after the cell breaks down by the application of more than 75 volts, a peculiar result is obtained. Unlike the aluminium cell, the chromium cell, after it has broken down, is still an asymmetrical resistance, but only when the platinum plate is made the anode. With chromium as the anode, the current now passes freely. If in this condition the cell is broken down by the application of too high an E.M.F. to the platinum anode, another reversal takes place, so that about 75 volts can again be stopped, using the chromium as anode. This change in the behav-

our of chromium is doubtless due to the change from the 'active' to the 'inactive' state (Hittorf, *Abstr.*, 1898, ii, 363; 1900, ii, 127).

The authors consider that these results confirm the theory that the action of the aluminium cell is due to the formation of a resistant film, as suggested by Norden (this vol., ii, 404; compare also Wilson, *Abstr.*, 1899, ii, 540). E. G.

Existence of Thermal Centres of Stability in Compounds. By GEOFFREY MARTIN (*Chem. News*, 1900, 81, 301—304).—The heat of formation of a compound varies with the temperature, and the kinetic theory leads to the conclusion that for an exothermic compound the heat of formation diminishes as the temperature rises. Victor Meyer has shown that the heat of formation of hydrogen iodide is at first negative, becomes zero at 324° , and at higher temperatures is positive; an example of an endothermic compound changing into an exothermic one. The author supposes that this is a general phenomenon, and that the exothermic compound may pass back again to the endothermic stage as the temperature rises. According to this view, the positive or negative value of the heat of formation is a periodic function of the temperature. Each temperature at which the heat of formation is zero would be a centre of stability. It is not to be expected that a gaseous substance would exist at all points on this curve, but it should exist at least at the centres of stability. The author discusses evidence in favour of this, and points out, *inter alia*, that silicon hexachloride, which at 800° is completely dissociated into tetrachloride and silicon, exhibits no dissociation if suddenly raised above 1000° . This compound, therefore, is stable above 1000° and below 350° , but cannot exist undissociated at intermediate temperatures. The maximum of conductivity shown by certain acids in solution is regarded as an analogous phenomenon. J. C. P.

Weight of Hydrogen Desiccated by Liquid Air. By LORD RAYLEIGH (*Proc. Roy. Soc.*, 1900, 66, 334).—The density of hydrogen dried by liquid air, acting as a cooling agent, is the same as that obtained when phosphoric oxide is used to effect desiccation. J. C. P.

Distillation of Liquid Air, and the Composition of the Gaseous and Liquid Phases. I. At Constant Pressure. By EDWARD C. C. BALY (*Phil. Mag.*, 1900, [v], 49, 517—529).—The experiments were made in order to render possible the determination of the temperature of boiling air by the analysis of the gas evolved. The results are summed up in two curves which show (1) the boiling point at 760 mm. of all mixtures of oxygen and nitrogen, (2) the temperature at which any mixture of oxygen and nitrogen will liquefy, and the composition of the liquid formed. When $r'/100$ is the ratio of the compounds in the gaseous phase, and $r/100$ the corresponding ratio in the liquid phase, then the most probable relation between r and r' throughout the distillation is found to be $r' = 0.2097 \times r^{1.03757}$ (compare Leffeldt, *Phil. Mag.*, 1895, [v], 40, 397). There does not appear to be any connection between the ratio of the vapour pressures and the composition of the gaseous phase in the distillation of oxygen and nitrogen at constant pressure. J. C. P.

Viscosity of Argon as affected by Temperature. By LORD RAYLEIGH (*Proc. Roy. Soc.*, 1900, 66, 68—74).—The time of passage of a quantity of argon through a capillary tube has been determined at two different temperatures. It was thought probable that the viscosity of argon would vary with the temperature in another manner than that of the diatomic gases, oxygen, hydrogen, and nitrogen, but the experimental work shows that there is no great difference. When $\mu'/\mu = [\theta'/\theta]^n$, where μ' and μ are the viscosities at the absolute temperatures θ' and θ , then n has the following values: air (dry), 0.754; oxygen, 0.782; hydrogen, 0.681; argon (impure), 0.801; argon (best), 0.815. J. C. P.

Influence of the Medium on the Velocity of Reaction. By GUSTAV BUCHBÖCK (*Zeit. physikal. Chem.*, 1900, 34, 229—247).—A previous investigation (*Abstr.*, 1897, ii, 398) has shown that the velocity of decomposition of carbonyl sulphide in various aqueous solutions depends partly on the viscosity of the solutions. This investigation has now been amplified on the basis of van't Hoff's theory, according to which the velocity of reaction in various media is defined by the equation $dC/dt = \kappa C/S$; here C is the concentration, and S represents the quantities of the reacting substance (carbonyl sulphide) which are in equilibrium with each other in the various media. The author has taken isosmotic solutions of a number of salts and acids, and determined the absorption coefficient and decomposition velocity constant of carbonyl sulphide in these solutions; he has further measured the viscosity of the solutions. In general it is seen that the greater the viscosity the smaller the value of κ . The product of the two has for inorganic solutions a fairly constant value (8.84), quite different, however, from the value obtained in the case of the organic acids. It is pointed out that the product of reaction velocity and viscosity is a linear function of the absolute quantity of water in the solutions; if allowance is made for this, it is seen that the velocity of decomposition of thiocarbonic acid in such aqueous isosmotic solutions as are in equilibrium with respect to thiocarbonic acid, is inversely proportional to the viscosity of the solutions. J. C. P.

Reply to Criticism. [Chemical Affinity.] By WILHELM VAUBEL (*Chem. Zeit.*, 1900, 24, 371—373).—A recapitulation of the author's theories (see this vol., ii, 264, 274), and a reply to Küster's criticisms in particular. J. C. P.

Affinity Constants of Acids containing a Ring of Seven Carbon Atoms. By W. A. ROTH (*Ber.*, 1900, 33, 2032—2035. Compare Willstätter, *Abstr.*, 1899, i, 651).—The following affinity constants in absolute units at 25° have been determined: α -Cycloheptatrienecarboxylic acid (α -isophenylacetic acid), $K = 0.003672$; β -cycloheptatrienecarboxylic acid (β -isophenylacetic acid), $K = 0.004101$; Δ^1 -cycloheptenecarboxylic acid, $K = 0.000992$ and for another solution, after correcting for the conductivity of the water, $K = 0.000928$. Δ^2 -Cycloheptenecarboxylic acid gave, in three different solutions, the corrected values $K = 0.00267$, 0.00260 and 0.002606 respectively; this acid appears to undergo a gradual chemical change resulting in a

diminution of the value of K , the highest number for which is hence probably the most accurate.

T. H. P.

Nature and Properties of Colloidal Solutions. By GIUSEPPE BRUNI and N. PAPPADÀ (*Atti Real. Accad. Lincei*, 1900, [v], 9, i, 354—358).—Solutions of the following colloids—silicic acid, ferric hydroxide, chromic hydroxide, ferric ferrocyanide, egg albumin, and gelatin—were prepared and submitted to dialysis for varying periods, never less than a fortnight, the external liquid being frequently changed. In no case was any of the colloid found to diffuse through the dialyser, and further, the freezing points of the colloidal solution and of the external liquid with which it is in equilibrium show only very small differences, which are in both senses and within the limits of experimental error. Vapour tension experiments, carried out by a modification of Ostwald and Walker's method, a current of air being passed through a series of five flasks, the first three containing the colloidal solution, and the others the corresponding exterior liquid from the dialysing apparatus, showed no variation in the vapour pressures of the various liquids. Semi-colloids, for example, dextrin or molybdic acid, in solution pass comparatively readily through a dialyser and also give small depressions of the freezing point, which are, however, quite appreciable and proportional to the concentration; dextrin, for example, gives a molecular weight 1135, corresponding with the formula $(C_6H_{10}O_5)_7$. Semi-colloids must hence be regarded as substances which, in solution, have very high molecular weights. With colloids, however, no real solution takes place, the substance remaining suspended in the liquid in a very fine state of subdivision. This view finds confirmation in the application of the phase rule to such solutions. If they are true solutions, on freezing there would be three co-existent phases—ice, solution, and vapour—the system being mono-variant, whilst in the case of a solution containing a solid in suspension, there would be another phase and the system would be non-variant. That the latter is the fact is shown by the constancy of the temperature of freezing, which in the former case would vary with the concentration. This conclusion is in accord with that of Stoeckel and Vanino (this vol., ii, 11), arrived at from a study of the optical properties of colloidal solutions of the metals.

T. H. P.

Nitrogen Peroxide as a Solvent. By GIUSEPPE BRUNI and P. BERTI (*Atti Real. Accad. Lincei*, 1900, [v], 9, i, 321—326).—The cryoscopic behaviour of solutions of the following compounds in nitrogen peroxide has been examined: nitromethane, nitroethane, acetic, butyric, trichloroacetic, picric, and nitric acids. Nitromethane, nitroethane, and picric acid show normal molecular weights, whilst all the other compounds examined show depressions of the freezing points less than the normal, hence nitrogen peroxide is not only devoid of dissociating power but must be classed with those solvents in which hydroxy-compounds are associated.

T. H. P.

Cryoscopic Behaviour of Nitro-derivatives in Formic Acid. I. By GIUSEPPE BRUNI and P. BERTI (*Atti Real. Accad. Lincei*, 1900, [v], 9, i, 273—279).—The cryoscopic behaviour of the

following nitro-derivatives in formic acid has been determined: Nitrobenzene, *m*-dinitrobenzene, 1:3:5-trinitrobenzene, 2:4:6-trinitrotoluene, 1-chloro-2:4:6-trinitrobenzene, picric acid, methyl picrate, *p*-nitrobenzoyl chloride, nitromethane, nitroethane, chloropicrin. The results show that the aromatic nitro-derivatives are all more or less dissociated in formic acid solution, whilst those of the aliphatic series show no signs of dissociation. Picric acid is not more dissociated than its methyl ether, the presence of the hydroxyl group being apparently without effect on the dissociation, which, however, tends to increase with the accumulation of electro-negative groups in the molecule. The presence of a small quantity of water in the formic acid does not increase its dissociating power.

This dissociation of aromatic nitro-derivatives in formic acid solution is probably due to the formation of an additive product of the type $R \cdot NO(OH)(CO_2H)$. Such compounds would be capable of dissociation and similar additive products should also be formed with acetic acid, but in this case they are not indicated by the cryoscopic behaviour, since acetic acid has no dissociating power. One fact in favour of this hypothesis is that solutions of aromatic polynitro-derivatives in anhydrous formic acid are colourless even at high concentrations, whilst with other solvents, whether possessed of dissociating power or not, they form intensely yellow solutions. T. H. P.

Behaviour of Nitro-derivatives in Formic Acid Solution. II. By GIUSEPPE BRUNI and P. BERTI (*Atti Real Accad. Lincei*, 1900, [v], 9, i, 393—400).—In formic acid solution, the following nitro-compounds all show abnormally small molecular weights on freezing: trinitro-*p*-xylene, *o*-, *m*-, and *p*-chloronitrobenzenes, *o*-, *m*-, and *p*-nitrobenzoic acids, methyl *o*-, *m*-, and *p*-nitrobenzoates.

The molecular weights of *s*-trinitrobenzene, 2:4:6-trinitroanisole, dinitromesitylene and trinitromesitylene were determined in boiling formic acid, the last two compounds being almost insoluble in the freezing acid. The molecular raising of the boiling point of formic acid is $\kappa = 34$, as determined for solutions of β -naphthol and benzoic acid. Of the four compounds mentioned, the first three show marked dissociation in boiling formic acid, whilst trinitromesitylene gives the normal molecular weight, whence the conclusion is drawn that for a compound to show dissociation in formic acid solution the presence of a mobile hydrogen atom in the molecule is necessary.

To test the hypothesis advanced in a former paper (see preceding abstract), according to which dissociation in formic acid is due to the formation of an additive product of the acid with the dissolved substance, the freezing point curve for mixtures of formic acid and *o*-chloronitrobenzene was studied. The curve is composed of two branches meeting in one cryohydric point, as is the case for mixtures of two substances which do not combine, and completely excludes the existence of an additive compound. T. H. P.

Oxidations with Free Oxygen. By WILHELM OSTWALD (*Zeit. physikal. Chem.*, 1900, 34, 248—252).—The occurrence of ozone in oxidation processes has been attributed to the primary formation of a higher oxide of the oxidisable substance, which then splits up into a

lower oxide and ozone. The author deals with the theoretical side of this view, and points out that ozone has a higher oxidation potential than the oxygen from which it is derived, and that the energy necessary to raise the oxidation potential must be obtained from some other reaction, namely, the formation of a more stable oxide. These two processes, however, must be intimately connected with one another, and expressible by a single chemical equation with definite integral coefficients. Thus, when ozone occurs in the oxidation of phosphorus, it is incorrect to suppose that (1) energy is derived from the oxidation of the phosphorus, (2) this energy converts oxygen into ozone, the two processes being independent; on the contrary, they must be intimately related, and this is done by postulating the intermediate formation of a higher oxide. The criterion for the formation of such an intermediate compound is the occurrence of the final products in definite chemical proportions.

J. C. P.

Crystallographic Characters of some Isomorphous Potassium Salts. By F. CORIO (*Zeit. Kryst. Min.*, 1900, 32, 524—526; from *Atti Soc. Sci. Nat. Modena*, 1898, 16, 73—117).—Optical and crystallographic determinations are given of potassium sulphate and potassium chromate and of crystals containing various proportions of these two salts.

L. J. S.

Comparative Crystallographical Study of the Double Selenates of the Series $R_2M(SeO_4)_2 \cdot 6H_2O$. I. Salts in which M is Zinc. By ALFRED E. TUTTON (*Proc. Roy. Soc.*, 1900, 66, 248—250).—In the double salts examined, R represents potassium, rubidium, and caesium. The characters of the rubidium double selenate lie invariably between those of the potassium and caesium salts. Comparison of the results obtained with those previously communicated (*Trans.*, 1893, 63, 337; 1896, 69, 344), shows that the replacement of sulphur by selenium is generally accompanied by a change in the morphological and physical constants similar to that accompanying the replacement of one alkali metal by another of higher atomic weight. In the heavier selenate molecules, however, the amount of change caused by varying the alkali metal is often less than in the case of the double sulphates.

J. C. P.

Acetylene Gas as Fuel in Chemical Laboratories. By ARTHUR LACHMAN (*Amer. Chem. J.*, 1900, 24, 39—45).—The author thinks that, in cost, convenience, or feasibility, acetylene cannot compete with "gasoline gas" (air saturated with gasoline vapour) as a laboratory fuel.

J. J. S.

Etymological Researches on the Names of the Chemical Elements, from which the International and National Symbols are derived, with Special Reference to the German Names. By PAUL DIERGART (*J. pr. Chem.*, 1900, [ii], 61, 497—531).—An etymological paper, which traces the derivation of the common names of the elements and throws much light on their history.

R. H. P.

Inorganic Chemistry.

Electrolysis of Concentrated Hypochlorite Solutions. By ANDRÉ BROCHET (*Compt. rend.*, 1900, 131, 340—343).—When a solution of sodium hypochlorite containing sodium hydroxide is electrolysed, the proportion of hypochlorite at first diminishes rapidly, and afterwards more slowly, finally becoming constant. At the same time, the proportion of chlorate increases, at first very rapidly, then more slowly, and afterwards at a constant rate. The reduction at the cathode is almost constant for some time, then diminishes somewhat rapidly, and afterwards becomes constant again; the oxidation at the anode is at first constant, then increases slowly, and finally reaches a limit. The presence of sodium hydroxide does not affect the reduction of the hypochlorite, but very materially affects the limits of the reactions. C. H. B.

Composition of Nitrogen Iodide. By F. D. CHATTAWAY (*Amer. Chem. J.*, 1900, 24, 138—158).—See *Proc.*, 1899, 15, 18.

Action of Light on Nitrogen Iodide. By F. D. CHATTAWAY and K. J. P. ORTON (*Amer. Chem. J.*, 1900, 24, 159—167).—See *Proc.*, 1899, 15, 18.

Transformation of Hyponitrous Acid into Hydrazine. By FREIHERR VON BRACKEL (*Ber.*, 1900, 33, 2115—2116).—An acid aqueous solution of hyponitrous acid was treated with sodium hydrogen sulphite in the cold; the product reduced Fehling's solution in the cold. It was concentrated under diminished pressure and reduced with zinc dust and acetic acid; the solution, when freed from zinc, reduced Fehling's solution in the cold, and gave a precipitate of benzalazine with benzaldehyde; it must therefore have contained hydrazine. O. F. B.

Nitrohydroxylaminic Acid. By ANGELO ANGELI and FRANCESCO ANGELICO (*Gazzetta*, 1900, 30, i, 593—595).—The *potassium*, $K_2N_2O_3$, *calcium* (with $\frac{1}{2}H_2O$), *strontium* (with H_2O), *lead*, and *cerium*, $Ce_2(N_2O_3)_3 \cdot Ce(OH)_3$, salts of nitrohydroxylaminic acid have been prepared. Solutions of the sodium salt rapidly absorb oxygen from the air, forming sodium nitrite, which in presence of excess of the nitrohydroxylamine partially undergoes further oxidation to nitrate. Nitrohydroxylaminic acid, which is unstable and could not be isolated, decomposes in various ways depending on the conditions; by means of acids it is broken up almost quantitatively according to the equation: $H_2N_2O_3 = 2NO + H_2O$, small quantities of nitrous and possibly of hyponitrous acid also being formed. On boiling the sodium salt with water, one half of the total nitrogen is evolved in the form of nitrous oxide and the rest remains as sodium nitrite, $2H_2N_2O_3 = 2HNO_2 + N_2O + H_2O$; this reaction indicates the structure $O:N(OH):N \cdot OH$.

for the acid. On heating the sodium salt to incipient fusion, sodium nitrite and hyponitrite are formed thus : $2\text{O}:\text{N}(\text{OH})\text{:N}\cdot\text{OH} = 2\text{HNO}_2 + \text{OH}\cdot\text{N}:\text{N}\cdot\text{OH}$. The aqueous solution of the sodium salt readily reacts with aldehydes with development of heat; with acetaldehyde, the sodium salts of nitrous and acetohydroxamic acids are formed. T. H. P.

Solubility of Quartz in Sodium Silicate Solutions. By GIORGIO SPEZIA (*Atti Accad. Sci. Torino*, 1900, 35, 750—761).—Dilute solutions of sodium silicate acting on quartz at high temperatures exert a decided solvent action on it. At lower temperatures, the quartz is re-deposited, Sterry Hunt's hypothesis that such deposition is due mainly to diminution in pressure being in this case untenable. T. H. P.

Constitution of Glass and Allied Products. By KARL ZULKOWSKI (*Chem. Centr.*, i, 1041—1042; from *Chem. Ind.*, 1900, 23, 108—114).—Like silicic acid, boric acid forms higher poly-acids of the type $\text{B}_{2n}\text{O}_{3n-1}(\text{OH})_2$ or $n\text{B}_2\text{O}_3, \text{H}_2\text{O}$. When melted with alkali carbonates, it behaves like silicic acid, and with excess of the carbonate tends to form a metaborate, hence in boron glass probably only polymetaborates are present. Compounds of borosilicic acid probably occur in silicate glass containing boric acid.

When silicate glass is rendered opaque by adding tin dioxide, polymetastannates which are less fusible and are insoluble in the fused mass are formed. The opaque particles of enamel glass probably also consist of these compounds. Whilst, however, polymetastannates of the type $\text{KO}\cdot\text{SnO}\cdot\text{O}\cdot\text{SnO}\cdot\text{OK}$ are formed by fusing tin dioxide with potassium carbonate, the ordinary metastannate, $\text{SnO}(\text{ONa})_2$ is obtained with sodium carbonate; the production of normal or acid stannates seems to be less dependent on the kind of alkali than on the melting point.

Unlike the anhydrides of the other glass-forming acids, calcium metaphosphate, when melted with potassium carbonate, forms an orthophosphate. The composition of pure phosphate glass corresponds with that of silicate glass, and the polymetaphosphoric acids formed are of the type $\text{P}_{2n}\text{O}_{3n-1}(\text{OH})_2$ or $n\text{P}_2\text{O}_5, \text{H}_2\text{O}$. Calcium metaphosphate is prepared by gradually heating and then melting crystallised monocalcium orthophosphate at an orange-red heat. E. W. W.

So-called Electrolytic Silver Peroxide [Silver Peroxynitrate. By OTTOKAR ŠULC (*Zeit. anorg. Chem.*, 1900, 24, 305—313. Compare Abstr., 1896, ii, 521).—The compound $\text{Ag}_2\text{NO}_{11}$, obtained by the electrolysis of a solution of silver nitrate, has been subjected to further investigation. When dissolved in ammonia, it liberates 2·8 per cent. of nitrogen, that is, 2 mols. of ammonia are oxidised by 3 of the oxygen atoms of the peroxide. When heated at 120° during 16 hours, it decomposes, evolving 8·46 per cent., or 5 atomic proportions of oxygen, whilst at lower temperatures the decomposition is slower, and does not proceed so far. From these results, the author proposes the formula $\text{AgNO}_3, 3\text{Ag}_2\text{O}_2, 2\text{O}$ for the substance (compare Mulder and Heringa, *loc. cit.*). E. C. R.

Manganese Compounds. I. Ammonium Permanganate.

By ODIN T. CHRISTENSEN (*Zeit. anorg. Chem.*, 1900, 24, 203—219).—Ammonium permanganate can be prepared by the action of ammonium chloride on potassium permanganate solution at 70—80°, or on finely-powdered silver permanganate, and purified by recrystallisation from water at 70°. When left in a closed vessel at the ordinary summer temperature, it is completely decomposed with the formation of ammonium nitrate and the insoluble manganese oxide, $22\text{MnO}_2, \text{MnO}, x\text{H}_2\text{O}$, crystallised in pseudomorphs of ammonium permanganate. At higher temperatures (42—50°), a similar decomposition takes place in a few days, whilst at 58° the salt decomposes in a few hours with explosive violence. The same compounds are obtained, together with a small quantity of nitrogen, on boiling the substance with water, whilst when it is heated with ammonia, the decomposition products are nitrogen, ammonium nitrite, a small quantity of ammonium nitrate, and a hydrated manganese oxide, which, after drying, contains 85.31 per cent. of manganous oxide and 14.69 per cent. of active oxygen. When heated with nitric acid, the hydrated manganese oxide $22\text{MnO}_2, \text{MnO}, 28\text{H}_2\text{O}$ is formed, containing, however, a small quantity of ammonia which cannot be eliminated. E. C. R.

Ferrous Iodide. By C. LORING JACKSON and I. H. DEEBY (*Amer. Chem. J.*, 1900, 24, 15—31).—Ferrous iodide was prepared by heating clean iron wire clippings in an atmosphere of nitrogen saturated with iodine vapour. The product forms deep red plates with a slightly brownish tinge, but in thicker masses is nearly black; it is extremely deliquescent, decomposes at a moderate heat in the presence of oxygen, and when exposed in a desiccator it turns white, but then gradually evolves iodine and becomes grey or black. The white compound is probably a hydrate, $\text{FeI}_2 \cdot 2\text{H}_2\text{O}$. Carius and Wanklyn's (*Annalen*, 1861, 120, 69) and Thomson's (*Compt. rend.*, 1862, 55, 615) methods for the preparation of ferrous iodide have also been tried, and the product obtained in each case had the appearance just described.

Anhydrous ferrous iodide readily absorbs ammonia gas, yielding a voluminous, white, amorphous powder of the composition $\text{FeI}_2 \cdot 6\text{NH}_3$, which is readily decomposed by water, and, when treated with bromine vapour, yields ferric bromide, ammonium bromide, and ammonium bromiodobromide, NH_4BrIBr . This compound, which may also be obtained by the action of an ethereal solution of iodine bromide on ammonium bromide, is a lustrous green substance, dissolves in ether, and readily decomposes when exposed to the air, leaving a residue of ammonium bromide. J. J. S.

Action of Potassium Persulphate on Cobalt Salts. By F. MAWROW (*Zeit. anorg. Chem.*, 1900, 24, 263—268).—A solution of cobalt sulphate or nitrate, when warmed with excess of potassium persulphate, yields a dark brown precipitate containing $\text{Co}_3\text{O}_4 \cdot 3\text{H}_2\text{O}$ mixed with sulphates. The oxide $\text{Co}_3\text{O}_4 \cdot 3\text{H}_2\text{O}$ is obtained by warming cobaltous hydroxide with excess of potassium persulphate, and, after washing with water, heating the product at 100° with dilute nitric acid. The yield amounts to one-third of the cobaltous hydroxide.

The oxide $\text{Co}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$, obtained by treating cobaltous hydroxide with excess of potassium persulphate in the presence of excess of potassium hydroxide solution of sp. gr. 1.18—1.3, is a black precipitate which oxidises oxalic acid to carbon dioxide when heated with it, and is insoluble in cold, and only partially soluble in hot, concentrated nitric acid.

E. C. R.

Preparation of the Blue Oxide of Molybdenum and of Metallic Molybdenum. By ALLEN ROGERS and F. H. MITCHELL (*J. Amer. Chem. Soc.*, 1900, 22, 350—351).—The blue oxide of molybdenum is obtained by the addition of stannous chloride to a solution of ammonium molybdate slightly acidified with nitric acid. The precipitate is washed as quickly as possible, drained, and dried at 100° ; it seems to have the composition Mo_2O_3 , and is more readily reduced than the trioxide when heated in a current of hydrogen. Small quantities may be quickly reduced by placing the substance in a cavity in the lower of two carbon poles, and passing the electric current in an atmosphere of hydrogen; the resulting molybdenum is a very hard, dull steel-grey mass.

E. G.

Double Nitrates of Quadrivalent Cerium and of Thorium. By RICHARD JOS. MEYER and RICHARD JACOBY (*Ber.*, 1900, 33, 2135—2140).—Basic ceric nitrate, $\text{Ce}(\text{NO}_3)_3 \cdot \text{OH}$, has been obtained crystalline. Double nitrates of quadrivalent cerium and of thorium have been prepared (not all for the first time) of the types $\text{M}'_2\text{M}^{\text{IV}}(\text{NO}_3)_6$ and $\text{M}''\text{M}^{\text{IV}}(\text{NO}_3)_6 \cdot 8\text{H}_2\text{O}$, where $\text{M}^{\text{IV}} = \text{Ce}$ or Th , $\text{M}' = \text{NH}_4$, Rb or Cs , and $\text{M}'' = \text{Mg}$, Zn , Ni , Co , and Mn (and also Sr , when $\text{M}^{\text{IV}} = \text{Th}$). In addition, a salt, $\text{NH}_4\text{Th}(\text{NO}_3)_5 \cdot 5\text{H}_2\text{O}$, belonging to a different type, was prepared. Details are to be published later.

C. F. B.

[Purification of] Commercial Thorium Nitrate. By WILHELM MUTHMANN and E. BAUR (*Ber.*, 1900, 33, 2028—2031).—To purify thorium nitrate, 840 grams of the commercial product were dissolved in 5 litres of water, and into the solution was passed steam under 3 atmospheres pressure while 1 litre of 6 per cent. potassium chromate solution was added in drops. By repeating this operation six times, crystalline thorium chromate, $\text{Th}(\text{CrO}_4)_2 \cdot 3\text{H}_2\text{O}$, was obtained which yielded 320 grams of the white oxide, containing impurities to the extent of about 0.3 per cent. Mantles for incandescent burners prepared from this purified oxide give a light 1.3—1.4 times as intense as those prepared from the impure thorium salt. Impurities in the small proportion (1 per cent.) of ceria used in the mantles exert a far less deleterious action on the amount of light than those of the thoria, which constitutes the main bulk of the heated mixture.

T. H. P.

Gadolinium. By EUGÈNE DEMARÇAY (*Compt. rend.*, 1900, 131, 343—345).—The author has examined the spark spectrum of gadolinium magnesium nitrate containing only minute quantities of terbium, yttrium, and $\Sigma - \text{Z}$, and has determined the wave-lengths and relative intensities (maximum = 16) of 108 lines, which are given in the paper. The two most persistent are 3549.3 and 3545.7 with intensities of 10.5

and 10 respectively. Estimations of the atomic weight yield a number approximately the same as that obtained by previous observers, $Gd = 155$.
C. H. B.

Action of Sodium Thiosulphate on Potassium Antimony Tartrate. By FR. FAKTOR (*Chem. Centr.*, 1900, i, 1211; from *Pharm. Post*, 1900, 33, 233—234).—When a cold solution of potassium antimonyl tartrate is added to a cold solution of sodium thiosulphate and the mixture boiled, a compound, $SbSO_2$, separates as a bright red precipitate which may be washed with water, alcohol, and carbon disulphide, and dried at 100° ; the yield amounts to 5 per cent. of the tartrate used. When suspended in water, this compound is not attacked by hydrogen sulphide even at 80° , but when exposed to sunlight it shrinks in volume, becomes of a darker colour, and then has the composition Sb_2SO_4 . A brown precipitate, Sb_2SO_5 , is also obtained by mixing boiling solutions of potassium antimonyl tartrate and sodium thiosulphate.

Mineralogical Chemistry.

Possibility of the Transference of Metals in Igneous Rocks through the Agency of Carbon Monoxide. By CLEMENS WINKLER (*Chem. Centr.*, 1900, i, 1307; from *Ber. k. sächs. Ges., Math.-phys. Kl.*, 1900, 52, 9—16).—It is suggested that the native iron found in the basalt of Disko Island, W. Greenland, may have been formed from iron and nickel carbonyls.
L. J. S.

Statement of Rock Analyses. By HENRY S. WASHINGTON (*Amer. J. Sci.*, 1900, [iv], 10, 59—63).—In order to introduce uniformity in the statement of rock analyses, so that the chemical character of a rock may be seen at a glance, it is suggested that the constituents be given in the following order, commencing with the eight principal oxides in the main portion of the analysis: SiO_2 , Al_2O_3 , Fe_2O_3 , FeO , MgO , CaO , Na_2O , K_2O , H_2O (ignition), H_2O (110°), CO_2 , TiO_2 , ZrO_2 , P_2O_5 , SO_3 , Cl , F , S (FeS_2), Cr_2O_3 , NiO , CoO , MnO , BaO , SrO , Li_2O .
L. J. S.

Calorimetric Examination of Pyrites and Marcasite. By ALFRED CAVAZZI (*Zeit. Kryst. Min.*, 1900, 32, 515; from *Rend. R. Accad. Sci. Ist. Bologna*, 1898, N.S. 2, 205—209).—The heat of combustion of pyrites and of marcasite is 1550 small calories for each mineral. Analyses of the material used gave:

	S.	Fe.	Si.	Total
Pyrites	47.53	52.09	0.30	99.92
Marcasite	47.56	52.17	0.22	99.95

L. J. S.

Sulpharsenites of Lead from the Binnenthal. By RICHARD H. SOLLY, with Analyses by HENRY JACKSON (*Min. Mag.*, 1900, 12, 282—297).—An historical account is given of the minerals sartorite, rathite, dufrenoyite, and jordanite which occur in the white saccharoidal dolomite of the Binnenthal in Switzerland, and a detailed crystallographic account is given of jordanite. The following new analyses, made only on crystals, lead to the formulæ: sartorite, $\text{PbS}_2\text{As}_2\text{S}_3$ (compare Abstr., 1896, ii, 109); rathite, $3\text{PbS}_2\text{As}_2\text{S}_3$ (compare Abstr., 1896, ii, 659); jordanite, $4\text{PbS}_2\text{As}_2\text{S}_3$. A collection is given of all the previously published analyses of these minerals; several, which were made on massive material, are placed under rathite, since they approximate to the new formula, $3\text{PbS}_2\text{As}_2\text{S}_3$, given above.

Carnotite and Associated Vanadiferous Minerals in Western Colorado. By WILLIAM F. HILLEBRAND and F. LESLIE RANSOME (*Amer. J. Sci.*, 1900, [iv], 10, 120—144).—Ores of uranium and vanadium occur as yellow and green impregnations in sandstone over a wide area in Western Colorado; one, of a bright yellow colour, has been described by O. Friedel and Cumenge under the name carnotite (Abstr., 1899, ii, 434), of which the composition was given as $2\text{U}_2\text{O}_3 \cdot \text{V}_2\text{O}_5 \cdot \text{K}_2\text{O} \cdot 3\text{H}_2\text{O}$. In the present paper, the mode of occurrence is described, and several very detailed analyses are given, which, however, show considerable variations and do not confirm the above formula. Under I is given the maximum and minimum amounts of the more important constituents in six recalculated analyses made on the portion of the carnotite ore which is readily soluble in cold dilute nitric acid. The important constituents of the less soluble portion, given under II, show this to be a vanadiferous silicate, possibly allied to roscoelite. Carnotite is therefore a mixture of minerals.

The green colouring and cementing matter of certain sandstones near Placerville resembles roscoelite in composition, but it has less vanadium and more aluminium; the more important constituents in the recalculated analysis are given under III. The colouring matter in other green sandstones in the same region was found to be due to chromium.

	SiO_2	UO_3	V_2O_5	V_2O_3	Al_2O_3	Fe_2O_3	CaO	BaO	MgO	K_2O	H_2O

Vanadinite (Endlichite) from Hillsboro', New Mexico. By VICTOR GOLDSCHMIDT (*Zeit. Kryst. Min.*, 1900, 32, 561—578).—A detailed crystallographic description is given of the sulphur-yellow crystals of "endlichite" from Hillsboro', New Mexico. They have the same degree of symmetry (hexagonal with pyramidal hemihedrism), and very nearly the same axial ratio [$a:c=1:0.7126$] as ordinary vanadinite. Analyses by P. Jannasch of the tabular and of the columnar crystals gave the results under I and II respectively, agreeing with those required for the vanadinite formula $3\text{Pb}_3\text{V}_2\text{O}_8 + \text{PbCl}_2$. In I, the ratio $\text{V}_2\text{O}_5:\text{As}_2\text{O}_5$ is 8.6:1, and in II it is 11.7:1.

L. J. S.

Perowskite from S. Ambrogio in the Valley of the Susa. By GIOVANNI BOERIS (*Atti Real. Accad. Lincei*, 1900, [v], 9, i, 52—55).—A description is given of perowskite crystals found in the zone of contact between the granite and the serpentine of S. Ambrogio. Analysis gave TiO_2 , 58.63; FeO , 0.86; CaO , 40.29, total, 99.78; formula, CaTiO_3 ; hardness between 5 and 6; sp. gr., 3.98. The colour varied from a honey-yellow through yellowish-brown to almost black. The mineral is accompanied by chlorite, apatite, magnetite, and ilmenite.

T. H. P.

Larderellite from the Suffioni of Tuscany. By GIOVANNI D'ACHIARDI (*Atti Real. Accad. Lincei*, 1900, [v], 9, i, 342—345).—Analysis of larderellite gives the following mean numbers: B_2O_3 , 72.06; $(\text{NH}_4)_2\text{O}$, 9.83; H_2O , 18.11 per cent. This indicates the formula $(\text{NH}_4)_2\text{B}_{10}\text{O}_{16} \cdot 5\text{H}_2\text{O}$, differing only in the water of crystallisation from the octahydrated ammonium pentaborate described by Rammelsberg in 1855. The specimen examined by Bechi, to which the formula $(\text{NH}_4)_2\text{B}_8\text{O}_{12} \cdot 4\text{H}_2\text{O}$ was given, probably contained impurities.

T. H. P.

Plumbogummite and Hitchcockite. By ERNALD GEORGE JUSTINIAN HARTLEY (*Min. Mag.*, 1900, 12, 223—233).—There is a want of agreement in the old analyses of the poorly crystallised lead aluminium phosphates, plumbogummite and hitchcockite; the following new analyses have therefore been made on carefully selected material. The pale lavender to bright smalt-blue material, formerly considered to be calamine, which encrusts quartz and pyromorphite from the old Roughten Gill lead mines near Caldbeck, Cumberland, gave analysis I; traces of copper and arsenic are also present; no water is lost at 100° . This agrees in composition with the white hitchcockite from Canton mine, Georgia, of which a new analysis is given under II. The formula for both is given as $5\text{PbO}, 9\text{Al}_2\text{O}_3, 4\text{P}_2\text{O}_5, 2\text{CO}_2, 24\text{H}_2\text{O} =$

Dark brown plumbogummite from Huelgoat, Brittany, gave the results under III and IV; about 1 per cent. of organic matter is present.

Deducting the amount of pyromorphite corresponding with the chlorine, and also lead sulphate and about 5 per cent. of water lost at 100°, the remainder agrees approximately with the formula given above. Associated with the dark mineral from Huelgoat is a lighter coloured crystalline material (anal. V) with some minute crystals having the form of pyromorphite; this is mainly pyromorphite with some lead aluminium phosphate.

	PbO.	Al ₂ O ₃ .	P ₂ O ₅ .	CO ₂ .	H ₂ O.	Cl.	Insol.	Total.
I.	37.03	28.74	18.64	3.12	12.73	—	—	100.26
II.	34.36	29.48	17.58	2.77	14.71	—	0.82	99.72
III.	43.24	19.04	18.37	4.59	14.50	0.29	—	100.03
IV.	38.91	20.98	19.14	4.66	15.44	0.16	SO ₃ 0.96	100.25
V.	75.93	2.78	16.81	0.44	1.96	2.32	—	100.24

Hitchcockite (from Georgia and Cumberland) therefore appears to be a definite mineral, and plumbogummite (from Huelgoat) to be a mixture of hitchcockite and pyromorphite.

L. J. S.

Beudantite. By ERNALD GEORGE JUSTINIAN HARTLEY (*Min. Mag.*, 1900, 12, 234—238).—The old analyses of beudantite differ so much that it is impossible to deduce any simple formula from them. The following new analysis was made on pure, dark green crystals supposed to be from the Glandore iron mines, Co. Cork (but possibly from Dernbach, Nassau). The material is soluble in strong hydrochloric acid. The formula is given as $3\text{PbO}, 4\text{Fe}_2\text{O}_3, \text{P}_2\text{O}_5, 3\text{SO}_3, 9\text{H}_2\text{O} = 3\text{PbSO}_4, 2\text{FePO}_4, 6\text{Fe}(\text{OH})_3$. Details of the method of analysis are given, and previous analyses are discussed.

PbO.	CuO.	Fe ₂ O ₃ .	P ₂ O ₅ .	As ₂ O ₃ .	SO ₃ .	H ₂ O.	Insol.	Total.
32.33	1.35	34.61	9.53	trace	12.72	8.45	0.56	99.37

L. J. S.

Florencite, a New Mineral from Brazil. By EUGEN HUSSAK and GEORGE T. PRIOR (*Min. Mag.*, 1900, 12, 244—248).—This new mineral has been found at three localities in Minas Geraes, namely, in the cinnabar-bearing sands of Tripuhy, in mica-schist near Tripuhy, and in diamond-bearing sands near Diamantina. The pale yellow crystals have a greasy to resinous lustre; they are rhombohedral [$\alpha : c = 1 : 1.1901$] with a fairly perfect basal cleavage. $H = 5$; sp. gr. 3.586; optically uniaxial and positive. Analysis gave:

Al ₂ O ₃ .	Ce earths.	Fe ₂ O ₃ .	CaO.	SiO ₂ .	P ₂ O ₅ .	H ₂ O.	F.	Total.
32.28	28.00	0.76	1.31	0.48	25.61	10.87	undet.	99.31

Water is only given off at a high temperature. The molecular weight of the cerium earths is 352, which is considerably higher than usually accepted; didymium appears to be present in only small amount. The formula is given as $3\text{Al}_2\text{O}_3, \text{Ce}_2\text{O}_3, 2\text{P}_2\text{O}_5, 6\text{H}_2\text{O} = \text{AlPO}_4, \text{CePO}_4, \text{Al}_2(\text{OH})_6$.

Florencite is related crystallographically and chemically to hamlinite, $3\text{Al}_2\text{O}_3, 2(\text{Sr}, \text{Ba})\text{O}, 2\text{P}_2\text{O}_5, 7\text{H}_2\text{O}$ (Abstr., 1898, ii, 123), and the two minerals are isomorphous, the strontium and barium of hamlinite

being replaced in florencite by cerium earths. These results support the conclusions of Wyruboff and others (Abstr., 1897, ii, 176) as to the isomorphism of many cerium salts with the corresponding salts of calcium and strontium, and the possible dyad character of the cerium earths.

L. J. S.

The Hamlinite-Florencite Group of Minerals. By GEORGE T. PRIOR (*Min. Mag.*, 1900, 12, 249—254).—It is pointed out that, owing to the difficulty of obtaining pure material and to imperfect methods of analysis and separation, mineral analyses are not so trustworthy as they are sometimes supposed to be when complex formulæ are deduced, and that when group relations can be made out, a more simple formula is sometimes preferable. On these grounds, it is suggested that hamlinite, florencite (preceding abstract), hitchcockite (this vol., ii, 600), beudantite (this vol., ii, 601), and svanbergite belong to the same isomorphous group of rhombohedral minerals, with the following formulæ and crystallographic constants:

	$a : c.$
Hamlinite, $2\text{SrO}, 3\text{Al}_2\text{O}_3, 2\text{P}_2\text{O}_5, 7\text{H}_2\text{O}$	1.1353
Svanbergite, $2\text{SrO}, 3\text{Al}_2\text{O}_3, \text{P}_2\text{O}_5, 2\text{SO}_3, 6\text{H}_2\text{O}$	1.2063
Hitchcockite, $2\text{PbO}, 3\text{Al}_2\text{O}_3, 2\text{P}_2\text{O}_5, 7\text{H}_2\text{O}$	—
Beudantite, $2\text{PbO}, 3\text{Fe}_2\text{O}_3, \text{P}_2\text{O}_5, 2\text{SO}_3, 6\text{H}_2\text{O}$	1.1842
Florencite, $\text{Ce}_2\text{O}_3, 3\text{Al}_2\text{O}_3, 2\text{P}_2\text{O}_5, 6\text{H}_2\text{O}$	1.1901

Here the group 2SO_3 is considered to be capable of replacing P_2O_5 without affecting the crystalline form; or writing hamlinite in the form $\text{SrHPO}_4, \text{AlPO}_4, \text{Al}_2(\text{OH})_6$, that is, as an ortho- instead of a pyrophosphate, the grouping SrHPO_4 may be considered as replaced in beudantite by PbSO_4 , in svanbergite by SrSO_4 , and in florencite by CePO_4 .

A new examination of svanbergite proves that the alkaline earth is mainly strontium and not calcium, as given in Blomstrand's analysis.

L. J. S.

Interpretation of Mineral Analyses: Constitution of Tourmaline. By SAMUEL L. PENFIELD (*Amer. J. Sci.*, 1900, [iv], 10, 19—32. Compare Abstr., 1899, ii, 304).—A reply to the criticisms of Clarke and Tschermak (Abstr., 1899, ii, 767; this vol., ii, 217). General remarks are made on the difficulties encountered in the analysis of minerals. Instead of deducing complex formulæ to suit particular analyses, it is better to assume the presence of some impurity.

L. J. S.

Asbestos [and Chrysotile]. By E. VAN DER BELLEN (*Chem. Zeit.*, 1900, 24, 392—393).—Light blue asbestos, in fibres 5—10 cm. long, gave on analysis the results under I, melting point 1150° ; hydrochloric acid (sp. gr. 1.124) dissolves 5 per cent. without destroying the silky lustre of the material. Greenish-brown "asbestos" [chrysotile], in fibres averaging 1 cm. long, gave II, agreeing with the serpentine formula $3\text{MgO}, 2\text{SiO}_2, 2\text{H}_2\text{O}$; melting point $1550\text{—}1570^\circ$; hydrochloric acid dissolves 57 per cent., leaving a residue consisting only of silica.

	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	FeO	CaO	MgO	K ₂ O(Na ₂ O)	H ₂ O	SO ₂
I.	56.79	3.85	8.03	—	1.00	20.48	5.93	3.73	0.59

L. J. S.

Lasur-Oligoclase from Lake Baikal. By PAVEL V. VON JEREMIEFF (*Zeit. Kryst. Min.*, 1900, 32, 493—496).—These crystallographic notes on lasur-oligoclase, albite, and sphene from the neighbourhood of Lake Baikal were published in Russian in 1873, and are now for the first time given in German. The first-mentioned mineral was described by Nordenskiöld in 1857 under the name "Lasur-Felspath" as a variety of orthoclase, but the present author finds that the crystallographic elements agree closely with those of oligoclase, and he proposes the name "Lasur-oligoklas." The crystals are colourless to white with blue spots; some are decomposed and contain enclosures of calcite. Sp. gr. 2.587—2.598. Analysis gave:

SiO ₂	Al ₂ O ₃	CaO	MgO	Na ₂ O	K ₂ O	H ₂ O	CO ₂	Total
52.80	22.90	4.67	3.82	7.75	trace	3.66	3.90	99.50

L. J. S.

Sanidine from Monte Cimino, Rome. By FERRUCCIO ZAMBONINI (*Zeit. Kryst. Min.*, 1900, 32, 533—534; from *Rivista Min. Crist. Ital.*, 1898, 20, 20—64).—A description is given of crystals of Sanidine from Monte Cimino, near Viterbo. Regular intergrowths of sanidine with black mica or with augite occur. Analysis gave:

SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	K ₂ O	Na ₂ O	CaO	MgO	TiO ₂	Total
65.20	18.51	0.41	11.37	3.40	0.65	1.23	0.12	100.89

The TiO₂, MgO, and Fe₂O₃ are probably due to enclosures of sphene and mica.

L. J. S.

Stokesite, a New Mineral from Cornwall. By ARTHUR HUTCHINSON (*Min. Mag.*, 1900, 12, 274—281).—A preliminary account of this new mineral has already been published (this vol., ii, 89); a more complete description is now given. The locality at which the only crystal known was found is Roscommon Cliff, St. Just. From the results of two analyses made on small amounts of material, the composition is given as follows:

SiO ₂	SnO ₂	CaO	H ₂ O	Total
43.1	33.3	13.45	8.6	98.45

At 220° there is a loss of 1.9 per cent., at 350° of 6 per cent., and the rest of the water is given off between 350° and dull redness. The formula H₄CaSnSi₂O₁₁ may be written in a variety of ways, as is the formula of catapleite, H₄Na₂ZrSi₂O₁₁, in different text-books.

Stokesite is the first example of a well crystallised definite compound containing silica and stannic oxide as essential constituents.

L. J. S.

[**Hornblende and Anorthoclase.**] By E. C. E. LORD (*Zeit. Kryst. Min.*, 1900, 32, 602; from *Amer. Geologist*, 1898, 22, 335—346).—In a paper descriptive of the dykes in the vicinity of

Portland, Maine, the following mineral analyses are given. I, a hornblende (sp. gr. 3.47) resembling barkevikite from a camptonite dyke; II, anorthoclase from the same rock.

	SiO ₂	TiO ₂	Al ₂ O ₃	Fe ₂ O ₃	FeO	CaO	MgO	Na ₂ O	K ₂ O	H ₂ O	Total
I.	37.80	4.54	12.89	6.14	12.55	13.64	4.10	5.26	3.24	—	100.16
II.	57.34	—	20.79	2.88	—	4.27	0.16	8.09	4.17	2.66	100.36

L. J. S.

Prehnite in Metamorphosed Limestone. By ALFRED LACROIX (*Compt. rend.*, 1900, 131, 69—72).—Prehnite (variety coupholite) is recorded as being associated with zoisite, grossular, and orthoclase in metamorphosed limestone in contact with granite, near Barèges, Haute-Pyrénées.

L. J. S.

Physiological Chemistry.

Elimination of Carbon Dioxide during Respiration. I. Influence of the Concentration of the Blood on the Tension of the Carbon Dioxide in it. By VALENTINO GRANDIS (*Atti Real. Accad. Lincei*, 1900, [v], 9, i, 130—137).—According to some observers, notably Pflüger, the phenomenon of gaseous exchange in the lungs obeys the laws of diffusion of gases, whilst others, among whom is C. Ludwig, hold that diffusion phenomena are incapable of explaining all the circumstances observed in the mutual relations of the gas in the lungs and ascribe to the epithelium of the pulmonary vesicles the power of secreting carbon dioxide and of absorbing oxygen. On bringing venous or arterial blood into contact with concentrated sugar or salt solutions in an apparatus designed to allow of the pressure being accurately measured by means of a water manometer, the author finds that, corresponding with the increase of the concentration of the blood, there occurs an increase in the pressure of the gas contained in the apparatus. It is hence concluded that, in the living animal, the concentration brought about in the blood circulating in the lungs by water being given up to the air in the lung passages causes a temporary increase in the pressure of the gas in the blood, with the result that a quantity of carbon dioxide is evolved greater than that corresponding with the pressure of this gas in the blood before concentration.

T. H. P.

Elimination of Carbon Dioxide during Respiration. II. Influence of the Hygrometric State on the Passage of Carbon Dioxide from the Blood to the Air. By VALENTINO GRANDIS (*Atti Real. Accad. Lincei*, 1900, [v], 9, i, 224—230. Compare preceding abstract).—A series of experiments, made on venous blood taken from the jugular vein of a dog, show that dry air is capable of withdrawing from blood a quantity of carbon dioxide greater than is the case with

air saturated with water vapour. Confirmation is thus lent to the conclusion (*loc. cit.*) that the concentration of the blood, when circulating in the lungs, causes an increase in the pressure of the contained gas. The experiments also show that one of the causes of the injurious effects of a moist climate on health is that the moisture of the air prevents the free escape of the gaseous products of metabolism from the blood.

T. H. P.

Temperature of the Body during Fasting and the Speed of Assimilation of Carbohydrates. By UGO LINO MOSO (*Atti Real. Accad. Lincei*, 1900, [v], 9, i, 77—84).—The temperature of a fasting dog shows after some days a gradual decline. Doses of 1—4 grams of sugar per kilogram of body weight cause the temperature of a fasting dog to rise rapidly in the first 10 or 15 minutes, the maximum being, however, reached in from 1 to 2 hours. The increase of temperature is maintained for a period of time directly proportional to the quantity of sugar administered. Sugar brings about the recovery of dogs in a critical state of hypothermia where the use of albumin is without effect.

Comparison of the effects of bread and sugar on the temperature of a fasting dog show that when the fast is of short duration and the temperature only slightly below the normal, the change is more rapid with bread than with sugar, the digestion still maintaining its activity. In the case of prolonged abstention from food, sugar causes the quicker rise of temperature. The quantities of bread and sugar required to produce a given heating effect are in the ratio 2 : 1.

T. H. P.

Rate of Absorption and of Assimilation of Proteids and Fats. By UGO LINO MOSO (*Atti Real. Accad. Lincei*, 1900, [v], 9, i, 122—129. Compare preceding abstract).—The effects caused by proteids and fats on the temperature of fasting dogs have been examined. The results show that veal and the constituents of yolk of egg are utilised only slowly in the production of heat, indicating that albumin and fat are mostly used in the formation of the tissues. Albumin does not serve as a means of keeping emaciated dogs alive, but this can be accomplished by administering sugar. Butter and pig's fat, like albumin, have no effect on the temperature of a well-fed dog when given in small quantities.

T. H. P.

Absorption of Fat. By LUDWIG HOFBAUER (*Pflüger's Archiv*, 1900, 81, 263—266).—A contribution towards the elucidation of the problem as to whether unsaponified fat can be absorbed. If all the fat of the food is absorbed in a form which is soluble in water, the fat globules in the epithelial cells and in the chyle should be colourless, if the fat has been previously coloured with pigments which are insoluble in water. If the fat particles remain coloured, then the fat globules of the emulsion must have been absorbed as such. The pigments used were alkana-red, and "Lackroth A," and in dogs it was found that the absorbed fat particles in cells and chyle were still red. They were never blue, although these pigments are turned blue by alkalis. A case of chyluria is referred to in which, after giving coloured fat, the fat particles in the urine were found to be coloured also.

W. D. H.

Pathological Fats. By ALONZO ENGLEBERT TAYLOR (*Pfûger's Archiv*, 1900, 81, 131—137).—Attention is directed to the results of others, who have failed to find an increase of fat in cases of phosphorus poisoning, and to the difference of opinion which exists in relation to the possibility of the formation of fat from proteid. In the present experiments, the liver fat in a case of acute yellow atrophy in man was found to contain 81 per cent. of olein and 3 per cent. of volatile fatty acids; the liver contained only traces of glycogen. In a series of cats, fatty infiltration of the kidney was produced by the use of sodium cantharidinate; the fat was compared with that of the healthy cat's kidney. The results are entirely negative as far as the question of the origin of the fats is concerned. The amount of fat from each pair of nephritic kidneys averaged 1.136 gram; from each pair of healthy kidneys, 1.640 gram. The most marked qualitative difference noted is an increase of olein in the pathological fat.

The following table gives the main results obtained; the normal fat was obtained from 12, the pathological from 9 pairs of kidneys.

	Normal fat.	Pathological fat.
Ether extract	19.686 gr.	11.230 gr.
Melting point of fatty acids	39.8°	34.7°
Acid number	6.8	12.9
Saponification number	218.8	178.8
Ether number	212	165.9
Reichert-Meissl number.....	5.7	3.6
Acetyl number	14.2	22.5
Olein per gram	0.3006 gr.	0.496 gr.
		W. D. H.

The Influence of "Saccharin" [*o*-Benzoisulphinide] on Digestion. By F. BERLIOZ (*Chem. Zeit.*, 1900, 24, 416—417).—The experiments on artificial gastric, and pancreatic digestion here recorded confirm those previously performed by Nencki (*Chem. Zeit. Repert.*, 1899, 23, 372), but are contrary to what has been stated by several previous experimenters. They show that "saccharin" does not hinder digestion.
W. D. H.

Phosphorus in Paranuclein from Casein. By HOLMES C. JACKSON (*Amer. J. Physiol.*, 1900, 4, 170—177).—The paranuclein, obtained by artificial gastric digestion from casein, contains phosphorus in organic combination. Chittenden's results in which the phosphorus recovered in the ash was equivalent to the total phosphorus of the paranuclein, are attributed to the large amount of ash in the products employed. If this is avoided and the formation of inorganic phosphates during ignition precluded, paranuclein yields over 2 per cent. of phosphorus.
W. D. H.

Influence of Experimental Modifications on the Consumption of Sugar. By ALBERT CHARRIN and A. GUILLEMONAT (*Compt. rend.*, 1900, 131, 126—128).—It has been previously shown in rabbits that the injection subcutaneously of a saline mixture increases their metabolic activity, whilst injection of various acids does the reverse. It

is now shown that if dextrose is injected as well, a certain quantity leaves the body by the urine, the remainder being utilised. The amount which is eliminated and the time during which the excretion lasts are increased greatly in the animals treated with acid.

W. D. H.

Behaviour of certain Artificial Hexoses in the Animal Body. By A. MÜNCH (*Zeit. physiol. Chem.*, 1900, 29, 493—516).—After the injection of formose into the jugular vein of rabbits, 71·5 per cent. appears unchanged in the urine. In well-fed rabbits, injection into the mesenteric vein causes glycosuria; the amount of glucose in the urine corresponds with that of formose injected. In starving rabbits, this does not occur, but about 11 per cent. of the formose appears unchanged in the urine. Formose serves to form glycogen, and thus may pass into the condition of dextrose. The digestive ferments have no action on it. Methose behaves qualitatively in the same way, but there are quantitative differences. The results with β -methylglucoside were also in the same direction.

W. D. H.

Uric Acid Formation after Splenectomy. By LAFAYETTE B. MENDEL and HOLMES C. JACKSON (*Amer. J. Physiol.*, 1900, 4, 163—169. Compare this vol., ii, 288).—Further experiments on dogs and cats are recorded, which show that the spleen has little or nothing to do with the production of uric acid. Experiments on the lymphatic glands are also negative.

W. D. H.

Results of the Extirpation of the Liver in Dogs. By SERGEI SALASKIN and J. ZALESKI (*Zeit. physiol. Chem.*, 1900, 29, 517—552).—The liver was removed in fourteen dogs; the urine was examined for nitrogen, urea, and ammonia. Full details of each experiment are given. Four animals died almost immediately; the majority between 5 and 6 hours later; one lived for 13 hours; the quantity of urine collected varied from 1·8 to 118·5 c.c. It had always an acid reaction; the percentage of urea sank, and that of ammonia rose, but these were not parallel. The blood and brain were also examined, but no rise of ammonia was found. There are thus differences between these results and those of Minkowski in geese. In dogs with an Eck's fistula, the toxic symptoms are due to accumulation of ammonia; in dogs with extirpated liver there is evidence of acid-poisoning.

W. D. H.

Proteolytic and Amylolytic Ferments in the Contents of the Human Colon. By JOHN C. HEMMETER (*Pflüger's Archiv*, 1900, 81, 151—166).—Extracts of human fæces, even in cases of atrophy of the stomach, have weak proteolytic, no lipolytic, and powerful amylolytic properties. The proteolytic ferment is not pepsin, as it will not act in an acid medium. The source of the ferments is probably the pancreas or the intestinal glands.

W. D. H.

Physico-chemical Relations of Animal Fluids and Tissues. By MAX OKER-BLOM (*Pflüger's Archiv*, 1900, 81, 167—221. Compare this vol., ii, 290, 356).—If potassium chloride, potassium sulphate, and

magnesium sulphate dissolved in serum are mixed with defibrinated ox-blood so that the osmotic pressure of the serum of the mixture is raised, they act on the blood corpuscles but little, whilst ammonium chloride and sulphate produce, under similar conditions, a marked effect. If aqueous solutions of potassium chloride or sulphate are mixed with the blood, they act on the corpuscles only when the osmotic pressure of their solutions is higher than that of the serum; they lose this property when the osmotic pressure of the serum is lowered. Magnesium sulphate in aqueous solution acts similarly. In the case of the ammonium salts, however, hypotonic as well as hypertonic solutions enter the corpuscles, but less forcibly. In all cases smaller quantities of the sulphates are necessary to produce the effects. These phenomena are related to that of electrical conductivity, which, although the method is but little used, forms a trustworthy guide to the power of electrolytes to penetrate the corpuscles. W. D. H.

Artificial Parthenogenesis. By JACQUES LOEB (*Amer. J. Physiol.*, 1900, 4, 178—184. Compare this vol., ii, 555).—Further experiments on this subject are stated to show that, by a certain increase in the osmotic pressure of the surrounding solution, the unfertilised eggs of some echinoderms can be caused to develop into normal blastulae or even plutei. This increase in osmotic pressure can be produced by electrolytes as well as by non-conductors. It is therefore probable that the parthenogenetic development is caused by the egg losing a certain amount of water. W. D. H.

Chemical Fertilisation of Eggs. By VIGNIER (*Compt. rend.*, 1900, 131, 118—121. Compare Loeb, this vol., ii, 555, and preceding abstract).—In a repetition of some of Loeb's experiments on the development of echinoid eggs, no grounds were found for believing his theory that any egg can develop parthenogenetically provided it is supplied with appropriate saline mixtures. In fact, magnesium chloride was found to hinder rather than favour development. Before accepting such sweeping ideas, it is necessary to show that the instances examined by Loeb were not accidental cases of true parthenogenesis. W. D. H.

Further Experiments on Tetanus Toxin and Antitoxin. By F. RANSOM (*Zeit. physiol. Chem.*, 1900, 29, 553—567. Compare this vol., ii, 558).—Antitoxic dog serum, like that of the horse, when injected into the blood-stream of dogs, divides itself between blood and lymph. Some time after the injection, there may be twice as much in the blood as in the lymph. The tetanus toxin, like the antitoxin, after being injected subcutaneously, passes into the blood *via* the lymph, but in the case of the toxin this takes place with great slowness. If the toxin is already in the blood and lymph, it is rapidly neutralised by injection of the antitoxin into the blood or lymph stream. W. D. H.

Composition of the Placenta: Its Solid and Liquid Components, Organic Compounds, Extractive Matter, and Albumoses. By VALENTINO GRANDIS (*Atti Real. Accad. Lincei*, 1900, [v], 9, i, 170—176).—The placenta was freed quickly from membrane and, after as much blood as possible had been removed, it was pounded into

a paste. On drying and igniting this paste, the mean numbers obtained were: dry substance, 16.09; water, 83.89; ash, 1.073 per cent. Extraction with water at 35° and removal of the albumin by coagulation gave the numbers: extractive matter, 1.925; dry albumin, 5.783; ash of albumin, 0.072. Further extraction under 2 atmospheres pressure removed 3.654 per cent., the insoluble residue amounting to 3.607 per cent. The water used for washing the placenta gave, on analysis: dry albumin, 1.37 and 2.16; ash, 0.017 and 0.064; whilst the red globules removed from the wash water gave: dry albumin, 1.58 and 2.39; ash, 0.017 and 0.024. These values, which vary very widely owing to the different amounts of blood retained, are calculated on the original weight of placenta. T. H. P.

Composition of the Ash of the Placenta. By VALENTINO GRANDIS (*Atti Real. Accad. Lincei*, 1900, [v], 9, i, 262—266. Compare preceding abstract).—Analysis of the ash of the placenta gives the following percentages: Cl, 11.4; S, 0.204; Na, 24.93; K, 6.57; PO₄, 33.46; CaO, 2.32. The ash of the albumin extracted by water from the placenta contains Na, 0.251 and PO₄, 55.18 per cent., whilst after previously washing the placenta with a 0.75 per cent. sodium chloride solution, the numbers are Na, 0.728, and PO₄, 44.5. The large proportion of phosphorus seems to indicate that the placenta fulfils a more important function than that of a mere mechanical organ of communication between the mother and the fœtus. It is noteworthy that the phosphorus is contained in substances which are extracted by water and are also precipitated together with the albumin from the aqueous solution. T. H. P.

Some Scientific and Ethical Questions of Biological Chemistry. By JOHN LEWIS W. THUDICHUM (*J. pr. Chem.*, 1900, [ii], 61, 568—575).—A controversial paper.

Chemistry of Vegetable Physiology and Agriculture.

Composition of Plankton. By K. BRANDT (*Bied. Centr.*, 1900, 29, 423; from *Naturw. Wochenschr.*, 1898, 13, 594).—Samples of plankton, and of its single constituents, obtained from Kiel Bay, were found to have the following composition:

	Proteids.	Fat.	Non-nitrog. extract.	Crude fibre.	Ash.
Plankton (autumn and winter) ...	20.2—21.8	2.1—3.2	60.0—68.9	8.5—15.7	
Peridinea	13.0	1.3	39.0	41.5	5.2
Diatoms	28.7	8.0	63.2	—	—

Samples of summer plankton consisted chiefly of animals and contained therefore a high percentage of proteids and not much carbohydrate; the amounts of fat varied considerably. N. H. J. M.

Influence of the Temperature of Liquid Air on Bacteria. By ALLAN MACFADYEN (*Proc. Roy. Soc.*, 1900, 66, 180—182, and with SYDNEY ROWLAND, 339—340).—In the first set of experiments, pure cultivations of ten organisms, including the very sensitive spirillum of *Cholera Asiatica* and the highly resistant spores of *Bacillus anthracis*, were exposed for 20 hours at the temperature of -182° to -190° . The bacteria lost none of their vital properties. The photogenic bacteria became non-luminous when cooled down, but their luminosity was restored as the temperature was allowed to rise. A sample of yeast cell plasma also was not altered by being subjected for 20 hours to the same temperature.

In the second series, broth emulsion cultures sealed in fine quill tubing were completely immersed in liquid air for 7 days. The vitality of the organisms was in no way impaired. N. H. J. M.

Influence of the Temperature of Liquid Hydrogen on Bacteria. By ALLAN MACFADYEN and SYDNEY ROWLAND (*Proc. Roy. Soc.*, 1900, 66, 488—489. Compare preceding abstract).—Exposure for 10 hours at a temperature of about -252° had no effect on the following organisms: *Bacillus acidi lacti*, *B. typhosus*, *B. diphtheria*, *Proteus vulgaris*, *B. anthracis*, *B. coli com.*, *Staphylococcus pyogenes aureus*, *Spirillum cholerae*, *B. phosphorescens*, *B. pyocyaneus*, a *Sarcina*, and a yeast. N. H. J. M.

Present Position of the Nitrugin Question. By JULIUS STOKLASA (*Zeit. landw. Versuchswes. Oesterr.*, 1898, 1, 78—88).—Pure cultures of *Bacillus radicola* promote the growth of leguminous plants, the amount of increase depending on the nature of the soil. The results of experiments in which lupin plants were deprived of their root-nodules, and afterwards grown in sterilised sand, indicated that fixation of nitrogen takes place, not in the nodules, but in the leaves. The bacteria seem to separate a kind of enzyme which causes the living protoplasm to assimilate elementary nitrogen. *B. radicola* does not fix free nitrogen, but some species of fluorescence bacilli, which assimilate free nitrogen, were obtained from soil. N. H. J. M.

Further Observations on Nitrugin, and the Nature and Functions of the Nodules of Leguminous Plants. By MARIA DAWSON (*Proc. Roy. Soc.*, 1900, 66, 63—65. Compare Abstr., 1899, ii, 785).—A study of the organisms from *Desmodium gyrans* showed they, as well as those from nitrugin and from pea nodules, grow readily on gelatin or agar containing an extract of pea straw, asparagine, and sugar, but very slowly on broth-gelatin. They do not peptonise milk. The organisms are aerobic, and may pass through a short motile stage.

Addition of nitrate to sterilised cultures of plants gave better results than inoculation, whilst the inoculation of plants manured with nitrate decreased the yield. N. H. J. M.

Fermentation without Cells. By FELIX B. AHRENS (*Zeit. angew. Chem.*, 1900, 483—486).—Yeast extract may be concentrated by cooling to a temperature not lower than -2° , stirring and expressing the liquor from the resulting magma of crystals. By repeating this pro-

cess several times, the sp. gr. of the liquor may be raised from 1.0378 at 12° to 1.0765 at 14°. This concentrated extract gave satisfactory results in experiments where the original extract was too dilute. The author considers that zymase is present as a colloidal substance, and not in a state of true solution; that its loss of activity is due to acidity, which always develops in a few hours, and that the fluorescence, which disappears when the extract is kept or used as a fermenting agent, is caused by the zymase itself. Samples of the extract, in its original form and after concentration, were fractionally precipitated, the dried products analysed, and their percentage composition calculated on an ash-free basis. The carbon shows the greatest variation, but no discussion of the tabulated results is attempted.

R. L. J.

Furfuroids of Plant Tissues. By CHARLES FREDERICK CROSS, EDWARD JOHN BEVAN, and J. S. REMINGTON (*J. Soc. Chem. Ind.*, 1900, 19, 307—310).—Direct experiment has proved that hydrolysed furfuroids are almost completely digested and assimilated by herbivorous animals such as the rabbit. Previous researches have shown that in “the permanent tissue”—the residue from the solvent action of alkaline (sodium hydroxide) and acid (hydrochloric acid) solutions in the cold—the ratio of furfuroids to other carbohydrates is greater than in the total plant. After ensilage, the opposite is true; for example, a permanent tissue gave a furfuraldehyde number of 6.1 per cent., whereas the total furfuraldehyde was 9.3 per cent. On the other hand, however, the furfuroids show an increased resistance to processes of acid hydrolysis after ensilage.

J. J. S.

Nature of the Reserve Carbohydrates in the St. Ignatius Bean and Nux Vomica. By ÉMILE BOURQUELOT and J. LAURENT (*Compt. rend.*, 1900, 131, 276—278. Compare this vol., ii, 498).—The albumen of the St. Ignatius bean was heated for an hour and a half at 110°, under pressure, with dilute sulphuric acid containing from 1—3 per cent. of acid. The total quantity of sugar formed increased with the concentration of the acid, whilst the ratio of mannose to galactose varied considerably, the proportion of galactose being higher the more dilute the acid. When the albumen of *nux vomica* is heated for varying periods of time with acid of constant strength (1:100), the proportion of galactose increases considerably with the duration of heating. These results indicate that the two sugars are not derived from a single mannogalactan, or from one mannan and one galactan, but from several mannans and galactans of different degrees of complexity, analogous to the dextrans in starch.

C. H. B.

Dissolution of the Nitrogenous Compounds in Malt. By PAUL PETIT and G. LABOURASSE (*Compt. rend.*, 1900, 131, 349—351).—Malt was treated with water for two hours at different temperatures, and one-half of each infusion was boiled for some time, cooled, and made up to its original volume. Estimations were made in both the boiled and unboiled portions of the total nitrogen, the nitrogen precipitated by phosphotungstic acid and sulphate of zinc respectively, and the nitrogen existing as ammonia after treatment with dilute hydrochloric

acid. The total soluble nitrogen gradually increased with the temperature, and reached a maximum at 55°, whilst the coagulable compounds gradually decreased, and the total nitrogen also began to decrease at and beyond 62°. The sum of the various quantities of nitrogen separately estimated in the manner indicated was considerably greater than the total nitrogen actually present. The results with the un-boiled infusions were somewhat irregular, probably owing to the action of enzymes, and the action of hydrochloric acid on the insoluble compounds. With the boiled portions, the results were more regular; the nitrogen precipitated by phosphotungstic acid and zinc sulphate increased up to 45° and then decreased, whilst the total soluble nitrogen increased up to 55°, and then gradually diminished. Arginine is formed under conditions which will be described subsequently.

C. H. B.

Formation and Decomposition of Albumen in the Plant. By ERNST SCHULZE (*Chem. Centr.*, 1900, i, 1031—1032; from *Ber. Deut. bot. Ges.*, 18, 36—42).—The fact that in young *Papilionaceæ* which contain large quantities of the decomposition products of albumin the increase of albumin is not accompanied by any decrease in the amount of asparagine present, is explained by supposing that the initial decomposition products of albumin are converted into glutamine and asparagine. In accordance with this theory, the young plants were found to contain more of the primary decomposition products of albumin than the older plants. Whilst asparagine is of use in the synthesis of albumin in the plant, the amino-acids have not proved to be good substitutes.

E. W. W.

Formation of Proteids in Plants. By ADOLF EMMERLING (*Landw. Versuchs-Stat.*, 1900, 54, 215—281. Compare Abstr., 1887, 615).—Further evidence is adduced in favour of the hypothesis that amino-acids in plants are produced from simple inorganic nitrogen compounds and organic matter already formed by assimilation. The process takes place mainly in the leaves. As time goes on and the amount of amino-acids is in excess of that required for leaf production, the acids are utilised in the development of seeds. The amount of amino-acids gradually decreases when the seeds ripen, not only in the seeds themselves, but in the leaves, &c.

Simultaneously with the production of amino-acids, other nitrogenous non-proteids are formed the nature of which is not known. These compounds are less prominent than the amino-acids in nearly all parts of the plant during the chief period of the synthetical formation of amino-acids and proteids. But as the seeds ripen, the "bases," as these compounds are provisionally termed, increase in quantity and finally predominate over the amino-acids both in the seeds and in the leaves, &c. It is probable that the "bases" are of physiological importance, but there is as yet no evidence to show in what manner.

N. H. J. M.

Conditions of the Production of Proteids Insoluble in Gastric Juice and their Importance for the Respiration of Plants. By WLADIMIR FALLADIN (*Bisd. Centr.*, 1900, 29, 478—481).—The proteids of the living substance of vegetable cells leave a nitro-

genous residue insoluble in gastric juice, whilst the "dead" proteids are dissolved.

Etiolated leaves of *Vicia faba* were kept for several days in 5 or 10 per cent. solutions of cane sugar, in darkness, in diffused daylight, and in yellow and blue light respectively. The amounts of dry matter, proteids, and indigestible proteids were determined as well as the amounts of carbon dioxide produced per hour.

The sugar was utilised much more readily in presence of light than in darkness, and the regeneration of proteids, which took place even in absence of light, was much more energetic in diffused light; blue light was more favourable than yellow. Undigestible proteids, which were present only in very small quantity in the etiolated leaves, were produced in the dark in presence of sugar, but the production was much greater under the influence of light.

The energy of respiration of leaves supplied with sugar was more than twice as great in presence of light than in darkness. It was greatest in white, and least in yellow light.

From the results of previous experiments (Abstr., 1898, ii, 248), it was concluded that the energy of respiration was directly proportional to the amount of "living proteid" at a given temperature and in presence of sufficient carbohydrate. It is now shown that there may be considerable variations.

N. H. J. M.

Germination of the Olive. By GIOVANNI SANI (*Atti Real. Accad. Lincei*, 1900, [v], 9, i, 47—51).—The constituents of olive seeds are as follows: Water, 9.82; fats, 42.00; reducing sugars after hydrolysis with 5 per cent. sulphuric acid, expressed in terms of glucose, 14.73; proteids (nitrogen \times 6.25), 17.02; ash, 2.87. After germinating for a week in the dark at 30°, the plantlets were dried at 110°, 10.63 per cent. of dry substance being obtained and analysed, the results being as follows: Fat, 6.23; reducing sugars present as such, in terms of dextrose, 4.60; further reducing sugars formed on hydrolysis, 26.34; pentosans, 9.51; nitrogen, 4.54. 1.3286 grams of the plants after treatment with water required 2 c.c. decinormal potassium hydroxide for neutralisation.

T. H. P.

Development and Injurious Effect of Mustard Oil from Rape-Cake. By B. SJOLLEMA (*Landw. Versuchs-Stat.*, 1900, 54, 311—318).—The introduction of an emulsion containing 0.2 gram of mustard oil into the stomach of a rabbit caused death. The same result was obtained by the simultaneous introduction of *Myronas Kalicus* (0.850 gram) and an extract of white mustard seed (6 grams). Both mustard seed and *Myronas Kalicus* were without effect when given alone. Mustard oil emulsion (0.2 gram), two days old, did not kill the rabbit, but otherwise produced the same symptoms. Another emulsion (0.3 gram), three weeks old, caused the death of the rabbit, but its action was slow.

The volatile oil, containing sulphur, which develops in rape seed by the action of an enzyme, is not identical with allylthiocarbimide and is much less poisonous. A rabbit which received 0.262 gram

of the oil showed no abnormal symptoms. The estimation of mustard oil in rape cake is, therefore, not to be depended on for ascertaining whether the cake is poisonous. The volatile oil obtained from rape boils at 173°, has an odour resembling that of mustard oil, but much less sharp, and floats on water. As regards the estimation of mustard oil, both the oxidation and Jørgensen's methods give somewhat low results.

Myrosin is rendered inactive by heating at 72°, but not at 65°. Neither pepsin alone nor pepsin and hydrochloric acid produce mustard oil from rape cake or *Myronas Kalicus*. Ptyalin acts with extreme slowness if at all. N. H. J. M.

Action of Calcium Hydroxide on Germination. By RICHARD WINDISCH (*Landw. Versuchs-Stat.*, 1900, 54, 283—309. Compare Sigmund, *Abstr.*, 1896, ii, 442).—Solutions, or emulsions, containing 0.066—3.9642 per cent. of calcium hydroxide had very little effect on the germination of barley, oats, and wheat; in the case of rye, the number of seeds which germinated was somewhat reduced by the weakest solution. In a second series of experiments, the effect of solutions or emulsions containing 0.1724 to 5 per cent. of calcium hydroxide on the germination of a variety of seeds was observed. The results showed that the solutions affect chiefly the energy of germination, but that the extent of the action has no relation to the concentration of the solutions. The more dilute solutions have relatively more effect than the more concentrated ones. Only the dissolved hydroxide can penetrate into the cells; on the other hand, the undissolved lime seems to have some mechanical action, since seeds sometimes failed to germinate in emulsions when a saturated solution had no effect. Ordinary lime water, diluted with 2—3 parts of distilled water, was in some cases beneficial, and in others injurious. Wheat was not injured by the greatest amount of lime; oats germinated better in presence of lime than in distilled water; the germination of maize was somewhat delayed by concentrated solutions, whilst oats were injured.

Cruciferous seeds were injured by dilute lime water, and leguminous seeds, which are the most sensitive in this respect, were killed by comparatively dilute solutions. N. H. J. M.

Finnish Moss-Berry (*Vaccinium oxycoccus*). By F. STOLLE (*Zeit. Ver. Deut. Zuck.-Ind.*, 1900, 609—610).—The moss-berry of Finland, which is an extremely valuable food-stuff, yields, on crushing, about 74 per cent. of its weight of juice having a sp. gr. 1.0373. After the addition of ammoniacal lead acetate and concentration of the filtrate, invert sugar separates out. From the lead precipitate glyoxylic acid has been isolated. T. H. P.

Composition of Fodders. By ADOLF EMMERLING (*Bied. Centr.*, 1900, 29, 454—457; from *Jahresber. agrik.-chem. Versuchs-Stat. Kiel*, 1898, 15).—The results of fifty complete analyses of fodders (residues from oil factories and distilleries, molasses, meadow and clover hay, and straw, &c.) are given in tables. Also the results of determinations of proteid, fat, and acidity in a number of oil-cakes. N. H. J. M.

Changes in Expressed Olives when Stored under Different Conditions. By OTTO KLEIN (*Zeit. angew. Chem.*, 1900, 635—637).—Analyses were made of compressed olives kept under the following conditions: (1), air dried; (2), compressed in a covered glass vessel; (3), not compressed, and moistened with the expressed fruit-water; and (4), compressed and moistened with the fruit-water.

The results showed that in practice it is best to dry the residues as quickly as possible, or else to compress them with, or without, addition of the fruit-water. The loss of fat then is only slight.

Expressed olives are not of much value either as food or as manure, and to increase their value it is of importance to return the fruit-water, which contains much of the proteids and ash constituents. In this way a product is obtained the composition of which more nearly approaches that of olives.

Analyses of olives, expressed olives, and of the fruit-water are given.

N. H. J. M.

Experiments on Feeding Cows with Mixed Grain and Maize. By F. FRIIS (*Bied. Centr.*, 1900, 29, 461—464; from *45-de Beretn. kgl. Vet. Landbohøjsk. Lab. landøk. Forsøg. Copenhagen*, 1899, 1—75).—The experiments were made at several farms with a large number of similar cows. Each group received cake, roots, hay, and straw, and in addition (A) mixed grain, (B) half mixed grain and half maize, and (C) maize.

Feeding with maize had no appreciable effect on the composition of the milk, but slightly increased the yield; there was also a slight increase in live weight. The butter from the cows fed with maize was of slightly better quality than when mixed grain was employed.

As regards the composition of the two foods the most important difference was in the amount of starch; the mixed grain contained 42.69, and the maize 56.74 per cent.

N. H. J. M.

Composition of the Alluvial Soil of Lodi. By FASCETTI and GHIGI (*Bied. Centr.*, 1900, 29, 421; from *Staz. sper. agrar. ital.*, 1899, 32, 131).—Analyses of the soil at different depths (0.5 m. to 3.1 m.) showed that it contained very little organic matter and nitrogen (N=0.079 to 0.019 per cent.), whilst the phosphoric acid, soluble in boiling hydrochloric acid, diminished from 0.194 at a depth of 0.5 m. to 0.125 per cent. in the lowest sample. The upper layers of the soil contained 0.61—0.70 per cent. of lime, and the lower layers 2.01 to 4.25 per cent. The amounts of potash dissolved by hydrochloric acid were 0.43—0.58 per cent. in the more sandy layers, whilst the layers with 10 or 11 per cent. of clay contained 0.70—0.84 per cent. of potash.

N. H. J. M.

Vegetation Experiments with Various Peat Soils. By HEINRICH IMMENDORFF and BRUNO TACKE (*Bied. Centr.*, 1900, 29, 443—446; from *Landw. Jahrb.*, 1898, 27, *Erg.-bd. IV.* 259—302).—The results of pot experiments with peat soil containing 2.52—3.39 per cent. of nitrogen showed that nitrogen manures were effective with oats, barley, and sugar-beet. The effect of nitrogenous manures is least in soils in which nitrification is most active, and this probably

depends to a great extent on the porosity of the soil, and the amount of water present. In the case of lighter soils, an excess of water is comparatively harmless, whilst dense soils are greatly injured. Light soils require, therefore, less drainage than dense soils.

The greatest yields of barley and oats were obtained when the soil was not quite saturated with water, but the greatest yield of nitrogen was observed under conditions of medium moisture. With oleaginous radish, the maximum yield was obtained under the same conditions; the maximum yield of nitrogen when the soil contained the greatest percentage of water. This is partly due to the greater evaporation from radishes.

Subsoil liming increased the yield of potatoes and oats by 16 and 18 per cent. respectively, whilst the yield of barley in field experiments was increased 70 per cent. (compare this vol., ii, 42). N. H. J. M.

Action of Animal Manure on Peat Soil. By PAUL HELLSTRÖM (*Bied. Centr.*, 1900, 29, 449—450; from *Tidskr. landtm.*, 1899, 20, 697—705).—Owing to the difficulties of obtaining lime and artificial manures in some parts of the north of Sweden, experiments were made to ascertain whether new peat land can be decomposed and thus rendered fertile by means of bacteria introduced along with farmyard manure, instead of by lime.

Peas were grown in zinc vessels and watered with extracts of horse-, sheep-, and cow-dung respectively. In each case, one pot had fresh and another sterilised extract. There were also two pots which had slaked lime, and two with soil alone.

All the extracts and the lime increased the yield of corn and straw; the fresh horse- and sheep-dung extracts were very much more effective than the same extracts sterilised. In the case of cow-dung extract, sterilisation had very little depressing effect. The results show, therefore, that horse- and sheep-dung are the best for peat land, not only as manures, but on account of the bacteria they contain. N. H. J. M.

Action of Burnt Lime and Marl on Sandy Soil. By BRUNO TACKÉ, HEINRICH IMMENDORFF, A. SALFELD, and FR. WOLFF (*Bied. Centr.*, 1900, 29, 448—449; from *Landw. Jahrb.*, 1898, *Erg.-bd. IV.*, 431).—When applied to the soil in the usual quantity, burnt lime does not injure the leguminous bacteria, but it acts with much greater vigour than marl on the nitrogenous constituents of the soil. In the case of poor sandy soil, marl is preferable to burnt lime.

The results of previous experiments in which lime seemed to act injuriously on the growth of the leguminous crop, whilst marl was not injurious, are now attributed partly to loss of soil nitrogen under the influence of lime, and partly to ineffective inoculation. The inoculation on the marled land was probably due to bacteria having been introduced along with the marl. N. H. J. M.

Top Dressing Experiments with Ammonium Sulphate and Sodium Nitrate. By KLÖPPER (*Bied. Centr.*, 1900, 29, 371—373; from Fühling's *Landw. Zeit.*, 1899, 114 and 138. Compare Abstr., 1899, ii, 512).—A reply to Wagner (Abstr., 1899, ii, 572) and Maercker (*Deut. landw. Presse*, 1898, No. 25 and 26).

The results of experiments with winter wheat, grown on heavy loam and on light sandy soils, in which the same amount of nitrogen was applied in the form of ammonium sulphate and as sodium nitrate, showed in each case a greater production of grain and straw under the influence of ammonium sulphate. The heavy soil contained 0.31 per cent. of lime and had previously been manured with dung, kainite and basic slag. The sandy soils contained 0.05 and 0.045 per cent. of lime.

In similar experiments with winter rye on loamy sand containing 0.62 per cent. of lime, sodium nitrate produced 17.5 kilos. more grain per hectare than ammonium sulphate, but 249 kilos. less straw. A second experiment with winter rye on soil containing 1.02 per cent. of lime showed that ammonium sulphate produced greater yields both of grain and straw (138 and 537 kilos.) than sodium nitrate.

Ammonium sulphate produced on the whole more grain than sodium nitrate, and the quality of the grain was better. N. H. J. M.

Sugar as an Aid to the Growth of Plants. By JOHN GOLDING (*J. Soc. Chem. Ind.*, 1900, 19, 324—325. Compare Abstr., 1899, ii, 689).—The results of sand-culture experiments with beans and lucerne showed that addition of sugar considerably increased the growth when the plants were inoculated. Sugar produced the same result with beans and sainfoin when the plants were manured with ammonium nitrate instead of being inoculated. Similar results were obtained in soil.

In absence of ammonium nitrate, or without inoculation, addition of sugar decreased the amount of produce, especially in the case of sainfoin and beans grown in sand.

Comparing the total yields of the different plants under the influence of inoculation and of combined nitrogen respectively, the results show in some cases inoculation, and in others nitrogenous manure to be the more effective.

Excess of sugar may kill the plants.

N. H. J. M.

Cultivation of Mulberry Trees. By V. ALPE (*Bied. Centr.*, 1900, 29, 422—423; from *Agric. Mod.*, 1899, 5, 121).—In the Italian method of cultivating mulberry trees the average quantity of wood and leaves removed yearly amounts to 20 and 25 kilos. respectively. The losses of manure constituents in the portions removed are as follows:—N, 510; P_2O_5 , 172; K_2O , 195, and CaO, 486 grams. The yearly application of 100 kilos. of farmyard manure to each tree supplies sufficient nitrogen and phosphoric acid, and an excess of potash. Artificial manures may be applied in the following amounts: Sodium nitrate, 3.5; 16 per cent. superphosphate, 1.1; and potassium chloride, 0.4 kilo. per tree per annum.

N. H. J. M.

Composition of the Gas Confined in Farmyard Manure. By PIERRE P. DEHÉRAIN and C. DUPONT (*Ann. Agron.*, 1900, 26, 273—294. Compare Abstr., 1884, 1412).—When farmyard manure is watered with liquid manure, carbon dioxide is rapidly produced even near the

surface, and if the damp condition of the manure is maintained there is practically no loss of ammonia.

Aërobic fermentation takes place at the surface when fresh litter is added to the heap; it is very active and causes the temperature to rise as high as 75°. When the manure contains less than 70 per cent. of moisture, aërobic fermentation extends, and oxygen is present in the lower portions of the heap. Decomposition of nitrogenous matter with elimination of free nitrogen may then take place. It is of importance for the manure to become consolidated either by being trampled on by cattle or by being watered with liquid manure.

Hydric fermentation occurs when air penetrates the manure with difficulty; nitrogen is sometimes liberated; carbon dioxide is often produced along with hydrogen, and this suggests that the liberation of hydrogen is accompanied by the production of acids, such as butyric and acetic, capable of decomposing carbonates. Hydrogen is only readily liberated when the manure is neutral or slightly acid, and is no longer produced when the manure is rendered alkaline by addition of liquid manure.

When manure is sufficiently consolidated to exclude air, carbon dioxide and methane alone are produced. Loss of nitrogen cannot take place, as even if nitrogenous matter is decomposed, ammonia alone will be produced and the great excess of carbon dioxide prevents the dissociation of the ammonium carbonate (compare Abstr., 1899, ii, 800).
N. H. J. M.

Phosphoric Acid in Presence of Saturated Solutions of Calcium Hydrogen Carbonate. By TH. SCHLOESING (*Compt. rend.*, 1900, 131, 211—215).—When a small quantity of phosphoric acid is added to a saturated solution of calcium carbonate in water containing carbon dioxide, there is no immediate precipitation, but if the carbon dioxide is expelled by means of a current of air, hydrated tricalcium phosphate is precipitated. Magnesium carbonate behaves in a similar manner.

If phosphoric acid is added in excess, the precipitate is a mixture of di- and tri-calcium phosphates, or consists of the crystallised dicalcium phosphate only, $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$, which is somewhat soluble in water containing carbon dioxide, provided that calcium carbonate is not also present.

The author concludes that superphosphates, when applied to soils, become converted into insoluble tricalcium phosphate mainly by the action of water containing calcium carbonate in solution, either with or without carbon dioxide. On the other hand, phosphates in solution in natural waters become precipitated in the form of tricalcium phosphate when they percolate through rocks and soils containing calcium carbonate, or when they come in contact with water containing calcium carbonate in solution.
C. H. B.

Solubility of the Phosphoric Acid of Basic Slag and Crude Phosphates in Peat Soils. Dependence of the Solubility on the Amount of Free Humic Acid in the Soil. By H. MINSEN and BRUNO TACKE (*Bied. Centr.*, 1900, 29, 447—448; from *Landw. Jahrb.*, 1898, *Erg.-bd.*, iv, 392).—The solubility of phosphoric acid

in peat soil depends on the amount of free humic acid present, and the application of lime in the usual amounts greatly diminishes the solubility of phosphoric acid, except in the case of basic slag.

The phosphoric acid of basic slag which is insoluble in citric acid is less soluble in peaty soil than that of crude phosphates, but seems to be more soluble in partially neutralised soil the more citrate-soluble the original slag.

Although the solubility of phosphates no doubt increases with increasing amounts of free humic acid in the soil, the numerical agreement is affected by the absorption by the soil of some of the phosphoric acid previously dissolved.

N. H. J. M.

Analytical Chemistry.

Examination of Sea Water by an Optical Method. By J. J. MANLEY (*Proc. Roy. Soc. Edin.*, 1900, 23, 35—43).—The relative densities and relative deviations of five samples of sea water of nearly equal total salinity have been determined. By relative deviation is meant the ratio S_D/W_D , where S_D and W_D are the minimum deviations of the D line by sea water and distilled water respectively, with a selected prism and at a standard temperature. The determination of relative deviations is recommended as a method of estimating the relative salinity of sea waters. The order of salinity of the five samples examined is the same whether the method of relative densities or relative deviations be employed; the latter method is at least as dependable, and much more rapid.

J. C. P.

Qualitative Analysis of the Ammonium Sulphide Group. By FERDINAND JEAN (*Chem. Centr.*, 1900, i, 1104; from *Ann. Chim. anal. appl.*, 1900, 5, 125—128).—The scheme is intended for solutions containing nickel, cobalt, iron, zinc, chromium, manganese, aluminium, and phosphates, borates, or silicofluorides of barium, strontium, calcium, and magnesium. After removal of any metals precipitable by hydrogen sulphide, the filtrate is evaporated to dryness in a platinum dish and the residue heated with strong sulphuric acid; the mixture is diluted with water, an equal volume of alcohol added, and the sulphates of the alkaline earths and any silica from silicofluorides are filtered off.

The filtrate freed from alcohol is mixed with 20—25 c.c. of concentrated ammonium citrate solution, ammonium chloride, and excess of ammonia, and strongly shaken. A precipitate indicates phosphoric acid and magnesia. If no precipitate is formed, a portion of the mixture is tested with sodium phosphate for magnesia, and another portion with magnesium chloride for phosphoric acid. If phosphoric acid is present, it is completely precipitated by further addition of magnesium chloride, the filtrate evaporated and the residue calcined.

in a platinum dish, dissolved in hydrochloric acid, and precipitated with ammonia and ammonium sulphide. This precipitate is treated with a mixture of 1 part of hydrochloric acid and 5 parts of water saturated with hydrogen sulphide which redissolves it with the exception of the sulphides of nickel and cobalt. The solution is heated with a little potassium chlorate and then boiled with excess of sodium hydroxide. Zinc is detected in the filtrate by means of hydrogen sulphide and aluminium by acidifying with hydrochloric acid and adding ammonia. A small portion of the precipitate caused by the sodium hydroxide is well washed and then tested for iron with potassium ferrocyanide. The other portion is boiled in a test-tube with nitric acid and lead dioxide; in the presence of manganese, it turns violet, and in the presence of chromium, yellow. In the first case, the filtered liquid is mixed with oxalic acid, which destroys the manganese colour and then shows any yellow colour due to chromium which may then be further tested with acetic acid and lead acetate; in the second case, the residue in the test-tube is washed a few times by decantation and boiled again with lead dioxide and nitric acid, when manganese will again give a violet colour.

The insoluble sulphates are repeatedly boiled with solution of sodium carbonate, and the residue is dissolved in hydrochloric acid. In one portion of the solution, barium is tested for by means of hydrofluosilicic acid; some alcohol is added and the filtrate examined for strontium by the flame-test. In another portion, any barium or strontium is precipitated with ammonium sulphate, and the filtrate is then tested for calcium with ammonium oxalate. L. DE K.

Standardising Normal Acids. By HERMANN THIELE and R. RICHTER (*Zeit. angew. Chem.*, 1900, 486—489).—The authors have noticed that when acids are standardised by means of Iceland spar, the results are slightly higher than when sodium carbonate is used. As the result of a lengthy investigation, using pure materials, they find themselves unable to account for this phenomenon. L. DE K.

Necessary Precautions in certain Acidimetric Estimations. By LOUIS MAGNIER DE LA SOURCE (*Chem. Centr.*, 1900, i, 1103—1104; from *Ann. Chim. anal. appl.*, 1900, 5, 121—125).—When titrating acids, using phenolphthalein as indicator, it is not a matter of indifference whether the operation is performed cold or hot, as the reaction is more sensitive in the cold. Moreover, some kinds of glass yield to hot water a distinct trace of alkali. When estimating sulphuric acid, it does not matter whether a strong or a more dilute solution is titrated, but when dealing with tartaric acid a strong solution should be used, otherwise the results will be too low. L. DE K.

Iodometric Experiments. By GUNNER JÖRGENSEN (*Zeit. anorg. Chem.*, 1900, 24, 183—187).—The reaction between potassium iodate, sodium thiosulphate, and hydrochloric acid takes place according to the equations: $\text{KIO}_3 + 6\text{HCl} + 6\text{Na}_2\text{S}_2\text{O}_3 = \text{KI} + 6\text{NaCl} + 3\text{Na}_2\text{S}_4\text{O}_6 + 3\text{H}_2\text{O}$ and $4\text{KIO}_3 + 3\text{Na}_2\text{S}_2\text{O}_3 + 3\text{H}_2\text{O} + \text{HCl} = 4\text{KI} + 6\text{NaHSO}_4 + \text{HCl}$. The ratio between the amounts of sulphuric acid and tetrathionic acid is dependent on the time allowed for the reaction. The results con-

firm the author's earlier work (Abstr., 1899, ii, 248), and are not dependent on the formation of iodine chloride as stated by Fessel (Abstr., 1899, ii, 802), since it is immaterial whether sulphuric acid or hydrochloric acid is employed.

E. C. R.

Improvement in Péligot's Absorption Apparatus for Ammonia Estimations. By F. PANNERTZ (*Zeit. anal. Chem.*, 1900, 39, 318—320).—The lower bulb of the Péligot U-tube is connected by a narrow tube inserted at the top of the bulb with the upper part of the first limb of the U-tube. By this means, all regurgitation of the absorbing liquid, occasioned by sudden condensation in the distilling flask, is prevented.

M. J. S.

Estimation of Sulphur Dioxide in Sulphites and Thio-sulphates. By MARTIN L. GRIFFIN (*J. Soc. Chem. Ind.*, 1900, 19, 321—323).—The author's experiments indicate that there is no need to strictly follow Bunsen's instructions regarding dilution when titrating sulphur dioxide with iodine, as it is oxidised equally satisfactorily in strong and weak solutions.

Sulphurous acid should be titrated in a closed bottle provided with a U-tube containing a little iodine solution and serving as a trap for any sulphur dioxide which may evaporate; there is but little fear of loss by oxidation. Some sulphites, notably the sodium salt, are so rapidly oxidised by atmospheric oxygen that they should be at once introduced into a vessel containing iodine solution without previous solution or dilution; the excess of iodine is then titrated with sodium thiosulphate.

L. DE K.

Detection of Nitrous Acid in Water. By H. MENNICKE (*Zeit. angew. Chem.*, 1900, 711—719).—The author has compared the relative sensitiveness of the reagents most frequently used for the detection and estimation of nitrous acid in water, namely, solutions of starch-potassium iodide or zinc iodide, the four modifications of Griess' reagent, Riegler's reagent, and Erdmann's reagent (this vol., ii, 243). The results are recorded in two tables, and the conclusion reached is that Erdmann's test is almost free from sources of error and the most delicate of those examined.

L. DE K.

Analysis of Nitric Acid and Mixed Acid [Nitric and Sulphuric]. By ARTHUR P. VAN GELDER (*J. Soc. Chem. Ind.*, 1900, 19, 508—509).—*Analysis of Nitric Acid.*—About 10 grams of the acid are weighed out in a bottle, which is then opened in a funnel under water, and the solution diluted to 1 litre. 100 c.c. of the solution are titrated with $N/3$ alkali, and the total acidity is calculated as nitric acid. To estimate the amount of the lower oxides, 10 c.c. of the original acid are diluted to 100 c.c., and titrated with $N/10$ permanganate.

Analysis of Mixed Acid.—In this case 100 c.c. of the solution are evaporated on a water-bath with the aid of a slight blast of air until the nitric acid has been driven off. A little boiling water is added, and the evaporation continued for 10 minutes; this is repeated three times so as to break up any combined nitrogen oxides. The residual liquid is then titrated, and the difference between the two titrations

represents the total nitric acid. The lower oxides are estimated as before, although the estimation may be interfered with by the presence of arsenic.

To obtain the original hydrogen nitrate in nitric and mixed acid, the amount of nitric acid corresponding with the nitrous acid found by titration with permanganate should be deducted from the total amount; to obtain the available nitric acid, only half the amount of nitrous acid should be allowed for.

L. DE K.

Elimination of Arsenic from the System from a Toxicological Standpoint. By D. SCHERBATSCHOFF (*Chem. Centr.*, 1900, i, 1040; from *Viertelj.-Schr. gerichtl. Med. u. Oeff. Sanitätsno.*, 1900, [iii], 19, 232—262).—Experiments with a rabbit and a dog showed that the arsenic was more rapidly eliminated from the system of the former than of the latter, hence no conclusion should be drawn as to what would happen in animals of a different species or in human beings.

The arsenic was tested for as follows: 20—30 grams of the substance were heated in a Kjeldahl flask with 20—30 c.c. of pure sulphuric acid and a little copper oxide, the solution was diluted with water, boiled to expel any sulphur dioxide (finally with addition of potassium permanganate), and then tested in Marsh's apparatus. When the substance contains much chlorides, some of the arsenic may volatilise; this may be prevented by moistening the mass first with ammonium sulphide, and then heating with a mixture of nitric and sulphuric acids.

L. DE K.

The Carbon Dioxide of the Atmosphere. By EDMUND A. LETTS and ROBERT F. BLAKE (*Sci. Proc. Roy. Dubl. Soc.*, 1900, N. S. 9, ii, 107—270).—In Pettenkofer's method for the estimation of carbon dioxide in the atmosphere, an important source of error is introduced by the employment of barium hydroxide, which, when kept in glass vessels, rapidly causes a superficial corrosion, and then becomes contaminated with alkalis and silica from the glass. The presence of the former causes an increase in alkalinity, and the latter interferes with the proper end reaction when titrating the excess of barium hydroxide, using phenolphthalein as indicator. Another source of error is the difficulty of preparing distilled water free from carbon dioxide, as the distillate from water rendered alkaline with sodium hydroxide rapidly absorbs it from the air. The chief source of error, however, leading to results about 30 per cent. too high, is caused by the absorption of carbon dioxide from the atmosphere and breath during the transfer of the absorbent from the receiver, and its subsequent titration in open vessels. The authors have succeeded in avoiding these sources of error by using the following process.

The standard barium hydroxide solution is preserved in a reservoir attached in the usual way to a bulb-shaped pipette delivering exactly 50 c.c., and provided with a stopcock. The reservoir is, as usual, provided with a soda-lime tube, which is closed when the apparatus is not being used. To prevent any action of the baryta on the glass, the inside of the reservoir, and also the lower part of the glass siphon tube, is coated with paraffin wax. The air to be examined is collected in a narrow-necked, tall jar holding about 6 litres, and also

coated inside with paraffin wax. Through the indiarubber cork pass two glass tubes, one of which is bent at a right angle, and both can be closed when required by plugs consisting of short glass rods attached to pieces of indiarubber tubing. The jar is filled by connecting it with an exhausting syringe attached to an indiarubber tube 12 feet long, so that there is no danger of the collecting area being contaminated by the breath of the operator. A pump is used which removes about 200 c.c. at each stroke, so when 100 strokes have been given, the air originally present in the bottle will have been completely displaced by the air to be tested. The plug of the straight tube is now temporarily replaced by a soda-lime tube, the rubber junction being pinched between the finger and thumb during the operation to prevent access of air. After removing the other plug with the same precaution, the rubber is connected with the pipette, and 50 c.c. of the baryta solution are introduced. After replacing the plugs with the same precautions, the receiving jar is placed on its side for some hours, and frequently rolled about so as to ensure complete absorption of the carbon dioxide.

The receiver is now inverted and clamped to a retort stand, a soda-lime tube attached to the straight tube, and the bent tube connected, with the usual precautions, to the titrating vessel. This consists of a ball-shaped, narrow-necked glass flask, furnished with a two-way stopcock, which communicates with a straight tube, and also with a bent tube, which may be connected with an air-pump. After exhausting the flask, it is connected with the receiving vessel, the stopcock is turned, and the liquid runs into the flask. The last traces of the liquid are removed as follows. The titrating vessel is first removed, and a glass-rod plug substituted for it. The receiver is unclamped and placed upright, and the nozzle of a measuring pipette filled with water containing a little phenolphthalein and carefully neutralised with barium hydroxide is now inserted instead of the plug. On opening the stopcock attached to the pipette, the water runs into the receiver, which, after being well rinsed, is again placed in the former position and connected with the titrating flask; the rinsings are then added in the way described.

The titrating flask is now connected with a delicate burette containing a solution of pure oxalic acid of such a strength that 1 c.c. represents 0.1 c.c. of carbon dioxide at N.T.P. The barium hydroxide solution, which should be titrated about the same time, should, if possible, correspond exactly in strength with the acid.

The test-analyses made with pure air mixed with definite volumes of carbon dioxide are very satisfactory.

The paper contains a summary and bibliography of previous work on the subject.

L. DE K.

Liquid Carbon Dioxide. By G. HOLSTE (*Zeit. anal. Chem.*, 1900, 39, 243—245; from *Zeit. gesamt. Kohlensäure Ind.*, 3, 461).—The principal gaseous impurities in commercial liquid carbon dioxide are nitrogen and oxygen, which remain gaseous in the storage cylinder. A sample of the gas taken when the cylinder is placed with the valve uppermost will therefore have a different composition from

one taken when the cylinder is inverted or laid horizontally. Both should be analysed. A convenient eudiometer for the purpose is described, and a method for calculating the average composition of the contents of the cylinder is given.

M. J. S.

Preparation of Sodium Cobalt Nitrite, and its Employment for the Detection of Potassium. By EINAR BILLMANN (*Zeit. anal. Chem.*, 1900, 39, 284—289. Compare Adie and Wood, *Trans.*, 1900, 1076).—For the detection of potassium in presence of much sodium, a solution of pure sodium cobalt nitrite is more sensitive than the spectroscope itself. To prepare the reagent, 150 grams of sodium nitrite are dissolved in 150 c.c. of warm water, and the solution cooled to 40—50°; 50 grams of crystallised cobalt nitrate are added, and then gradually 50 c.c. of 50 per cent. acetic acid, the mixture being vigorously shaken. A brisk current of air is then passed through the mixture for half-an-hour. The mixture is allowed to subside during two hours, and then filtered. The clear filtrate and washings, amounting in all to 300 c.c., are precipitated by the gradual addition of 250 c.c. of 96 per cent. alcohol. The salt is collected on a suction filter, washed four times with 25 c.c. of alcohol, twice with 25 c.c. of ether, and air-dried. For use, 0.3—0.5 gram is dissolved in 2—3 c.c. of water, and added cold to the solution to be tested. This solution must contain only potassium and sodium as chlorides, nitrates or sulphates, and must be free from phosphates, mineral acids, or caustic alkalis. Small amounts of acetic acid, alkali carbonates, magnesium, and calcium salts do not greatly impair the sensitiveness. It is possible with this reagent to detect 0.0009 milligram of potassium in presence of 2363 parts of sodium. The reagent is not permanent when dissolved; the solution must be prepared when required.

M. J. S.

The Estimation of Zinc as Phosphate. By H. D. DAKIN (*Zeit. anal. Chem.*, 1900, 39, 273—284).—Guyard ["Hugo Tamm"], who first proposed the estimation of zinc as zinc ammonium phosphate (*Abstr.*, 1871, 1214), admitted the existence of several sources of error, and did not furnish proof analyses of pure substances. Austin, who supplied this deficiency (this vol., ii, 49), assumed that the presence of at least 10 per cent. of ammonium chloride in the solution was essential. The author, starting with zinc oxide purified with great care, shows by numerous proof analyses that accurate results can be obtained without the use of large quantities of ammonium chloride. The use of ammonium phosphate, instead of sodium phosphate, avoids the error caused by the presence of sodium in the precipitate. Traces of zinc can generally be detected in the filtrate by ammonium sulphide, but never more than 2—3 decimilligrams. The precipitate, dried for 2 hours at 100—105°, has the composition ZnNH_4PO_4 ; it suffers no loss by prolonged drying at this temperature, and can be accurately converted into zinc pyrophosphate by gradual heating in an open crucible. If rapidly exposed to a red heat, reduction takes place. The following method of precipitation is recommended. The acid zinc solution, in a platinum basin, is nearly neutralised with ammonia, diluted to 150 c.c., and heated on the water-bath. About 10 parts of ammonium

phosphate for each part of zinc supposed to be present are added, and the heating is continued for a quarter of an hour. After a little further delay ($\frac{1}{2}$ —24 hours) the precipitate is collected on an asbestos filter in a Gooch crucible, washed thoroughly with a hot 1 per cent. solution of ammonium phosphate, and the latter removed by several washings with aqueous alcohol. It is then dried and weighed, or, if ignition is preferred, the Gooch crucible is placed inside a platinum crucible. The precipitate is then removed from the filter by dilute nitric acid, and the crucible dried (or ignited) as before. This mode of obtaining the tare is preferable to weighing the crucible before filtration, as the phosphate solution slightly attacks the asbestos. The results were as accurate when only 1 gram of ammonium chloride was present, as with 10 or 20 grams. A large amount hastens the crystallisation of the precipitate, but introduces inconvenience in the washing.

M. J. S.

Detection of Sodium in the Presence of Potassium. By N. SCHOORL (*Chem. Centr.*, 1900, i, 1140; from *Ned. Tijdschr. Pharm.*, 1900, 12, 116—118).—The microchemical test for sodium by means of uranyl acetate is interfered with by the presence of much potassium. The author now proposes to evaporate a few times with perchloric acid, and then to extract with alcohol. Potassium perchlorate remains undissolved, and the filtrate contains the sodium which may then be tested for by the uranium method.

L. DE K.

Colour Reactions for Detecting Calcium Salts in Organic Tissues. By VALENTINO GRANDIS and C. MAININI (*Atti Real. Accad. Lincei*, 1900, [v], 9, i, 280—283).—The piece of tissue or section is placed in a saturated alcoholic solution of purpurin and left until it is strongly coloured, the time required being from 5 to 10 minutes. When removed from the solution, it is not uniformly coloured, but exhibits dark patches which are hard. These dark patches, due to the deposition of the colour on salts of calcium, usually the carbonate and phosphate, may be made clearer by immersion for a few moments in a 0.75 per cent. solution of sodium chloride, which causes the formation of a small quantity of calcium chloride and consequent precipitation of the purpurin in an insoluble form in those positions where calcium salts are present. The coloured tissue is then soaked several times in 70 per cent. alcohol until no more colour is removed.

The presence of calcium salts can also be localised by treating the well-washed tissue with pyrogallol, which is fixed specially on those parts where calcium salts are situated. After remaining in contact with the air for some time to allow the pyrogallol to oxidise, the tissue is washed quickly in water, dried, and preserved in balsam. The presence of calcium salts is denoted by dark brown patches, the remainder of the tissue having only a pale, brownish-yellow colour.

T. H. P.

Detection of Barium, Calcium, and Strontium, and the Action of Ammonium Chloride on Strontium Chromate. By ERNEST DUMESNIL (*Ann. Chim. Phys.*, 1900, [vii], 20, 125—135; *Zeit. Ver. Deut. Zuck.-Ind.*, 1900, 531—537).—The ordinary methods

for detecting the presence of barium, calcium, and strontium in mixtures of salts fail when the proportion of strontium is small. To obviate this difficulty, the following method is proposed. The precipitate, consisting of the mixed carbonates, is dissolved in the least possible quantity of 10 per cent. hydrochloric acid, the solution evaporated to dryness to expel excess of acid, and the residue dissolved in water. To a small portion of the solution, strontium chromate solution is added; the formation of a precipitate indicates the presence of barium. If no precipitate forms, another portion of the neutral liquid is mixed with calcium chromate solution, the formation of a precipitate on warming showing the presence of strontium. If baryta is present, however, the remainder of the neutral chloride solution is precipitated by means of potassium chromate, the liquid being then heated to boiling and filtered; the precipitate is then boiled for a few moments with ammonium chloride solution and filtered. To the clear filtrate sodium carbonate is added, the liquid filtered, the precipitate washed once on the filter, and then treated with 10 per cent. acetic acid. Part of the liquid thus obtained is neutralised with ammonia and then warmed with calcium chromate solution; the formation of a precipitate shows the presence of strontium. Another part of the acetic acid solution is heated with an acetic acid solution of strontium oxalate, by which means any calcium is precipitated.

Ammonium chloride solution dissolves strontium chromate, and the solution deposits orange-yellow, tabular crystals having a composition corresponding with the formula $2(\text{NH}_4)_2\text{Cr}_2\text{O}_7\cdot\text{NH}_4\text{Cl}$. T. H. P.

Action of Carbon Dioxide on the Borates of Barium. By HARMON N. MORSE and D. W. HORN (*Amer. Chem. J.*, 1900, **24**, 105—137).—Jones' adverse criticism (*Abstr.*, 1898, ii, 640) of Morse and Burton's method (*Abstr.*, 1888, 755) of estimating boric acid is valueless, since it is based on experiments made with aqueous, instead of strongly alcoholic, solutions; trustworthy results can be obtained by adhering to the original directions. Contrary to Jones' statement, boric acid is not lost by volatilisation as ethyl borate, when, following the method, the alcoholic liquid containing the insoluble metaborate and excess of barium hydroxide is treated with an excess of carbon dioxide, and then distilled in an atmosphere of the gas; under Jones' conditions, using aqueous solutions, there is also no loss.

In order to obtain satisfactory results with the method, care has to be exercised in heating the mixture of barium borate and carbonate, as, when dried at 100° , it contains no small quantity of water; on drying for about 50 hours at 175° , or, more rapidly, at just below a red heat, it is rendered anhydrous; but on exposure to the air it rapidly absorbs water. At a full red heat the metaborate attacks the carbonate with evolution of carbon dioxide; if from this cause the weight of the mixture is too small, the necessary correction can be made by absorption of carbon dioxide from the air and subsequent drying in a desiccator, or at 500° . When once completely dehydrated, the mixture is comparatively indifferent to atmospheric moisture.

W. A. D.

Cement Testing. By O. H. KLEIN and STEPHEN F. PECKHAM (*J. Soc. Chem. Ind.*, 1900, 19, 644—645).—The authors recommend that the sample should be analysed in the same condition as received, and not dried beforehand, either at a low or high temperature; also that any insoluble matter not volatilised by treatment with hydrofluoric acid should not be called silica, although a small amount may be disregarded (compare Shimer, *Abstr.*, 1899, ii, 520).

L. DE K.

Diphenylcarbazide as a Sensitive Reagent for Metals. By PAUL CAZENEUVE (*Compt. rend.*, 1900, 131, 346—347).—The coloured products formed when diphenylcarbazide is oxidised by metallic salts (this vol., i, 465) furnish very sensitive reactions for the detection of metals, and especially of copper, mercury, and iron. A cold saturated solution of the carbazide in benzene is agitated with the aqueous solution of the salt, or, if the latter solution is not too dilute, an alcoholic solution of the carbazide may be used. Cupric salts yield a violet compound, which dissolves in benzene, and is not affected by agitation with potassium ferrocyanide solution; mercuric salts give a dull blue compound; ferric salts form a peach-flower coloration, which becomes brown if the liquid is agitated with potassium ferrocyanide solution. The reaction will detect 1 part of the metals in 100,000 of solution, and is not given by other metals. The colorations are destroyed by inorganic acids, and by excess of organic acids. Solutions of silver and gold salts yield rose colorations with precipitation of the metal.

If a solution of chromic acid, or a chromate containing 1 part in 1,000,000, or even less, is acidified with dilute hydrochloric acid and mixed with an excess of solid diphenylcarbazide, a splendid violet coloration is developed, stable in presence of inorganic acids, and quite distinct from the reactions already described. No other metal behaves in the same way. The coloured product is not removed from water by benzene, but dissolves in amyl alcohol.

O. H. B.

Action of Sodium Thiosulphate on Mercuric Salts. By FR. FAKTOR (*Chem. Centr.*, 1900, i, 1246; from *Pharm. Post*, 1900, 33, 253—254).—Aqueous solutions of mercuric salts are precipitated at the boiling point by sodium thiosulphate, with formation of mercuric sulphide. One mol. of sodium thiosulphate corresponds with 1 mol. of mercuric chloride. The process may also be applied to mercurous salts.

L. DE K.

Effect of Oxidising Agents on the Reduction of Mercuric Chloride by Oxalic Acid. By J. H. KASTLE and W. A. BEATTY (*Amer. Chem. J.*, 1900, 24, 182—188).—The reduction, in direct sunlight, of mercuric chloride by ammonium oxalate in aqueous solution is greatly accelerated by the presence of a trace of potassium permanganate. Ferric chloride and most other oxidising agents also accelerate the action, but a few, such as chromic acid and potassium chromate or dichromate, retard it. The same substances have a similar accelerating action on the reduction of thallic chloride by ammonium oxalate. The explanation given is that probably the oxidising substance used is reduced by the ammonium oxalate, and

then oxidised again by the mercuric or thallic chloride, thus acting as a "carrier" of oxygen from the oxalate to the chloride.

W. A. D.

Volumetric Estimation of Mercuric Chloride. By ERWIN RUPF (*Arch. Pharm.*, 1900, 238, 298—301).—Twenty c.c. of a solution of mercuric chloride containing about 4 grams per 100 c.c. are shaken for an hour with a little pulverised iron. The liquid is filtered and 10 c.c. are titrated with standard potassium permanganate after adding 5 c.c. of dilute sulphuric acid and 5 c.c. of a 10 per cent. solution of manganous sulphate. One mol. of ferrous chloride represents 1 mol. of mercuric chloride.

If the substance to be tested contains besides mercuric chloride any oxidisable matters or coal-tar colouring matters, potassium permanganate is added in slight excess, and this in turn destroyed by cautious addition of tartaric acid. The resulting ferric chloride is then estimated in the usual way by means of potassium iodide and sodium thiosulphate.

L. DE K.

Composition and Estimation of Cerium Oxalate. By FREDERICK B. POWER and FRANK SHEDDEN (*J. Soc. Chem. Ind.*, 1900, 19, 636—642).—Cerium oxalate has the composition $\text{Ce}_2(\text{C}_2\text{O}_4)_3 \cdot 10\text{H}_2\text{O}$. Commercial cerium oxalate is frequently contaminated with the oxalates of lanthanum and didymium. The former may be recognised by the reddish-brown colour, and the latter by the alkaline reaction of the ash, provided that no other alkaline matters are present. On the other hand, traces of cerium may be detected in the presence of lanthanum and didymium oxalates by heating 0.1 gram of the mixture with 0.5 c.c. of sulphuric acid until all effervescence ceases. The solution is then diluted with 10 c.c. of water, and after adding 1 gram of ammonium persulphate, it is again boiled, a bright yellow colour being developed if cerium is present even in traces (compare von Knorre, *Abstr.*, 1898, ii, 311).

L. DE K.

Colorimetric Estimation of Nickel in Steel. By RUDOLF FIEBER (*Chem. Zeit.*, 1900, 24, 393—394).—A series of standard samples of nickel steel in which the nickel varies from 1 per cent. upwards with a difference of about 1 per cent. between each sample are selected, and of each a solution is made as follows: 6 grams are dissolved in nitric acid, the solution is evaporated to the smallest possible volume, and rinsed into a 200 c.c. flask. The iron is then precipitated with ammonia, and when cold, the liquid is diluted to the mark; after thoroughly shaking, it is filtered and kept in a 200 c.c. flask for future use. Six grams of the sample to be examined are now treated in the same way, and the resulting filtrate is compared as regards its colour with the stock solutions. Should it not correspond with any of these, the one lighter in colour is selected as standard, and the sample is diluted with water until it shows the same colour. The percentage of nickel is then found by a simple calculation. The results are sufficiently accurate for technical purposes. The presence of chromium somewhat interferes with the test.

L. DE K.

Analysis of Titaniferous Iron Ores. By CHARLES BASKERVILLE (*J. Soc. Chem. Ind.*, 1900, 19, 419—420).—Silica is estimated in the usual manner after fusing 1 gram of the ore with 5 grams of sodium carbonate and 1 gram of potassium nitrate. After weighing the crude silica, it is heated with hydrofluoric and sulphuric acids and then reignited; the loss in weight represents pure silica.

Sulphur and phosphorus are estimated by fusing 2 grams of the ore with 20 grams of the above fusion mixture, using 'gasolene' as a source of heat. The fused mass is then extracted with water, and to the filtrate are added 25 c.c. of ferric chloride containing 0.1 gram of metallic iron. Slight excess of hydrochloric acid is added, the liquid boiled, reprecipitated with ammonia, and the sulphuric acid estimated in the filtrate. The phosphoric acid is contained in the iron precipitate, and may be estimated by the molybdate process (Abstr., 1894, ii, 253).

Titanium is estimated by fusing 0.5 gram of the ore with 0.5 gram of sodium fluoride and 5 grams of potassium hydrogen sulphate for 15 minutes. The fused mass is dissolved in boiling water containing 3 c.c. of nitric acid, ammonia is added, and the excess expelled by boiling. The well-washed precipitate is dissolved in dilute hydrochloric acid, and dilute ammonia is added until a slight permanent precipitate is obtained, which is then redissolved in a drop or two of dilute hydrochloric acid (1:100). The titanium is now precipitated as usual by saturating the liquid with sulphur dioxide and boiling for a few minutes; it is then collected, ignited, and weighed as dioxide. When many assays have to be made, Weller's colorimetric process (Abstr., 1883, 381) is preferable. 0.5 gram of the ore is fused with sodium fluoride and potassium hydrogen sulphate as directed, care being taken to completely expel the fluorine; the fused mass is dissolved in water containing 10 per cent. of sulphuric acid, and finally made up to 500 c.c. One hundred c.c. of the filtrate are then mixed with 5 c.c. of hydrogen peroxide, and the colour thus produced is compared with that of a series of ferruginous solutions to which a varying amount of titanium and 5 c.c. of hydrogen peroxide have been added.

Iron is estimated by the dichromate method in the filtrate from the silica.

L. DE K.

Estimation of Benzene and Ethylene in Coal-gas. By FRITZ HABER (*Chem. Centr.*, 1900, 1, 1309—1310; from *Journ. f. Gasbel.*, 43, 347—350).—The author has made further experiments with the process recommended by himself and Oechelhäuser (Abstr., 1897, ii, 128) and has found it to be trustworthy.

L. DE K.

Estimation of Reducing Sugar by Means of a Centrifuge. By PH. CHAPPELLE (*Chem. Centr.*, 1900, i, 1108; from *Ann. Chim. anal. appl.*, 1900 5, 140—145. Compare this vol., ii, 112).—In the presence of several reducing sugars, the total cuprous oxide obtained is not the theoretical quantity. The cuprous oxide corresponding with a single sugar is determined by means of a factor K = cuprous oxide/sugar, which depends on the nature of the sugar and the amount of precipitated cuprous oxide. A table is given for the value

of *K* for 20 to 250 milligrams of cuprous oxide, and for dextrose, invert sugar, and lactose. An example is given showing the estimation of two of these sugars in the presence of each other; the author has not yet succeeded with a mixture containing the three.

The method is also applicable when using Sachsse's alkaline mercuric iodide solution; the mercury should be dried below 150°. The author has somewhat altered the composition of this solution, and prepares it by dissolving 22.7 grams of mercuric iodide, 40 grams of potassium iodide, and 100 grams of sodium hydroxide in water and diluting to 1 litre, and its value for dextrose and invert sugar is given; the solution is, however, sensibly affected by sucrose. L. DE K.

Estimation of Cellulose. By CONSTANTIN COUNCLER (*Chem. Zeit.*, 1900, 24, 368—369).—A criticism of the methods for the estimation of cellulose proposed by Lange, Müller, and Schulze-Henneberg. The results obtained by the first process are far too low. The others give better results, but are so difficult of execution that they are of no practical use. The author's attempt at modifying Müller's process by subjecting the wood to a preliminary treatment with calcium hydrogen sulphite ended in failure. A good and practical process is much to be desired. L. DE K.

Estimation of Cell-wall Constituents, Hemicelluloses, and Cellulose in some Plants and Parts of Plants. By ALBERT KLEIBER (*Landw. Versuchs-Stat.*, 1900, 54, 161—213).—The methods of Lange, Hoffmeister, and F. Schulze for determining cellulose gave unsatisfactory results. Concordant, if not quite satisfactory, results were obtained by boiling the cellulose, obtained by Hoffmeister's or Schulze's method, for 2 hours with 1.25 per cent. sulphuric acid. In the case of Hoffmeister's method, the same results are usually obtained whether boiling with sulphuric acid precedes or follows treatment with chlorate.

Methods for determining the cell-wall constituents are described, in which the substance was extracted with 0.15 and 0.42 per cent. aqueous potassium hydroxide. It is thought that in some cases the results obtained are too high, owing to the presence of insoluble non-nitrogenous substances which do not belong to the cell-wall; on the other hand, the cell-wall itself may be attacked. The results were always higher than obtained with the crude fibre; the crude fibre does not, therefore, include the whole of the cell-wall.

Hemicelluloses are determined by boiling the residues obtained in the estimation of cell-wall constituents with 1.25 per cent. sulphuric acid. The proteids and ash are again determined in the residue. By deducting the non-nitrogenous matter in the residue from the amount of non-nitrogenous matter present before boiling with acid, numbers are obtained representing the amount of non-nitrogenous matter dissolved. The method is, for different reasons, imperfect, but it furnishes useful results. N. H. J. M.

Simple Distinction between Glue and Dextrin or Gum Arabic. By HUGO BORNTRÄGER (*Chem. Centr.*, 1900, i, 1109; from *Oesterr. Chem. Zeit.*, 1900, 3, 188—189).—The suspected product is

heated with 50 per cent. hydrofluoric acid. Glue emits at once an odour of butyric acid. On evaporating on the water-bath, a white mass is obtained which gives the usual alkaloidal reactions with phosphotungstic acid, Nessler's test, and other reagents, but has not been fully investigated by the author. L. DE K.

Estimation of Carvone in Volatile Oils. IV. By F. W. ALDEN and F. G. EHLERT (*Pharm. Archives*, 1900, 3, 9—18).—Further investigation has been made of the influence exerted by the conditions of experiment on the error of the method previously described (this vol., ii, 117). When much resin is present in the oil, the carvoxime will not crystallise, and it is necessary to distil the oil with steam and perform the estimation with the oil that distils over. When there is resin present, but not enough to prevent crystallisation, the crystals are contaminated with it, and in consequence the result is considerably too high. Better crystals are obtained if the sodium hydrogen carbonate is used in amount exactly equivalent to the hydroxylamine hydrochloride, instead of in excess, and also if a large excess of hydroxylamine is avoided. C. F. B.

Oxidation [of Oxalic Acid by Potassium Permanganate]. By GEORG VON GEORGIEVICS and L. SPRINGER (*Monatsh.*, 1900, 21, 413—421).—When an oxalic acid solution is titrated with a solution of potassium permanganate in presence of sulphuric acid, it is always observed that the beginning of the reaction is very slow, but afterwards the permanganate is instantly decolorised. The following explanation of this is suggested. The first few drops of the permanganate solution are slowly reduced to manganese sulphate; this at once reacts with an excess of permanganic acid, forming manganese dioxide, which is instantly reduced by oxalic acid. R. H. P.

Mercurisalicyclic Acid and Millon's Reaction. By CARL J. LINTNER (*Zeit. angew. Chem.*, 1900, 707—711).—When mercuric salicylate is heated for some time at 110° or boiled with water, it is decomposed into salicylic acid, which either volatilises or dissolves, and a compound formerly regarded by Lajoux and Grandval (*Abstr.*, 1893, i, 642) as a basic salicylate, but now described as mercurisalicyclic acid, $(C_7H_5O_2)_2Hg = C_7H_5O_8 + C_7H_4HgO_3$. The latter is monobasic, dissolves without separation of mercury in aqueous sodium hydroxide or ammonium sulphide, and when boiled with water and sufficient sulphuric, hydrochloric, or nitric acid to obtain a clear liquid, gives, with sodium nitrite, a yellow colour which changes to red on adding mercuric nitrate solution. When testing for salicylic acid with Millon's reagent, mercurisalicyclic acid is probably formed on boiling with mercuric nitrate, and this, in contact with nitrous acid, gives a nitroso-compound soluble with a red colour in excess of mercuric nitrate.

The action of Millon's reagent is solely due to mercuric nitrate and nitric and nitrous acids; mercurous nitrate is inert. The best way of detecting salicylic acid by its aid is as follows: The solution is boiled with a few drops of a 10 per cent. solution of acid mercuric nitrate for 2 minutes, 2—3 drops of dilute sulphuric acid

are added, and then a few drops of a solution of sodium nitrite. The red colour shows immediately. Proteids may be similarly tested for.

L. DE K.

Commercially Pure Oleic Acid and Purified Oleic Acid. By HUGO DITZ (*Chem. Zeit.*, 1900, 24, 462—464).—Many samples of oleic acid contain a small percentage of an oily, slightly volatile, and unsaponifiable substance, varying in composition, and absorbing a considerable amount of iodine; the presence of this substance causes the turbidity noticed when titrating the sample in the usual way with alkali. From the author's investigation, it is probably an impurity introduced during the process of manufacture, and not gradually formed during the storage of the acid.

L. DE K.

Estimation of Tannic and Gallic Acids. By FERDINAND JEAN (*Chem. Centr.*, 1900, i, 1107—1108; from *Ann. Chim. anal. appl.*, 1900, 5, 134—140).—2·7 grams of iodine and 5—6 grams of potassium iodide are dissolved in water to a litre and the solution is standardised, first with a 0·1 per cent. solution of tannin, and then also with gallic acid. Ten c.c. of either solution are mixed with 5 c.c. of a cold saturated solution of sodium hydrogen carbonate contained in a beaker having a 50 c.c. mark. The iodine is slowly run in until a drop of the liquid strikes a blue colour on paper impregnated with dry starch; the liquid is now diluted to 50 c.c., and more iodine added until a blue spot is again formed. The solution of the iodine is of the requisite strength when 10 c.c. of the tannin requires 10—10·5, and 10 c.c. of the gallic acid 13 c.c. of iodine. A blank experiment showing the effect of the dilute alkali should also be made; this will generally amount to 0·4 c.c.

The decoction to be tested should contain about 0·1 per cent. of tannin, and 10 c.c. are titrated as described. Another portion is then treated as follows: Fifty c.c. are mixed in a 100 c.c. flask with 15 c.c. of a solution of albumin (2 grams of albumin rubbed to a thick paste with strong glycerol, and afterwards diluted with water to a litre), 20 grams of sodium chloride, and water added up to the mark. Twenty c.c. of the filtrate are then freed from albumin by adding a drop of acetic acid and boiling; the filtrate is titrated as before, allowance being made for the influence exercised by the salt and albumin as found by another blank experiment. The difference between the two titrations represents the tannin, whilst the second titration represents the gallic acid.

Tanning materials containing soluble starch are exhausted with alcohol. Sulphites may be allowed for by titrating with iodine in an acid solution.

L. DE K.

Rapid Estimation of the Iodine Number of Fats. By J. BELLIER (*Chem. Centr.*, 1900, i, 1109; from *Ann. Chim. anal. appl.*, 1900, 5, 128—131).—When dealing with fats having a somewhat varying iodine number and where consequently no need exists for an accurate estimation, the author uses the following process:

One gram of the fat is dissolved in 20 c.c. of a mixture of equal vols. of glacial acetic acid and chloroform previously saturated with mercuric chloride. After adding 10 c.c. of a 10 per cent. solution of potassium

iodide (1 dissolved in acetic acid) the mixture is titrated with the iodine solution until it is permanently coloured for 5 minutes. This iodine solution is prepared as follows: 50 grams of iodine and 10.2 c.c. of bromine or 33.5 grams of iodine and 13.5 c.c. of bromine are dissolved in 950 c.c. of glacial acetic acid and the liquid is saturated with mercuric chloride. After a few days, 5 c.c. of either of the solutions (the second one acts the quicker, but gives off fumes) is titrated with sodium thiosulphate and then diluted with acetic acid to such an extent that 1 c.c. represents exactly 0.1 gram of iodine.

More accurate results may be obtained by adding a large excess of the reagent to the solution of the fat and then titrating the excess with thiosulphate.

L. DE K.

Iodine and Bromine Values of Oils and Fats. By ROWLAND WILLIAMS (*J. Soc. Chem. Ind.*, 1900, 19, 300—301).—A table giving the iodine value by Wijs' solution, the calculated bromine value, the same as found by direct experiment, the bromine addition value, and the bromine substitution value of cocoanut oil, tallow, butter-fat, lard, castor oil, rape oil, two samples of cotton-seed oil, two samples of maize oil, japanese wood oil, menhaden oil, and nine samples of linseed oil.

Wijs' method gives excellent results if care is taken to add at least twice the amount of iodine likely to be absorbed. In some cases, notably with linseed oil, there are great discrepancies between the calculated and experimentally found bromine values.

L. DE K.

Linseed Oil Analysis. By PARKER C. McILHINEY (*J. Soc. Chem. Ind.*, 1900, 19, 320—321).—The author recommends the determination of the sp. gr. and the bromine addition and substitution numbers (this vol., ii, 178). If unsatisfactory, a portion of the sample should be distilled in a current of steam and the distillate examined for turpentine, petroleum, &c. The volatile matter may easily be separated from the aqueous layer and measured or weighed. For the separation of turpentine and petroleum, Burton's nitric acid process is recommended (*Abstr.*, 1890, 669). The non-volatile matter is then collected and dried. Its acidity figure is taken, and if found to be very high, points to the presence of rosin, which must then be estimated by Twitchell's method (*Abstr.*, 1892, 389). Another portion is treated in the usual way for unsaponifiable matter (rosin oil, mineral oil). This and the distillation test are no doubt the most valuable and conclusive, as they allow of the actual separation of some of the adulterants. Finally, the saponification figure may prove to be of value.

L. DE K.

Refractometric Butter Analysis. By ALFRED PARTHEIL and J. VON VELSEN (*Arch. Pharm.*, 1900, 238, 261—279).—The authors have redetermined the refractive index of different fatty compounds at various temperatures, using sodium light, and have calculated the temperature coefficients and molecular refractions. The following compounds were tested: triacetin, tributyrin, trilaurin, tripalmitin, tristearin and triolein. Samples of butter-fat, margarin, ground-nut

oil, olive oil, cotton-seed oil, and sesamé oil were also examined and the results are recorded.

It is shown that the refraction of butter increases with the iodine figure, but not to the extent expected with the Reichert-Meissl number; there is also no fixed relation between the latter and the temperature coefficient.

L. DE K.

Normal Refractometric Value for Butter. By A. LAM (*Chem. Zeit.*, 1900, 24, 394—395).—The limit of refraction of butter at 40° has been fixed in Germany at 44.2. The author, as the result of a large number of analyses of butters of Dutch origin and undoubted genuineness, states that for these butters the limit should be fixed at 46.

L. DE K.

Rancidity of Butter. By Jos. HANUŠ (*Zeit. Nahr.-Genussm.*, 1900, 3, 324—328).—A butter was again analysed after having been exposed for three months to the action of air and light. The iodine, Reichert-Meissl, and saponification numbers were but little affected, but the acidity had increased from 5.1 (?) to 75.2 c.c. of N/10 soda per 100 grams of butter fat.

The sample was melted, the fat dissolved in ether, and neutralised with sodium hydroxide, using phenolphthalein as indicator; the soaps were dissolved by shaking with water at 25°, the solution was evaporated to dryness and traces of fat removed by washing with light petroleum. After completely drying the soap, a large portion was dissolved in an Erlenmeyer flask in 150 c.c. of water, 15 c.c. of dilute sulphuric acid (1:5) were added, and the whole distilled in a current of steam until the volatile acid had completely passed over; the distillate was then titrated. The neutralised solution was evaporated, the residue dried at 100° and weighed, and the percentage of volatile acids calculated by Henriques' formula (*Abstr.*, 1899, ii, 258).

The non-volatile acids were estimated by Hefner's method and their molecular weight calculated from the saturation number. The unsaturated acids were calculated indirectly from the formula $100I/90.07$, where I represents the iodine number. The result was 2.10 per cent. of volatile acids with a mol. weight of 104; saturated non-volatile acids, 40.90; unsaturated non-volatile acids, 26.20; joint mol. weight, 278. From these data, the relation of the volatile and non-volatile acids in the isolated free acids is 1:32 (*a*), of the unsaturated to the saturated acids 1:1.5 (*b*), of the volatile to the unsaturated acids 1:13 (*c*), and to the saturated acids 1:20 (*d*). Assuming that fresh butter contains on an average 5.5 per cent. of volatile, 33 per cent. of unsaturated, and 53 per cent. of saturated acids, then $a' = 1:16$, $b' = 1:1.6$, $c' = 1:6$, and $d' = 1:9.6$.

The acidity of four fresh butters was taken and also the acidity of the distillates; the proportion of the latter to the former was approximately as 1:10, but after they had become rancid the proportion was about as 1:25.

These experiments show that the glycerides of both series of acids (volatile and non-volatile) are hydrolysed during the exposure of the butter, the non-volatile acids being set free sooner and in larger pro-

portion than the volatile ones. The glycerides of the saturated and unsaturated acids seem to be equally affected.

There is little doubt that the peculiar taste and odour of rancid butter is partly due to traces of aldehydes.

L. DE K.

Detection of "Saccharin" [*o*-Benzoic sulphinide] in Articles of Food. By J. DE BRÉVANS (*Chem. Centr.*, 1900, i, 1105; from *Ann. Chim. anal. appl.*, 5, 131—133).—Truchon's process (this vol., ii, 377) when applied to some kinds of wine and beers or to infusion of liquorice gives untrustworthy results owing to the presence of tannins soluble in the ether-petroleum mixture. The following modification is proposed. The liquid is mixed with an excess of ferric chloride and then with a slight excess of calcium carbonate. The filtrate is then treated as directed. No 'saccharin' is retained by the iron precipitate and a subsequent violet colour is exclusively due to the presence of 'saccharin.'

L. DE K.

Estimation of Sugar in Diabetic Urine. By JULIUS TROEGER and W. MEINE (*Arch. Pharm.*, 1900, 238, 305—309).—The copper solution used by the authors differs from the ordinary Fehling's solution by containing 100 grams of glycerol per litre instead of Rochelle salt. Its exact strength in copper is determined by weighing this as subsulphide.

Sixty c.c. of the copper solution are heated in a porcelain basin with 5—20 c.c. of the sample of urine for 15 minutes. The liquid is made up to 100 c.c. in a measuring flask graduated at 45°, the warm liquid is shaken with a little talc to remove the suspended cuprous oxide, and then rapidly filtered. By estimating the copper as subsulphide in an aliquot part of the filtrate, the amount of copper oxide which has been reduced by the dextrose may be found.

L. DE K.

Estimation of Oxalic Acid and the Occurrence of Oxaluric Acid in Urine. By ERNST SALKOWSKI (*Zeit. physiol. Chem.*, 1900, 22, 437—460).—The author states that the usual process of estimating oxalic acid in urine by direct precipitation with calcium chloride in the presence of ammonia and free acetic acid gives results which are too low and proposes the following method.

500 c.c. of unfiltered urine are concentrated to about one-third. When cold, 20 c.c. of hydrochloric acid are added and the mixture is shaken three or more times in succession with 200 c.c. of a mixture composed of 9—10 vols. of ether and 1 vol. of alcohol. The united ether extract is passed through a dry filter and the ether recovered by distillation. The residual alcoholic liquid is poured into a deep basin, 10—15 c.c. of water are added, and the whole heated until the alcohol has evaporated and the liquid become clear. After filtering, the liquid is rendered faintly alkaline with ammonia and then again faintly acid with acetic acid; if this should produce a turbidity, the liquid must be again filtered. The oxalic acid is now precipitated by adding 2 c.c. of a 10 per cent. solution of calcium chloride and after 24 hours the calcium oxalate is collected, converted into oxide and

weighed. The same process may be applied to the estimation of oxalic acid in tissues.

It was accidentally discovered that the amount of oxalic acid is much increased by evaporating urine with hydrochloric acid to a syrupy consistence. 750 c.c. of a urine which yielded 6.1 milligrams of calcium oxide gave 10.2 milligrams when evaporated with 20 c.c. of hydrochloric acid. This increase is due to the hydrolysis of oxaluric acid by the hydrochloric acid. This oxaluric acid seems, according to the author's experiments, to exist in a pre-formed condition and to a larger extent than hitherto believed. If larger quantities of urine are evaporated, there is a danger of some of the oxalic acid being reconverted into oxaluric acid.

L. DE K.

A Quantitative Reaction of the Ureides and Purine Derivatives. II. By ADOLF JOLLES (*Ber.*, 1900, 33, 2119—2121. Compare this vol., ii, 454).—When oxidised with permanganate and sulphuric acid under the conditions already described, caffeine, hydroxycaffeine, theophylline, paraxanthine, and heteroxanthine yield as many mols. of methylamine as they contain methyl groups; the rest of the nitrogen is obtained as carbamide in the case of caffeine and hydroxycaffeine, as ammonia in the case of paraxanthine and heteroxanthine, and to about an equal extent as carbamide and as ammonia in the case of theophylline. In the case of heteroxanthine, when only about one-quarter the usual quantity of sulphuric acid was employed a very considerable amount of carbamide was formed.

C. F. B.

Estimation of Allantoin in Urine. By OTTO LOEWI (*Zeit. anal. Chem.*, 1900, 39, 266—267; from *Arch. exp. Path. Pharm.*, 1900, 44, 1).—The feebly acid urine is precipitated with mercurous nitrate to which some mercury is added. The filtrate is freed from mercury by hydrogen sulphide, and the latter expelled by warming. It is then treated with silver nitrate and magnesia, which precipitate the allantoin. In this precipitate, after thorough washing, the nitrogen may be estimated by Kjeldahl's process, or the precipitate may be decomposed by hydrogen sulphide and the filtrate evaporated to dryness, the dry residue extracted with hot water, the extract precipitated with mercuric nitrate, and this precipitate treated with hydrogen sulphide. The filtrate from the mercuric sulphide leaves the allantoin on evaporation.

M. J. S.

Estimation of Allantoin in Urine. By R. PODUSCHKA (*Zeit. anal. Chem.*, 1900, 39, 267; from *Arch. exp. Path. Pharm.*, 1900, 44, 59).—The urine (50—100 c.c.) is precipitated with an equal volume of lead acetate solution and filtered. An aliquot part of the filtrate is freed from lead with sodium sulphate; silver nitrate (5—10 per cent. solution) is then added in excess. A measured portion of the filtrate is treated with very dilute ammonia (2 c.c. of a 1 per cent. solution for 50 c.c. of the original urine) and 50—100 c.c. more of silver nitrate. The flocculent precipitate of silver allantoin is thoroughly washed on a suction filter and its nitrogen estimated.

M. J. S.

Detection of Bile Pigments in Urine. By OLOF HAMMARSTEN (*Zeit. anal. Chem.*, 1900, 39, 269—270; from *Skand. Arch. Physiol.*, 9, 313).—A mixture is made of 19 vols. of 25 per cent. hydrochloric acid and 1 vol. of 25 per cent. nitric acid, and allowed to remain for some hours, or until it has become yellowish; then, just before use, one part is mixed with 5 parts of 95—97 per cent. alcohol, and a little of the urine is added. One part of bilirubin in 50,000 parts of urine produces a characteristic green colour. Should other colouring matters be present, 10 c.c. of the urine are mixed with a few c.c. of barium chloride (or, in some cases, calcium chloride, followed by sufficient ammonia to produce neutrality), and the deposit, collected by a centrifugal machine, is treated with 1—2 c.c. of the reagent, and again centrifuged, when the presence of bile will produce a green solution.

M. J. S.

The Volumetric Estimation of Vegetable Alkaloids by Titration with Acids. By CARL KIPPENBERGER (*Zeit. anal. Chem.*, 1900, 39, 202—229; 290—314).—With the object of ascertaining which alkalimetric indicators are most suitable for the titration of alkaloids by standard acid, the author has submitted to titration small quantities (about 0.1 gram, in order that the conditions might be similar to those occurring in chemico-legal investigations) of the most generally occurring alkaloids, using eleven different indicators. The general method consisted in adding an excess of standard sulphuric acid to about 2 grams of the alkaloid, making up to a litre, and titrating the excess of acid in 50 c.c. by *N*/50 sodium hydroxide. With some indicators, the amount of acid consumed was much below the theoretical; with others, above; many of the indicators gave results of approximate accuracy, but the following gave the most satisfactory results: Atropine, morphine, veratrine, codeine, cocaine, nicotine, coniine, papaverine, narcotine with lacmoid; thebaine, codeine, emetine, coniine with iodococin; atropine with uranin (sodium fluorescein); coniine, morphine, thebaine, emetine, brucine, pelletierine with cochineal; aconitine, strychnine, and quinine with azolitmin; sparteine and quinine with hæmatoxylin. Narceine and caffeine could not be titrated with any of the indicators. Methyl- and ethyl-orange gave approximate results only with atropine, emetine, and coniine; phenolphthalein and alkannin could be used for sparteine, but for no other alkaloid, and Congo-red only for coniine. The cases where the consumption of acid falls below the theoretical amount are in general explicable by the fact that in such highly dilute solutions as those employed a considerable proportion of the alkaloid salt, as well as of the indicator, undergoes dissociation, such cases being most conspicuous when the indicator is of a feebly acid character and the alkaloid a weak base; in other cases, it would seem as if a compound of the alkaloid with the indicator were non-existent. With strongly acid indicators and feebly basic alkaloids, the amount of indicator used has considerable influence. Too large a consumption of acid was especially noticeable with the indicators methyl-orange, ethyl-orange, and Congo-red. This phenomenon does not seem to admit of any general explana-

tion ; in some cases, it is clearly due to the formation of a compound of the alkaloid with the acid radicle of the indicator, which is not decomposed by dilute mineral acids, but as a similar effect is sometimes observed with indicators which contain no acid group, the cause remains obscure.

The above methods of titration have been applied to investigate the subject of the extraction of alkaloids from their aqueous solutions by shaking with organic solvents. It was formerly assumed that, with few exceptions, the alkaloids could not be removed by chloroform or ether from strongly acid aqueous solutions, but this is shown to be by no means the case. From a solution strongly acidified with hydrochloric acid, chloroform removes almost the whole of the papaverine and caffeine present, besides smaller amounts of codeine and cocaine in the form of free bases, strychnine, brucine, aconitine, veratrine, narceine, pelletierine, narcotine, and thebaine, in varying amounts, partly as base, and partly as hydrochloride, as well as small quantities of atropine and emetine. Morphine, quinine, nicotine, coniine, sparteine, hyoscyamine, daturine, and scopolamine are not extracted, or only in traces. From sulphuric acid solutions, large proportions of papaverine and caffeine are removed as free bases, and narcotine partly as base and partly as sulphate, whilst quantities varying from 5 per cent. to a trace were extracted of strychnine, brucine, aconitine, veratrine, narceine, emetine, and pelletierine. From solutions saturated with sodium chloride, narcotine and aconitine were wholly removed by chloroform, chiefly as salts, and atropine and quinine partially. Traces of strychnine and brucine could be removed by chloroform from solutions acidified with tartaric acid, and caffeine almost wholly from an oxalic acid solution.

Ether extracts from a hydrochloric acid solution only narcotine and caffeine in weighable amounts, besides traces of aconitine, narceine, and emetine, and from a sulphuric acid solution only caffeine in noteworthy quantity. It does not remove strychnine or brucine from a tartaric acid solution, but extracts much caffeine from one acidified with oxalic acid.

These results support the view that, even in strongly acidified solutions of the alkaloids, a large amount of dissociation into acid and base occurs.

The extraction of morphine, narceine, and strophanthin from alkaline (sodium carbonate) solutions by a mixture of chloroform and alcohol is greatly assisted by saturating the solutions with sodium chloride.

A scheme is given in the paper for the extraction and partial separation of the alkaloids, contained in an aqueous solution, based on the above facts.

M. J. S.

Quantitative Estimation of Alkaloids by means of Standardised Solution of Iodine. By MAX SCHOLTZ (*Arch. Pharm.*, 1900, 238, 301—304).—A controversy with Kippenberger (this vol., ii, 583) on the subject of the value of the iodometric method of titrating alkaloids. The author upholds his previous views.

L. DE K.

Chemico-toxicological Study of Coniine. By DIOSCORIDE VITALI and CESARE STROPPA (*L'Orosi*, 1900, 23, 73—80).—A description is given of the method employed by the authors for the detection of coniine in the contents of the stomach of a victim of hemlock poisoning. Two new reactions of the alkaloid are given: (1) If to a little coniine or one of its salts there be added a few drops of a solution of 1 part of potassium permanganate in 200 of concentrated sulphuric acid and the mixture stirred with a glass rod, the original green colour of the acid permanganate is changed to violet. (2) On evaporating a small quantity of coniine to dryness with a few drops of concentrated nitric acid, the liquid becomes yellowish and leaves an orange-yellow residue having a peculiar aromatic odour. If to this a little potassium hydroxide solution be added, reddish-brown, oily drops separate, a very pronounced odour of hemlock is evolved, and the liquid assumes an orange-red tint. If this be evaporated to dryness, there is obtained a brown, almost black, deposit, soluble in concentrated sulphuric acid to a nearly colourless solution which, when diluted with water and carefully mixed with excess of ammonia, yields a yellow liquid.

T. H. P.

Scheme for the Analysis of Rubber Wares. By OCTAVE CHÉNEAU (*Zeit. Nahr.-Genussm.*, 1900, 3, 312—318).—To ascertain whether the article is of uniform quality, it is generally sufficient to take several samples and determine the sp. gr. and the amount of ash. The latter does not, of course, always represent the true amount of added mineral matter. Many samples contain excess of resinous matters which may be extracted with hot alcohol. The further analysis which may occasionally be considerably shortened is briefly as follows.

The finely divided sample is heated with dilute acetic acid containing a little sugar to decompose any lead dioxide. This treatment removes chalk, white lead, red lead, zinc oxide, alkalis, decomposes any ultramarine, and dissolves potato starch. The extracted mass is washed, dried at 105° and weighed, whilst the dissolved metals are estimated in the acetic acid solution. A portion of the extracted sample is now boiled for a few hours with normal alcoholic soda under a reflux condenser, the alcohol distilled off, and the residue thoroughly washed first with boiling water, then with water acidified with acetic acid, and finally with boiling water; the extraction may be repeated in case of any doubt. After drying at 105° the mass is reweighed, the loss in weight representing "factis," free and "factis"-combined sulphur, natural and added resinous matters, pitch, &c. Inferior, although not adulterated, samples may contain a rather large quantity of matters soluble in sodium hydroxide.

The residue is exhausted with acetone, which dissolves unsaponifiable mineral or rosin oils and asphalt. The acetone is distilled off, the residue dissolved in ether, and after evaporation of the latter, the unsaponifiable matter is dried at 100° and weighed.

The mass left after the treatment with acetone is extracted with cold nitrobenzene, which dissolves unvulcanised rubber and the remaining asphalt. When fully exhausted, the mass is boiled with water to re-

move the adhering nitrobenzene, dried, and weighed. It is then extracted with light petroleum, benzene, or chloroform to remove paraffin and any remaining non-vulcanised rubber. Three grams of the mass are now boiled under a reflux condenser with 3 c.c. of chloroform and 50 c.c. of nitrobenzene for an hour; when cold, 100 c.c. of ether are added, the undissolved matter is collected on a filter, washed with benzene, dried, and weighed. It may contain talc, kaolin, ochre, heavy spar, vermilion, lead sulphide, lead sulphate, and, more rarely, graphite, rasped leather, or cork, vegetable fibres, &c. These are then estimated by the usual methods, the vermilion preferably by the dry process.

The total sulphur is estimated in a separate portion by Henriques' process (this vol., ii, 124). By deducting the amount of sulphur contained in the mineral constituents, the free and organic-combined sulphur is obtained, and by deducting from this the sulphur present in the vulcanised rubber, the free and "factis"-combined sulphur is found. By deducting the sulphur found in the final residue from the sulphur left in the residue from the petroleum extraction, the sulphur in combination with rubber is obtained.

Carbon dioxide is estimated as follows. The finely divided sample, extracted if necessary with hot chloroform and nitrobenzene, is treated with dilute hydrochloric acid. The gas evolved is freed from hydrogen sulphide by passing it over pumice stone moistened with copper sulphate, dried over sulphuric acid, and finally absorbed in a weighed soda-lime tube.

L. DE K.

Chemistry of Tobacco. By RICHARD KISSLING (*Chem. Zeit.*, 1900, 24, 499—500. Compare Abstr., 1898, ii, 659, and 1899, ii, 821).—Seventeen kinds of tobacco were tested and the results recorded. The chief object was to isolate the various resins, some of which are soluble in light petroleum, others in ether, and the remainder in absolute alcohol.

The samples were dried over sulphuric acid, powdered and extracted with light petroleum (b. p. 35—55°) in the apparatus previously described. After evaporating the solvent, the residue was treated with a known weight of potassium hydroxide and distilled in a current of steam to remove nicotine, which was then estimated by the author's process. The alkaline liquid was neutralised with hydrofluosilicic acid, evaporated to dryness, and extracted with boiling absolute alcohol to dissolve resins, and a kind of wax which was quantitatively recovered by cooling to 0°; the resin was then obtained by evaporating the alcohol.

After being extracted with light petroleum, the samples were extracted first with ether and then with absolute alcohol. The extracts so obtained were treated in the same way as the petroleum extract. They contained no wax, but the alcoholic extract contained a large proportion of matters soluble in hot water, which were duly separated from the accompanying resin.

It appears that the nicotine is partly present as a resinate. There is, however, no strict relation between the amounts of nicotine and resins.

L. DE K.

General and Physical Chemistry.

Spectrum of Radium. By CARL RUNGE (*Ann. Phys.*, 1900, [iv], 2, 742—745. Compare Demarçay, this vol., ii, 586).—The author has made a spectroscopic investigation of a radium preparation with stronger dispersion than that employed by Demarçay (this vol., ii, 83). The wave-length determinations of the latter are not regarded as sufficiently exact for the characterisation of the new radium lines. Of the fifteen lines given by Demarçay as characteristic of radium, the author is able to confirm three, λ 4826.14; 4682.346; 3814.591; of the remaining twelve, some are not to be seen, others are probably barium lines. These three radium lines were also detected in a barium bromide preparation. They are not among the lines of the solar spectrum as measured by Rowland. J. C. P.

Electrical Conductivity of Compressed Powders. By FRANZ STREINTZ (*Monatsh.*, 1900, 21, 461—481).—Platinum black, amorphous carbon, and graphite have been investigated, all in the form of compressed cylinders. Special precautions have been taken to secure good and permanent contact of the powder and the electrodes. Compared with the values for solid platinum, the specific resistance of the compressed platinum black (sp. gr. = 11.6) is 6.5 times as great, whilst the temperature coefficient is about half as great. Cylinders of amorphous carbon alter their resistance after their exposure to low temperatures, and are some time in reaching a stable condition, and the specific resistance of this element decreases 1 per cent. for every 1° rise in temperature, facts that point to amorphous carbon being more nearly allied to electrolytic conductors. The compressed cylinders of graphite powder (sp. gr. = 3.0) have a temperature coefficient about twice as great as that of solid graphite, a result probably connected with the difference in density. In respect both of the absolute value of the specific resistance and of the temperature coefficient, graphite is much more nearly allied than amorphous carbon to the metallic conductors. J. C. P.

Gaseous Polarisation in the Lead Accumulator. By WALTHER NEERNST and F. DOLEZALEK (*Zeit. Elektrochem.*, 1900, 6, 549—550).—When dilute sulphuric acid is electrolysed with platinum electrodes, the evolution of hydrogen and oxygen begins at an E.M.F. of about 1.7 volts, whereas in an accumulator (where the acid is electrolysed with lead electrodes) no gas is evolved at an E.M.F. of about 2 volts, the products formed being lead and lead peroxide until all the available lead sulphate has been decomposed, after which hydrogen and oxygen begin to be evolved at an E.M.F. of about 2.3 volts. This discrepancy is explained by the recent experiments of Caspari (this vol., ii, 7), which show that the minimum E.M.F. required for the liberation of hydrogen depends on the nature of the metal of which the electrode is made, metals which occlude hydrogen most readily requiring the smallest E.M.F. The accuracy of this explanation is confirmed by the following experiment. A platinum and a leaden dish of equal size were filled with solid lead sulphate and dilute

sulphuric acid. Into the acid in each a plate of lead peroxide dipped. The same small current was passed through both cells, the dishes forming the cathodes. In the platinum, dish the E.M.F. between anode and cathode was 1.6 volts, in the leaden dish it was 1.92 volts, and after three weeks the lead sulphate in the platinum dish was found to be unaltered, whereas that in the leaden dish was almost wholly reduced to lead. T. E.

Gaseous Polarisation in the Lead Accumulator. By STRASSER and GAHL (*Zeit. Elektrochem.*, 1900, 7, 11).—The E.M.F. required to charge an accumulator depends, other things being the same, on whether the grating of the negative plate is made of hard or of soft lead. The authors find that this is due to the fact that a smaller E.M.F. is required to liberate gaseous hydrogen on a surface of antimony than on one of pure lead, the alloys of the two metals occupying intermediate positions. The E.M.F. also depends on the surface; it is smaller for spongy metal than for a smooth surface. The E.M.F. of the accumulator is not affected by the addition of antimony to the negative plate. The phenomenon is, therefore, another example of the influence of the nature of the metal forming the cathode on the E.M.F. required to liberate gaseous hydrogen on its surface (compare preceding abstract). T. E.

Potentials of Copper Electrodes in Solutions. Copper Precipitates of importance in Analysis. By CL. IMMERWAHR (*Zeit. anorg. Chem.*, 1900, 24, 269—278).—The author insists on the importance of knowing the solubility of the precipitates so often met with in analytical work, and by determination of a number of potentials calculates the copper ion concentrations in saturated solutions of these precipitates. The potentials of copper electrodes in contact with the complex ammonia and potassium cyanide solutions alter gradually, showing that the concentration of the copper ions changes. In the case of the cuprous salts, only the relative ionic concentrations could be determined. J. C. P.

Oxidation Potentials. By F. CROTOGINO (*Zeit. anorg. Chem.*, 1900, 24, 225—262).—Oxidising agents are divided into two classes; (1) those which give up oxygen; (2) those which take on or give up ionic charges. One of the most important influencing factors in the case of the second class is the acid concentration. It is shown on the lines of Jannasch and Ashoff's work (*Abstr.*, 1893, ii, 295), that by regulation of the acid concentration, a complete separation of combined iodine, bromine, and chlorine can be effected. An electro-metric method of estimating an iodide is described. A platinum electrode is immersed in the solution to be titrated and the system is connected with a normal electrode. As standard potassium permanganate is gradually added to the iodide, the potential at the platinum electrode slowly alters until all the iodine is liberated, at which point a sudden change in the value of the potential is observed (compare Behrend, *Abstr.*, 1893, ii, 387). An attempt was made to measure a number of oxidation potentials on the lines of Bancroft's work (*Abstr.*, 1893, ii, 58), but constant values could be obtained only in cases where the concentration of the hydrogen ions remains

unchanged during the action—in particular for iodine. A platinum electrode immersed in potassium iodide solutions of different strengths, but always saturated with iodine, showed a potential π in agreement with the formula: $\log. K = \pi/0.0259 + \log. (I')^2/(I_2)$, where K is a constant, (I') the concentration of the iodine ions, and (I_2) that of the free iodine. The results were found to be independent of the acid concentration. When different quantities of iodine are dissolved in potassium iodide of given concentration, a form of concentration cell can be set up, and the application of Nernst's formula in this case shows that when the concentration of free iodine is very small, the E.M.F. of the cell should approach a limiting value; this is borne out by the experiments made.

The E.M.F. of an oxygen-air cell exhibits great variations: the maximum value obtained agrees well with that of Smale (Abstr., 1894, ii, 436), but it is seven times the theoretical value. J. C. P.
